LATE RESULTS OF OPERATIONS FOR FALLOT'S TETRALOGY

BY

MAURICE CAMPBELL, D.M., F.R.C.P.

From the Cardiac Department, Guy's Hospital, and the Institute of Cardiology, London

Fallot's tetralogy is the most common form of morbus caeruleus: its frequency was mentioned by Peacock in his excellent account in 1866. Its surgical treatment is therefore of great importance, and three methods are now available: (1) subclavian-pulmonary anastomosis or some modification of this; (2) Brock's direct operations of pulmonary valvotomy or infundibular resection or both; and, more recently, (3) open operation with closure of the ventricular septal defect and relief of the stenosis.

This paper describes the results of the first two methods, but I am able to mention my first patient, on whom Sir Russell Brock used the third method in October, 1956. A girl who was aged 4 at the time of her operation, and who was deeply cyanosed and could walk only 30 yards, is now acyanotic and can run about freely with other children, so that symptomatically she could hardly be better. The result, however, is not ideal, for, though her ventricular septal defect seems to have been closed, she still has some stenosis, with a larger heart and right bundle-branch block.

Clearly this third method is the only cure, and will become standard treatment when the present difficulties have been surmounted. The results of anastomotic operations may then be mainly of historic interest, but will serve as a comparison with the results of open operation after another ten years. Valvotomy and infundibular resection will, of course, remain an essential part of any surgical treatment, so that the success they can achieve is of great interest.

Inevitably, as time passes, the child who has had a successful operation for Fallot's tetralogy tends to be compared with the normal child of his age and less with the severely disabled child he was, both by the patient and his parents and by the physician as well. To this extent there is less enthusiasm than at first, and sometimes it needs to be remembered how many patients are leading normal quiet lives at school or at work who previously had no such prospect. This change of attitude is even more important when the patient was only somewhat improved; parents who were delighted at first think mainly of the great disability that remains after a few years.

ANASTOMOTIC OPERATIONS

All types of morbus caeruleus were included in our previous report of the results of 200 anastomotic operations (Campbell and Deuchar, 1953). This makes the conclusions less precise and less easy to follow, so here we are considering only those diagnosed as Fallot's tetra-

logy: this still includes some where necropsy revealed more complex lesions, but it excludes those with pulmonary atresia or tricuspid atresia where the results are not so good.

After this modification there are 130 patients who obtained good or very good results—127 from the start and 3 from later who were originally classed as "improved" only (see Table I). Those in whom the results

TABLE I.—Early Results of Anastomotic Operations

	No.	Died at Operation	No Op. Possible	No Im-provement	Slight Im-provement	Good	Very Good
Fallot's tetralogy	165	14	4	5	15-3*	33+3	94
Pulmonary atresia	19	6	5	0	3	3	2
Other conditions	16	4	2	1	1	3	5
	200	24	11	6	19	39	101

* Three of these subsequently achieved good results, making 130 (94+33+3) whose further progress is considered.

of operation were good and those in whom they were very good have behaved in much the same way, and it is simpler to take them together.

During the period covered in our previous report, up to four years after operation, few of the patients with good results had relapsed. During the subsequent four years we became less satisfied, for several returned to hospital having lost all their improvement. A further follow-up has been more reassuring, for we had seen nearly all those who were doing badly but few of those who were doing well, as they had felt no need to attend hospital.

Of the 130 who obtained good results, we have seen 126 recently or have had reports from them or their doctors. Eight of these (6%) have died and 17 (14%) have lost much or all of their improvement, but 101 (80%) are as good or nearly as good as they were. These have been followed for an average period of over seven and a half years: 11 are well after ten years, 10 after nine years, 28 after eight years, 36 after seven years, and 16 after six years.

Good Results Maintained

Most of these 101 patients have kept all their improvement, though seven have lost some of it—enough for the results to be called good rather than very good. The first 10 patients, most of whom were very disabled before operation (Campbell, 1948), have their cases described briefly to illustrate the results, which were very good in the first five but more varied in the second five. None of them, except Case A5, has an unduly large heart, and all show less

5106

anoxaemia and lower haemoglobin percentages (see Table II), the average of the first five being 104 instead of 136%, though generally they are still a little cyanotic. It is only fair to add that Mr. Alfred Blalock was working at Guy's Hospital and performed some of these first operations, lest others feel that their start was not so successful. The

TABLE II.—Changes in Heart Size and Haemoglobin Percentage in Patients Who Have Done Well for 9 or 10 Years After Anastomotic Operations

Case No.	Heart Size (Cardiothoracic Ratio)						Haemoglobin (%)		
	Before Op.	1 Yr.	3 Yr.	5 Yr.	7 Yr.	9 or 10 Yr.	Before Op.	After 4 Yr.	After 9 or 10 Yr.

* A = anastomosis.

These two patients were in good health after 9 years but died in the tenth year from cerebral abscess.

ages given are those at the time of operation unless otherwise stated. The prefix "A" indicates anastomotic operations.

Case A1.—A boy aged 7 was enabled to lead a normal life at school except for games. After ten years he can walk five miles and get about his father's farm most of the day, but would find it difficult to earn his living on a farm and is still a little cyanotic.

Case A2.—A boy aged 13; now leads a normal quiet life and is married. For two years he worked long hours in a garage but found this hard, and is now in an accountant's office. His colour looks normal.

Case A3.—A boy aged 3; is now leading a normal school life, except for football. He can walk five miles and can run and play cricket. He has minimal cyanosis.

Case A4.—A boy aged 11 could not walk more than 50 yards, but now walks 10 to 15 miles and his colour is almost normal.

Case A5.—A girl aged 6 could not walk more than 25 yards.

After ten years she attends school regularly but has to take things at her own pace. The heart became much larger, but not progressively so.

Case A6.—A girl aged 3 lost her improvement when the anastomosis closed in the seventh year (see below).

Case A7.—A boy aged 7 was very well when his family emigrated to Canada after two years.

Case A8.—A student aged 25 was less disabled than most. He has done well as regards his heart, but has been handicapped by the effects of a cerebral thrombosis after operation and by tuberculosis of the lungs.

Case A9.—A girl aged 5 was greatly improved and the operation probably saved her life, but four years later she was still disabled enough to need a second operation.

Case A10.—A boy aged 3 has continued to do well. In the tenth year he had bacterial endocarditis, but has not lost any ground after it.

Most of these patients were children, who on the whole do best after operation, but some adults do very well. Generally, if patients over 20 can earn their living the obstruction to the pulmonary flow cannot be great, and I have thought it better for them to carry on without operation. However, one man aged 20 who had never worked is now employed regularly as a painter and decorator, and can walk as far as he wants; another, aged 26, is so much better that he sometimes plays football in addition to doing his regular work; both have remained well for six years.

Some patients included among the good results are not as good as the best of these. They cannot do so much and show obvious cyanosis: a doctor seeing them for the first time would diagnose Fallot's tetralogy and might think they needed surgical treatment. Of three such patients, the first is not as well as he was and the other two are still examples of fairly severe Fallot's tetralogy (see bottom of Table II), but it is difficult not to call the results good when two who could not walk 50 yards before operation can now earn a living and the third can attend an ordinary school and walk much further than before.

Case A62.—A boy aged 6 lost some of his improvement after six years and the haemoglobin rose again; but after nine years he is earning his living and can walk a quarter of a mile, instead of 50 yards before operation.

Case A55.—A boy aged 11 was deeply cyanosed and could walk only 50 yards. Nine years later he is doing clerical work and can walk two miles, although his haemoglobin has risen again. He would be better if he had a larger blood flow to the lungs, but his heart might not be able to cope with this, as it has always been rather large.

Case A83.—A girl aged 6 had severe cyanotic attacks and could walk only 400 yards. After operation she could walk two

miles and attend an ordinary school, but her colour and her haemoglobin did not improve much. After nine years she is almost as well, but is less contented because she cannot keep up with her friends.

Some patients who obtained a good result as regards their heart are handicapped in other ways. For example, one has some residual disability from post-operative cerebral thrombosis, another from a cerebral abscess, and a third from bronchiectasis. Two are dissatisfied because they are unable to work since leaving school, but this is because they are not intelligent enough to overcome their lack of schooling, and not because the heart has become worse.

Many of the patients are better in summer and can do much less on cold days in winter. Apart from this, any suspicion of deterioration has generally been confirmed by the subsequent course. However, two patients who were thought to be losing ground in the third and fourth years—a period of rapid growth—are as well as ever after seven years.

Good Results Lost

These patients have been divided into three groups: (a) those who have died, (b) those who have lost all their improvement, and (c) those who have lost much of it. The loss is not always due to the anastomosis closing.

Eight Patients Who Have Died

In our earlier report three had died (the fourth included there had tricuspid atresia). When we started this longer follow-up only two more had died, but during the tenth year three who were in excellent health after nine years have died. This may be chance, but shows the need for a long follow-up to get a reliable picture.

Of the three first, a woman aged 20 died suddenly in the street 18 months after operation, no obvious cause being found at necropsy; a girl aged 7 died unexpectedly from pulmonary oedema while on holiday 37 months after operation; and a boy aged 3 died with a cerebral abscess in the third year after.

Of the next two, a boy aged 11 remained well until he had acute nephritis in the sixth year; he recovered, and his blood pressure, which had risen to 170/130, returned to 120/90 mm., but five months later he died at home, probably from a recurrence of the nephritis. Our oldest patient, aged 35, did well for seven years, but then died with carcinoma of the bronchus.

The last three are particularly disappointing, for they had been leading active lives with few symptoms, and when examined nine years after their operation only one had signs that caused any anxiety—anaemia and a large heart; yet they died within a year. Two of them, boys aged 6 and 19, died from cerebral abscesses, both in the tenth year (Cases A16 and A23): the latter had made a good recovery after operation for a cerebral abscess at a different site seven years previously. The last, a girl aged 6, did very well, but her heart became much larger than usual (c.t.r. 47–60%). After nine years it was still larger (Fig. 1), but we hoped part of this was due to her anaemia (haemoglobin 71%) and might be reversed by

treatment. Nine months later, however, she was admitted with sudden severe dyspnoea, congestive failure, and anaemia: she seemed to be recovering, but became more breathless and vomited, and died suddenly a few hours later. At necropsy the immediate cause was a mesenteric thrombosis, but she should be regarded as dying from heart failure (Case A25).

Rather surprisingly, none of these patients showed any cardiac deterioration until their terminal illness; we have no reason to think that the anastomosis had closed, and have necropsy proof that it was open in five of the eight. One death from carcinoma of the bronchus was quite incidental and one from nephritis may or may not have been, for we find nephritis rather common in these patients; three were from cerebral abscess; and only three from some form of heart failure.

As the average period of follow-up for all our patients is over seven years, this is a mortality of about 1% per annum. In those who have died the average period after operation was just over three years in four and just under nine years in four.

Loss of All Improvement

Ten other patients have lost all their improvement. When the loss has taken place fairly suddenly—though sometimes in more than one stage—and the continuous murmur can no longer be heard, the reason is clear and in several operation or necropsy confirmed that the anastomosis had closed. This happened in the first five patients shown in Table III, and they reverted to the same state as before operation.

When the loss is gradual it is more difficult to explain in this way, and Case 45 was becoming worse for four years before there was any noticeable change in the continuous murmur: it seems that the stenosis was becoming more severe and that only towards the end was the anastomosis nearly closed. In the last four patients, however, the continuous murmur could be heard as well as before: we think they were showing the natural tendency for the stenosis of Fallot's tetralogy to become more severe, though in some the anastomosis was probably carrying less blood than it had originally.

In all these patients the haemoglobin percentage had risen again—in all but one to about its original level (see Table III). In four of the six where we know about the heart size, it had become smaller again, and in three of these the anastomosis was known to have closed. When the haemoglobin rises to its original level and the heart becomes smaller the anastomosis has probably closed. Short descriptions of these patients follow: four of them have obtained good results after subsequent direct operations.

Case A6.—A girl aged 3 lost nearly all her improvement suddenly after pneumonia in the seventh year. The anastomosis was thought to have thrombosed.

Case A15.—A boy aged 10 did well till he had three epileptiform fits in the fifth year: during the next two years he lost ground and the continuous murmur became inaudible. He died after pulmonary valvotomy, with cerebral softening; at necropsy the anastomosis had closed.

TABLE III.—Some Details of Patients who Lost All the Improvement Produced by Anastomotic Operations

Case No.	Anastomosis	Time of Deterioration	Hb Percentage			Heart Size (c.t.r.)			Remarks
			Before Op.	After Op.	Final	Before Op.	After Op.	Final	
A6	Closed	7th year, after pneumonia	157	110	141	49	54	51	2nd op. Good

A82	"	5th to 7th years, after nephritis	130	108	120	47	47	57	" Died

* Presumably anaemic.

FIG. 1.—Exceptional enlargement of a small heart of a patient with Fallot's tetralogy. Left: Before operation (c.t.r. 48%). Centre: One year after operation, a larger heart (c.t.r. 57%), with lung fields that are much better filled. Right: Nine years after with a very large heart (c.t.r. 70%). She was then well, but died later that year with congestive heart failure. Slight rib-notching can be seen on the fifth right rib from the anastomotic channels from the aorta to the right arm after division of her right subclavian artery and, in retrospect, very slightly even in the radiograph one year after operation. Case A25.

Case A44.—A girl aged 10 lost some ground in the seventh year. In the ninth year she had to give up her work, having become cyanotic again and having lost all her improvement within a few months: the continuous murmur could no longer be heard.

Case A143.—A girl aged 10 became almost acyanotic and could walk three miles. During the course of five months in the fifth year she lost all her improvement and the anastomosis had closed without any obvious reason.

Case A147.—A girl, aged 16, remained well for five years. After this she became bluer and more short of breath, and some months later had to give up her work: no continuous murmur could be heard.

Case A45.—A boy aged 3 obtained a very good result. In the fourth year his mother thought he was not as well, and by the sixth year there was no doubt about this: the haemoglobin was higher (123%) and the heart was smaller (c.t.r. 48%). His continuous murmur was still as loud, but this was not so in the seventh year, when he had become as disabled and as cyanosed as ever: the heart was even smaller (c.t.r. 42%) and the haemoglobin 139%. A severe high infundibular stenosis was resected, but he died two days later. At necropsy the lumen of the anastomosis admitted a probe only.

Case A40.—A boy aged 8 remained well for six years. Then he could do rather less and his headaches recurred; some months later he had "pneumonia," after which he lost all his improvement and resumed squatting. It seemed likely that the anastomosis had closed, but the heart had not become smaller and the murmur was as loud as before. There must, I think, have been increasingly severe stenosis, though a year later, when admitted for a direct operation, which was very successful, the continuous murmur could no longer be heard.

Case A47.—A Cypriot boy aged 11 did well for five years. In the sixth year he lost most of his improvement, but we do not know if the continuous murmur can still be heard.

Case A54.—A girl aged 5 lost some ground in the fourth year after a cortical thrombophlebitis, but the result was still good. She lost most of her improvement in the seventh year, mainly in one month. Her smaller heart and higher haemoglobin suggested the anastomosis was closing, but the continuous murmur remained quite loud.

Case A82.—A girl aged 5 remained very well for five years, but then lost ground after scarlet fever and nephritis, and more so during the next two years though the continuous murmur was still loud: her heart became steadily larger, and she often complained of swelling of the ankles and had some albuminuria. She died after an infundibular resection. At necropsy there was nothing to suggest occlusion of the anastomosis before its recent ligation. Her deterioration seems to have been due to increasingly severe infundibular stenosis, the passage having become almost atresic.

Loss of Much Improvement

The anastomotic channel had not closed in any of these seven cases, but, certainly in the first and probably in others, it was carrying less blood to the lungs. In the first two the continuous murmur was less easy to hear. In all except the last, the haemoglobin had increased, and in two (Cases A41 and A120) the heart had become smaller; by analogy this made us think the anastomosis was closing, but in both it proved to be open at operation. We think, therefore, that many of them were worse because the stenosis was becoming more severe. Some details are given in Table IV. Only two are described briefly, the first as an example of partial thrombosis of her anastomosis at necropsy, and the second as evidence of increasingly severe stenosis.

Case A46.—A girl aged 16 could walk three miles and worked as a telephonist for six years, though before operation trivial

exertion provoked cyanotic attacks with unconsciousness. During the sixth to ninth years she lost much of her improvement. Her continuous murmur was heard less easily and her haemoglobin had risen again. She died from cardiac arrest a day after infundibular resection. At necropsy the anastomosis was only partly occluded by a firmly adherent thrombus.

Case A120.—A boy aged 3 lost much, but not all, of his improvement in several stages during the seventh and eighth years. Recently he was taken to America for operation by Mr. Kirklin with an extracorporeal circulation. In spite of the small heart and rising haemoglobin percentage, the continuous murmur was well heard and the anastomosis was found to be functioning well. There was a very severe infundibular stenosis, with an orifice that was almost pin-point, and the ventricular septal defect was large and at the usual site. So far, he is doing well.

Second Operations

Ten of the 17 who lost all or much of the improvement have already had direct operations: six obtained very good results, but the other four died. For some time a direct operation after an anastomotic one that had failed proved disappointing, and the mortality is still much higher than for primary direct operations.

Two other patients have had second operations because their original disability had been so extreme that even after great improvement they still needed more. One has improved greatly, but the second has not benefited.

Progress of 21 Patients who Obtained Little or No Benefit

The four patients in whom no operation was possible, five who were not improved, and 12 only somewhat improved, making 21 in all, can to some extent serve as a control. Eight of these 21 have died. Two proved to have a single ventricle and pulmonary stenosis; a third died with meningitis, and a fourth with a pulmonary abscess, all within 18 months of operation. These four were reported in our previous paper, and four have died since. One boy who was very disabled and had frequent fits died three years later. One boy, who after two years had a second anastomotic operation that did not help much, died suddenly five years later. One woman, aged 29, gradually relapsed and died five years later. The eighth was in hospital several times with congestive failure, and died with this six years after: her heart was large for an uncomplicated Fallot's tetralogy, and we think she had some additional lesion.

Four patients lost even the slight improvement they had gained at two to six years after operation. This was due to the anastomosis closing. Four others were much the same for three or four years, when they had second operations; and second operations may be needed in the remaining five, who are much the same after from six to nine years.

In summary, the prognosis of these 21 patients has proved poor. Eight (38%) died after an average period of three years, only three living longer than this. Seven are much the same as before, and six had a subsequent operation, so that the period of follow-up was abridged: two of these had anastomotic operations that did not help much and four had direct operations, of which two proved fatal and two produced good results.

TABLE IV.—Patients who have Lost Much of the Improvement

Case No.	Anastomosis	Time of Deterioration	Hb Percentage			Heart Size (c.t.r.)			Remarks
			Before Op.	After Op.	Final	Before Op.	After Op.	Final	
A46	Less	Gradual 6th to 9th years	135	108	122	47	52	52	2nd op. Died
A153	? Less	Gradual 4th year	120	95	118	48	49	50	
A41	Open	6th and 7th years: severe infundibular stenosis	128	114	130	50	51	46	2nd op. Good
A61	"	6th year, after transient hemiplegia	151	116	166	49	51	53	
A108	"	Gradual 6th and 7th years	157	105	120	54	60	57	Recent op.
A120	"	7th and 8th years	150	110	145	51	54	51	
A132	"	8th year, more dyspnoeic and syncopal attacks	154	100	90	54	55	55	

It would not be fair to take these as representative of untreated Fallot's tetralogy, because some of them had more complex lesions, and this may have been partly why they did not benefit much from their operations. They do, however, show a striking contrast with the patients who obtained good results.

DIRECT OPERATIONS FOR FALLOT'S TETRALOGY

The results of pulmonary valvotomy and infundibular resection in the first 100 patients operated on by Sir Russell Brock have been reported (Campbell *et al.*, 1954). The operative mortality was 15%; there was little or no improvement in 14%, and a good result in 71%—figures that were not very different from those after anastomotic operations, except that the operative mortality was higher. Our conclusions were based mainly on the 61 patients that had been treated at Guy's Hospital.

We are now reporting a longer follow-up of these 61 patients and adding another 50 operated on in 1953-6, making 111 in all. The operation was mainly infundibular resection in 47, mainly valvotomy in 42, or both procedures in 22 cases. Infundibular resection, which at one time had a higher operative mortality, has now become about the same; but perhaps rather surprisingly it is followed by a good result more regularly; otherwise there was not much difference in these groups, so they have been considered together for most purposes.

Of the 111 patients, 19 died at or soon after operation, 13 obtained little or no improvement, and 79 (71%) obtained good results. None of these 79 has been lost sight of, and they have been followed for an average period of nearly five years—32 for from six to nine years, and all but seven for two years or more.

The operative mortality was higher than for anastomotic operations—17% for all, but 12% for those operated on since 1952. If we exclude 11 who had second operations in which the mortality has been twice as high, it is further reduced to 15 and to 10% respectively. The number with slight or no improvement is 12%—about the same as in the other series. Sometimes this may be because there are other abnormalities that have not been diagnosed or because of some feature that makes surgical correction difficult. Here, too, however, the proportion has been falling in recent years, especially since the fuller realization of the importance of infundibular stenosis even when at first the stenosis appears to be mainly valvular.

Good Results Maintained

Of the 79 who obtained good results, 70 (89%) have remained well during the subsequent years, including most of the earlier patients.

Infundibular Resection

The first eight who had successful results after infundibular resection were given in detail in our previous paper, and, partly because I know them so much better than the later ones and know what they can do, their present condition is given briefly (see also Table V).

Case IR1.*—A girl, aged 13, has kept well for nine years and is now working as a dressmaker, but does not attempt more than this, and leads a quiet home life.

Case IR2.—A young woman, aged 20, is much more active, but her heart is larger (c.t.r. 58%) and she is limited by paroxysmal tachycardia if she does too much.

Case IR3.—A young man aged 19 could do very little, but now is very active and earns his living in Rhodesia. In the ninth year he had bacterial endocarditis, but is able to do just as much after it, though we do not know if his heart, which was still of normal size, has become larger.

*The case numbers are the same as in our previous papers and are the consecutive operations of that particular type. Thus, IR2 indicates the second patient who had infundibular resection without valvotomy. The consecutive V numbers indicate all who had valvotomy with or without infundibular resection as well: they include those with a closed ventricular septum, who are not discussed in this paper.

TABLE V.—Changes in Heart Size and Haemoglobin Percentage in Patients 7 to 9 Years After Direct Operations

Case No.	Heart Size (c.t.r.)			Haemoglobin Percentage		
	Before Op.	After 3-4 Yr.	After 7-9 Yr.	Before Op.	After 3-4 Yr.	After 7-9 Yr.
<i>After Infundibular Resection</i>

* Presumably "anaemic."

Case IR4.—A boy aged 14 has kept as well for eight years and is prevented from greater activity more by his mental backwardness than by his heart.

Case IR6.—A boy aged 14 is now working as a shop assistant and cycles and plays tennis.

Case IR7.—A boy aged 12 is now working as a telephone operator and can cycle and play cricket.

Case IR8.—A young woman aged 20 was rather slow in getting her full improvement, but now works in a shop and can walk two miles and go dancing.

Case IR10.—A girl aged 7 is exceptionally good after eight years and leads an active life with no obvious cyanosis.

Case IR21.—A girl aged 15 had an exceptionally good result and lost all her cyanosis, but we feared that the pulmonary flow and the heart were too large. Six years later, however, she is leading a very active life and the heart is smaller (c.t.r. 49 to 66%, but 62% after six years).

The results of recatheterization in Cases IR3, IR7, IR8, and IR21 were included in our earlier paper, and the arterial oxygen saturations had risen to 86, 90, 95, and 98% respectively, and the pulmonary flows to 80, 120, 156, and 208% of the systemic flow. It has been suggested that successful direct operations would convert the condition into Eisenmenger's complex. If the underdeveloped outflow tract became completely unobstructed this would be so, but it still provides enough resistance to prevent this; and the last of these four patients is the only one in whom the pulmonary arterial pressure has risen above normal, and then only to 38/12 mm.

Pulmonary Valvotomy

The early patients who obtained good results after pulmonary valvotomy, with or without infundibular resection as well, are nearly as good.

Case V2.—A girl aged 18 is earning her living as a musician though she still shows obvious cyanosis and has to walk slowly.

Case V3.—A girl aged 11 is more active and leads a normal life without obvious cyanosis after nine years. Looking to the future, however, she has T inversion from V₁ to V₄, suggesting right ventricular strain.

Case V10.—A man aged 22 has kept well and at regular work. Even more significant, his haemoglobin has remained about 111% for eight years, although it was 180% with the consequent risk of cerebral thrombosis.

Case V20.—A boy aged 11 was much improved and later could earn his living and walk four miles, although his haemoglobin did not fall. This, as so often, was a correct guide, for in the sixth year he lost some ground and the haemoglobin rose higher than before (see Table V), but he can still work and walk a mile.

Case V25.—A boy aged 9 does everything at school except the more energetic games which he would like to play, but he developed pulmonary regurgitation after operation and the heart became larger. After seven years the regurgitant murmur is still loud, but he is able to do as much and the heart has become smaller again (c.t.r. 51 to 56 to 53%).

Case V32.—A girl aged 18 has maintained all her improvement: she has married and can carry out her household work.

Case V34.—A boy aged 10 has kept well and is working as a laboratory technician.

Case V35.—A boy aged 14 was improved enough to start as a medical student, and, though delayed by tuberculosis of the lung, he is well and working after seven years.

These patients give a representative picture of the results of direct operations. Case V20 has certainly lost some of this improvement, but, like Cases A55 and A83, not enough to prevent one still calling the result good. With increasing experience the surgeon may succeed in producing good results more regularly, but it seems remarkable how often he did so from the start. I do not think many of the later patients are better than these, and indeed it would be hard to be much better than Cases IR3 or V3 or several others. After recent operations there are, however, fewer of the disappointing results that show some improvement but not enough to be called good.

Good Results Lost

Patients Who Have Died

Only 2 of the 79 patients have died. A woman aged 31 was much improved, but died nine months later with Landrey's acute ascending myelitis (Case IR19). A boy aged 9 could walk two miles instead of 100 yards, but in the fifth year he became ill and was thought to have hydrocephalus. At necropsy the brain was flattened by gross dilatation of the ventricles, and the hydrocephalus was attributed to the attack of basal meningitis two years before his valvotomy (Case V51).

Loss of All or Much Improvement

Only two patients have lost all their improvement, but five have lost much of it. Those who have had direct operations are not, of course, exposed to the risk of the anastomosis closing and there is little evidence of re-stenosis at the site of the operation. We think that some patients who have lost ground in both groups are examples of the natural tendency in Fallot's tetralogy for the stenosis to become more severe as the patient gets older.

Short notes about the patients who have lost their improvement follow. The first of these patients, one of the only two who had lost it all, is reported on more fully because the infundibular stenosis must have increased after operation in spite of the larger flow through her pulmonary valve. The sixth girl was beginning to show the effects of her large left-to-right shunt in the same way as Case A25, who died in the tenth year after an anastomotic operation. The seventh and last patient who lost ground (Case V91) seems to have done so because of pulmonary regurgitation.

Case V29.—A girl aged 17 could do a full day's work and go dancing after it: her haemoglobin fell and her heart became larger (see Table V). After "influenza" in the third year she could manage only half-time work. Catheterization showed that the gradient was mainly between the right ventricle (110/0) and the infundibulum (30/0) and only slightly between this and the pulmonary trunk (12/3)—figures much the same as those found at her second operation three years later. She still kept some of her improvement, but in the fourth year she had to give up work and was as bad as ever. Clearly the failure to relieve her infundibular stenosis meant that the operation had been incomplete, but the great improvement for three years and its subsequent loss show that this must have become worse and it was found to be very severe when subsequently she had a successful infundibular resection.

Case V22.—A girl aged 12 had an excellent result and could lead a normal life, sometimes walking as far as nine miles. After "influenza" in the fifth year she could walk no more than a mile. In the sixth year she became worse again and was little, if any, better than at the start.

Case IR25.—A boy aged 9 could walk a mile and attend school regularly. In the fifth year he could not get about so well, and his haemoglobin had risen from 104 to 119%.

Case IR41.—A boy aged 2 was so disabled with frequent attacks of unconsciousness that pulmonary atresia seemed likely. He became much better, both in colour and in capacity, and this lasted for two years. After this he could not walk more than 50 yards and squatted more often, though the attacks of unconsciousness did not recur.

Case V113.—A boy aged 5 was much improved, though he still squatted sometimes. After five years he could not do so much and his heart was smaller (c.t.r. 52 instead of 57%), but this may have been due to the growth of his chest. This patient and the next one had infundibular resection as well.

Case V117.—A girl aged 9 could walk only 50 yards. After open cardiomy she was greatly improved and lost all her cyanosis, but the heart enlarged more than usual (c.t.r. 48 to 60%). Four years later she still seemed well, but her lungs were pleon-aemic with a hilar dance and the heart was still as large. She was more dyspnoeic, and sometimes after doing too much was orthopnoeic at night.

Pulmonary Regurgitation

This has proved a less important complication than was feared—much less important with pulmonary than with aortic valvotomy, presumably because the relevant pressures are so much lower and the valve is rarely calcified. Pulmonary regurgitation of significant degree has occurred in three patients. In the first (Case V25) and in the second it did not seem very important, but in the third it was.

Case V60.—A boy aged 7 has maintained his good result for six years, but his heart has stayed larger (c.t.r. 48 to 57%).

Case V91.—A girl aged 12 was greatly improved after operation, but developed pulmonary regurgitation. A year later, after pleurisy, she became increasingly dyspnoeic. After another year she was readmitted with a loud pulmonary diastolic murmur, a raised venous pressure, and a greatly enlarged liver; her heart had become enormous (c.t.r. 51 to 71%). With rest, salt restriction, digitalis, and mersalyl she improved, but it seemed that she would be permanently disabled. She gradually improved, however, and a year later was able to stop all treatment except digitalis and to resume work as a dressmaker, though her liver was still palpable: her heart has become smaller again (c.t.r. 64%). In retrospect it seems that she might have had some infection with a pericardial effusion, but there was no other evidence of this.

OBJECTIVE EFFECTS OF BOTH OPERATIONS

The success of these operations has been judged subjectively by the improvement in the patient's capacity and colour. This is the best way when the doctor knows his patients well, for it measures the essential change. In our earlier follow-up there was good correlation between this subjective judgment and the objective changes in the polycythaemia and haemoglobin percentage. The more important findings—the continuous murmur, squatting, the haemoglobin percentage, and the size of the heart—are now discussed. All these, except the first, apply equally to anastomotic and to direct operations.

Physical Signs.—An easily heard continuous murmur indicates a good flow through the anastomosis. If it becomes more difficult to hear, the flow to the lungs is smaller and it is likely to become inaudible: then there are generally other reasons for thinking that the anastomosis has closed. A large flow will often produce some increase in the pulse pressure, but a patient may obtain a very good result without this, and an easily heard continuous murmur is generally a more useful sign. The auscultatory signs are not much use in judging the results of direct operations, and it is still possible to diagnose some stenosis in most of the successful cases; further, a loud murmur may be due to the irregularity of the outflow tract after operation rather than to the severity of the obstruction.

Squatting.—When the result is good the patient ceases to squat: it is surprising that a habit so long-established should be stopped so suddenly. Patients forget about it and may seem surprised when they are questioned on it. Older patients may, however, force themselves to stop squatting for social reasons, so its absence is not always reliable. Resumption of the habit always means that the patient has become worse and often that he has lost all his improvement.

Haemoglobin Percentage and Polycythaemia.—A fall towards normal in the haemoglobin percentage and in the red-cell count is generally a reliable sign of a better blood flow to the lungs and of less anoxaemia. They will, of course, fall if the patient becomes anaemic from loss of blood or otherwise, and then he is worse off. Sometimes the real degree of anoxaemia is more severe than is suggested by the relatively small increase of haemoglobin, because the patient is "anaemic": a red-cell count that is high in relation to the haemoglobin percentage will often give an indication of this. Otherwise, any subsequent rise is a reason for thinking the patient is not as well as before.

In our earlier series the mean haemoglobin of all the patients with good results fell from just under 130 to 103%, and the fall was almost the same for anastomotic as for direct operations. The percentage was generally between 120 and 159 before operation and between 90 and 119 after it, though there was, of course, a wide range.

Most of the patients with good results have maintained this improvement in their colour and in their blood count. In some, however, who have not lost their improved capacity the haemoglobin has risen above the lowest level to which it had fallen. There is more evidence of this after anastomotic than after direct operations. In 50 cases of the former the average haemoglobin fell from 132 to 104% after three to four years, and had risen to 111% after eight to ten years. In 20 cases after direct operations it fell from 127 to 107% after three to four years, and was still 106% after seven to nine years, but the difference is small. It could be explained by the anastomosis becoming somewhat smaller or even by its failing to grow as much as the patient.

A rise of haemoglobin to near the original level is one of the most reliable signs that the patient is not doing well, and often means that the anastomosis has closed (see Table III).

The electrocardiogram is not very useful in judging the result. The right ventricular preponderance is not likely to diminish, for the right ventricle is still working against the same high pressure, and the patient's increased activity must increase the work of the right side, and, sometimes perhaps after anastomotic operations, of the left side of the heart as well. There is some tendency, as the years pass, for the T inversion and the signs of right ventricular strain to increase, but the patients with these signs are not showing any harmful effects from them so far. If patients escape the other hazards of Fallot's tetralogy, right-sided failure seems likely to follow some time in the near future, but over the ten-year period this has not been important.

Changes in the Size of the Heart

The increase in the size of the heart after anastomotic operations was noticed almost at once, and at first there was some

fear that this might be progressive and lead to heart failure. The same increase occurs after direct operations. We found that the average change in the cardiothoracic ratio was from 50 to 53% after anastomotic operations and from 48 to 52% after direct operations, with the same wide range of variation after both, and that the increase had generally reached its maximum a month or two after operation and was not progressive (Campbell and Deuchar, 1953; Campbell *et al.*, 1954).

Our observations on the size of the heart in this longer follow-up are not so complete, but include nearly all those who have been followed for from 8 to 10 years. Many of the figures given in Tables II and V show that up to 10 years the increase is rarely progressive and the average size after 8 to 10 years is much the same as after three to four years. Where figures are available the average increase in the cardiothoracic ratio is rather less than one-tenth (from 49 to 53.5% after three to four years and to 53% after 8 to 10 years), and this is the same after anastomotic and after direct operations. These average figures hide large individual variation, as is shown in the Tables, and even in patients with very good results the increase may be less than this or much more.

In Fallot's tetralogy the heart is often small and undeveloped, partly, perhaps, from lack of use. Some increase in its size must be expected if the patient is to have an

FIG. 2.—More usual heart size in two patients nine years after successful operations for Fallot's tetralogy. Both had equally good results clinically, but the increase in the blood flow to the lungs is more obvious in one than in the other, where the lungs are still oligoemic. (A) C.t.r. 51% (12/23.5 cm.) Case A24. (B) C.t.r. 51% (13.5/26.5 cm.) Case A23.

FIG. 3.—Teleroadiograms of two patients eight years after anastomotic operations for Fallot's tetralogy. Generally the two lungs seem equally filled, but from the better filling of one lung it is easy to see that the operation was on the left side in one (Case A133) and on the right side in the other (Case A34). The left pulmonary artery was unusually large in A before operation. Both results are extremely good, and the hearts are not unduly enlarged (c.t.r. 54%).

adequate pulmonary blood flow and is to lead a more active life. An increase of one-tenth in the cardiothoracic ratio where it was 45% before operation leaves it of normal size and has no drawbacks, and where it was 50% the same increase leaves it still only slightly enlarged. Examples of both these degrees are given in Figs. 2 and 3. We have no anxiety about an increase to 55 or even 57% unless, as is unusual, it is progressive. With figures over 60% we are more anxious, and such a size is, of course, reached more easily if the heart was large before operation. Patient A25, who was notable from the start as showing pleonaemic lungs and one of the largest hearts (see Fig. 1), illustrates the risk, for she died in the tenth year with congestive heart failure, and we are anxious about the outlook for Case V117. Sometimes, however, the heart may become rather smaller as it becomes habituated to the new conditions, both after anastomotic and after direct operations (see Cases A5 and IR21).

DISCUSSION

Many authors have published their results after operation, but there are few long follow-up studies. The recent one of Taussig and Blalock's cases by White *et al.* (1956) is most valuable, but only 73% of the 500 cases had been traced. Of the 212 patients with Fallot's tetralogy who obtained a good result, 69% have kept this for from five to eight years, 20% have lost ground, and 11% have died during this period, but this is reduced to 9% if second operations are excluded. The great value of successful operation is shown by the contrast of this mortality with one of 44% among those who obtained only fair results from operation. In our series there is a similar contrast with rates of 6 and 38% respectively.

The best age for operation seemed to be between 8 and 12 years, for here the number who had maintained good results reached over 80%. The effect of age, however, is not great in our series, for the figure was 80% in each five-year period except in infants and in those over 20, where the results were less good originally and less well maintained afterwards.

Bacterial endocarditis had occurred in 6% of their series, about 1% per annum, but only 1 in 15 of these patients died. This incidence is higher than in our series, but for cerebral abscess it is much lower than ours. Few of the 33 deaths were due to heart failure; seven were after a second operation and the remainder from a variety of causes.

Potts's Aorto-pulmonary Anastomoses.—The immediate results are not very different from other anastomotic operations—an operative mortality of 9% and a good result in 68%. Only three of my patients have had this variety. Potts *et al.* (1955) have followed up their first 100 cases for about the same period as we have, and find that good results have been maintained at least as well as after other anastomotic operations: there were five deaths—one from a heart attack, one from a brain abscess, one from rheumatic fever, and two from "pneumonia" which may have been partly pulmonary congestion from too large a flow. Though it is not easy to compare the exact degree of enlargement of the heart, it seemed generally to be rather greater, but again was not often progressive.

Comparison of Anastomotic and Direct Operations

No other follow-up study of a large series of patients after direct operations has been found, and in any case it seems better to compare our own patients, who have so far as possible been assessed in the same way. Scientifically, it would have been better if direct operations had been started at the same time and done alternately, but this was not possible. All these anastomotic operations were done in 1947–51. Most of the direct operations were done in 1949–52, but some up to 1956. The selection depended mainly on Sir Russell Brock's view of what was the best surgical procedure at the time, but the earlier patients were, I think, generally the more severe.

The results of direct and anastomotic operations were very similar in our earlier reports, except that the former had a higher operative mortality. This longer follow-up makes them more equal, for there are fewer deaths and fewer complete relapses after direct operations. We thought from an early stage that they more often relieved all the cyanosis, and this is also the view of Wood (1956), but the average reduction in the polycythaemia and haemoglobin level was the same at first and is only a little better maintained after direct operations. The degree of improvement is, however, more varied, from slight or moderate improvement to good or very good results according to the degree of success of the pulmonary valvotomy or infundibular resection. Successful anastomotic operations, on the other hand, tend to produce a more uniform degree of improvement, since the extrapulmonary blood flow through the subclavian anastomosis will generally be proportional to the body size.

The patients who obtained good results but later died or lost ground after each type of operation have been described. Good results have been maintained in 80% after anastomotic and in 89% after direct operations, and this means that the patients were able to work or attend an ordinary school. Allowing for the different length of the follow-ups, the figures for direct operations are not much better, but the real advantage is greater, for the annual death rate and the proportion losing all improvement are only half those after anastomotic operations, the totals being made nearer equality by the larger number who lost only some improvement (see Table VI). It is,

TABLE VI.—Results of Anastomotic and Direct Operations Compared

Operation	Total No. With Good Results Traced	Subsequent Progress				Annual Loss (Percentage)			Total
		Good Results Maintained	Died	Lost All Improvement	Lost Much Improvement	Died	Lost All Impr.	Lost Much Impr.	
Anastomotic	126	101	8	10	7	0.9	1.1	0.7	2.7
Direct	79	70	2	2	5	0.5	0.5	1.4	2.4

however, a more severe test for the latter, because there have been several relapses and deaths during the tenth year, a period that has not yet been reached by many who had direct operations.

The loss of all improvement after anastomotic operations generally occurred because the anastomosis had closed. Sometimes, however, and more often when only some improvement was lost, it seemed due to the natural tendency for the stenosis to become more severe; and this is probably the main reason for the deaths in childhood of those who have not had operations.

None of the deaths was due to the anastomosis closing, except indirectly, when it led to their needing second operations. About one-third were due to heart failure in some form, and probably this was at least hastened by the increased activity of the patients; about one-third were due to incidental causes; and the remaining third to cerebral causes, mainly cerebral abscess.

Cerebral abscess is a well-known complication of Fallot's tetralogy, and we have discussed the reasons (Campbell, 1957). Even so, among 130 patients, three dying from cerebral abscess* and three others making good recoveries after operations for it is a high proportion. We do not think it has any connexion with the anastomosis, except in the broad sense that the patients could lead more active lives with the consequent exposure to fatigue and infection. It is all the more remarkable since during the same period of follow-up only four of these patients suffered from

*Since this was written, two more patients, a boy aged 15 and a girl aged 4, both of whom did well for seven years after anastomotic operations, have died with cerebral abscesses and both in the eighth year after operation. Of the 10 patients who have died, five died with cerebral abscesses.

bacterial endocarditis: all recovered and were no worse afterwards.

So far, no patient who had a successful direct operation has died with a cerebral abscess. A girl aged 3 who was only improved died with convulsions in the second year after pulmonary valvotomy; at necropsy the posterior cusp of a valve that was bicuspid had been split, and a large area of the brain supplied by the middle cerebral artery was necrotic (Case V96). This supports the view that a cerebral abscess may develop from a primary thrombosis (Campbell, 1957), but in this case the thrombosis was so extensive that it led to her death before this could happen.

Future Outlook

Even after a successful operation there is still Fallot's tetralogy, though in a slight rather than a severe form. A larger proportion will reach the stage that one sees occasionally without operation, subjects who can lead a quiet life up to 40 or 50 years. Bedford (1956) reported two such patients whom he had observed for 27 years. One, who died when she was 52, had got on tolerably well until the last four years of her life, when she developed slight congestive failure and cerebral symptoms with increasing cyanosis and dyspnoea. The other was still without failure when she was 52: her haemoglobin had been up to 170% and her cerebral symptoms were relieved from time to time by venesection. White and Sprague (1929) described the well-known example of longevity—the composer Henry Gilbert, who died when he was nearly 60. Marquis (1956), in an important paper on the longevity and the early history of the tetralogy of Fallot, described the case of a woman who lived to the age of 64.

Our oldest patient is now 53: though cyanosed from birth and squatting frequently as a child, she could lead a quiet life at home but could not go to work. Since the age of 48 she has been more breathless and can walk only 100 yards, and, though she has had a large heart (c.t.r. 63%) and gross right ventricular strain with T inversion from V1 to V4 and congestive failure, is losing ground only slowly.

It is possible now to estimate how many of the patients who have had a successful operation are likely to be reasonably active till middle age. Assuming that the number losing ground will continue at the same rate and that the mortality among those who have lost their improvement will be much higher (38% in seven years), a rough forecast of the position after 7, 14, and 21 years, based on our figures for anastomotic operations, is given in Table VII.

TABLE VII.—Estimated Condition of 100 Patients Who Have Had a Successful Operation for Fallot's Tetralogy

	Patients Who Will Have Died	Patients Severely or Moderately Disabled	Patients Leading a Satisfactory Quiet Life
After 7 years	6	14	80
" 14 "	17 (6+6+5)	19 (14-6+11)	64 (80-16)
" 21 "	29 (17+8+4)	20 (19-8+9)	51 (64-13)
31.5 years (average age)			

We think that half the patients who obtained good results will be reasonably well after 21 years, but the average age will still be only about 31 years. Perhaps one-quarter will be able to carry on in this way till they are 50; but this is even more speculative, and is mentioned only in the hope that someone will prove or disprove it by following the patients for another twenty years. The proportion maintaining their good results after direct operations should become relatively higher as the years pass, for, so far, fewer have died or lost all their improvement. The number of these patients who are able to work and enjoy life in a way that was impossible before is even more important than the prolongation of life.

SUMMARY AND CONCLUSIONS

Some of the patients who obtained a good result after an anastomotic or after a direct operation for Fallot's tetralogy have lost all or part of their improvement during the subsequent 8 to 10 years. Often this is due to the inevitable risks of the condition, for all these patients still have Fallot's tetralogy, though the stenosis has to some extent been relieved, directly or indirectly. These causes, especially cerebral complications, were responsible for more than a third of the deaths; the heart could not support the increased pulmonary flow and the increased activity that it allowed in another third; but in the final third the cause was not directly related to the heart condition or to the operation. In many patients who lost all their improvement after anastomotic operations, however, this was due to the anastomosis closing. In others, and in most of those who lost some of their improvement after both sorts of operations, it seemed to be due to the tendency for the stenosis to become more severe.

Of those who obtained good results, 80% have maintained them for an average period of seven years after anastomotic operations and 89% for five years after direct operations. The long-term advantage of the latter is greater than appears from these figures, for there were only half as many deaths and half as many who lost all their improvement with direct as with anastomotic operations. We think that perhaps half of those who obtained good results may be reasonably well 20 years after operation.

After anastomotic operations, increasing difficulty in hearing the continuous murmur is a bad sign, and if it cannot be heard the anastomosis has probably closed. The auscultatory signs after direct operations are not so much help.

The reduction in the anoxaemia and resultant polycythaemia and high haemoglobin percentage that was found three or four years after operation has been maintained in most patients for the six to ten years of this longer follow-up, but not, of course, in those who had lost their clinical improvement.

The heart increases in size within a few weeks after a successful anastomotic or direct operation. On the average the cardiothoracic ratio increases by one-tenth (49 to 54%) and remains at this level for 8 to 10 years. There are no drawbacks to some increase in the size of the smaller hearts. The ideal is a limited increase, large enough to indicate a reasonable pulmonary flow that will enable the patient to do more, but not large enough to throw an undue strain on the heart, and this is generally about 10%: it is unlikely to be progressive and there is no reason to be anxious about it. In fact, if a heart that has become larger returns to near its original size, especially if the haemoglobin returns to its original level, the anastomosis has probably closed or the increased pulmonary flow has been lost by the stenosis becoming more severe.

Neither of these operations for Fallot's tetralogy is curative, for, of course, the ventricular septal defect remains and the right ventricle is working against the systemic pressure. These results show, however, that generally they produce great improvement that lasts for many years. The good results after direct operations suggest that when the ventricular septal defect can be closed it should not be difficult to relieve the infundibular or valvular stenosis.

It is a pleasure to thank Sir Russell Brock, not only for his outstanding work in developing these direct operations, but for allowing and even encouraging me to judge the success of his results; also Dr. Charles Baker for his help and for the inclusion of some of his patients; and Mr. Holmes Sellors and Mr. Ian Hill for operating on some and for keeping me so well informed about what they had done. I also thank Drs. S. S. Suzman, Geoffrey Reynolds, and D. C. Deuchar for help at different stages in the follow-up of so many patients for up to ten years, and Drs. Deuchar, R. J. Shephard, and L. Brotmacher and the registrars at the National Heart Hospital for the results of catheterization.

VACCINATION AGAINST POLIO-MYELITIS WITH LIVE VIRUS VACCINES

4. A REVIEW OF THE PRESENT POSITION

BY

G. W. A. DICK, M.D., D.Sc., F.R.C.P.Ed.

Professor of Microbiology

AND

D. S. DANE, B.A., M.B., B.Chir.

Lecturer in Microbiology

The Queen's University, Belfast

In a report recently published by the World Health Organization (1958), the Expert Committee on Poliomyelitis strongly recommended that controlled field trials of live attenuated poliovirus vaccines should be carried out. The committee suggested suitable circumstances and populations for the trials and specified the strains of virus which it considered should be used. Trials are now in progress in many parts of the world, and a preliminary report of one of them has already been published (Courtois, Flack, Jervis, Koprowski, and Ninane, 1958). The purpose of this review is to give the reader who is unfamiliar with the subject some idea of the progress that has been made in the development and testing of attenuated poliomyelitis vaccines.

The possible advantages of living attenuated poliovirus vaccines over formalinized vaccines (Salk type) are that they can be given by mouth, that they are cheaper to produce, and that they may give a better immunity. They certainly give a broader type of immunity which will for a time prevent or modify subsequent infection of the alimentary tract with poliovirus. This is in contrast to the immunity at present produced by vaccination with formalinized vaccines which does not modify subsequent alimentary infection, at any rate to the same degree. The difference in the immunity produced by the currently available formalinized vaccines and attenuated virus vaccines is important because the use of attenuated virus vaccines in a community might interfere with the natural spread of virus, and so far there is no evidence that formalinized vaccine is capable of doing this (Langmuir, 1957; Fox, 1957a, 1957b).

In the last few years there have been a number of small laboratory-studied trials of attenuated poliovirus

vaccines, and there has been much progress in their development (Sabin, 1957a, 1957b), but the rapid emergence of a successful formalinized vaccine in 1955 removed some of the urgency which might have led to their earlier trial in the field. This delay allowed time for cautious progress, which may have been a good thing because attenuated poliovirus vaccines have certain novel features not previously encountered in human vaccines.

The poliovirus strains incorporated in current living vaccines developed by Sabin (1957b), by Cox and his associates (see da Silva, McKelvey, Bauer, Prem, Cooney, and Johnson, 1957), and by Koprowski (1957) have all been grown in monkey-kidney-tissue culture and selected for their comparative lack of neurotropism when inoculated into the C.N.S. of monkeys in large amounts. The vaccine viruses are given orally and cause an inapparent infection. They multiply in the alimentary tract like natural polioviruses, and the vaccinated subjects develop an immunity which is probably similar to that following an infection with one of the less invasive naturally occurring strains.

Attenuated poliovirus vaccines, like any other vaccines, require testing in the field for safety and effectiveness, both to the individuals vaccinated and to the community as a whole. For reasons of clarity these different aspects are considered separately.

Safety to the Vaccinee

The safety of attenuated poliovirus vaccines to vaccinees has been assessed both by direct clinical observation and, indirectly, by studying alterations which may occur in the character of the vaccine virus after multiplication in the human host.

To the best of our knowledge no illness definitely attributable to the use of attenuated poliovirus vaccines has so far been reported among thousands of persons who were observed carefully after vaccination in different trials with several different attenuated virus vaccines. This is a most encouraging fact, but we must bear in mind that nearly all natural poliomyelitis infections are mild or inapparent, especially with types II and III poliovirus, and that many of the people vaccinated in these trials have either been immune before vaccination or have been selected in a manner which has been far from ideal.

The indirect assessment of safety is made by testing the properties of the virus excreted by vaccinees. While there is a wide spectrum of monkey neuropathogenicity among naturally occurring or wild polioviruses, markedly neurotropic strains have always been recovered from the faeces of paralysed patients. If the excreted vaccine virus remains considerably less neurotropic for monkeys than wild polioviruses, which have been isolated from the faeces of paralytic cases, then it is usual to presume that the vaccine virus will do no harm to the vaccinee.

So far only one vaccine virus has been shown to change greatly in its neurotropism after growth in the human gut (Dane, Dick, Connolly, Fisher, and McKeown, 1957). This was the rodent-adapted TN type II poliovirus (Koprowski, Norton, Jervis, Nelson, Chadwick, Nelsen, and Meyer, 1956), and there is general agreement that it is unsuitable for further trial (Dick and Dane, 1957; World Health Organization, 1958). All the other vaccine viruses which have been grown in monkey-kidney tissue culture and have been tested have shown some change towards greater neurotropism, but these changes have been insufficient to cause anxiety for the safety of vaccinees. If safety for the individuals receiving vaccine were all that was required of a vaccine, then there would be few problems in planning progressively larger trials of the currently available attenuated strains, though opinions would vary on the relative importance of direct clinical assessment and the indirect laboratory

study of excreted virus; and they would also vary on the degree of neurotropism theoretically permissible in the attenuated virus.

Unfortunately the vaccine viruses now undergoing trials have been shown on numerous occasions to spread from vaccinees to their associates. Spread has not always occurred, but neither does it always occur with natural polio-virus infections. Because of this ability to spread by contact infection we have to consider carefully the safety of the vaccine viruses to the community in which they are used.

Safety to the Community

The spread of a poliomyelitis attenuated vaccine virus from vaccinees to their contacts was first demonstrated by Koprowski *et al.* (1956) with SM type I virus. His subjects in this trial were incontinent institutional children. Later we demonstrated that SM virus could spread in a normal household (Dick, Dane, Fisher, Connolly, and McKeown, 1957). With the more recently developed attenuated polio-viruses spread of virus from vaccinees to their contacts has been shown (Paul, Horstmann, Melnick, Niederman, and Deutsch, 1957; da Silva *et al.*, 1957; Smorodintsev, Drobitshevskaya, Gorev, Iliencko, Kluchareva, and Kurnosova, 1958; Smorodintsev, personal communication). To date no significantly greater change towards neurotropism has been reported for virus recovered from infected contacts than has been observed in the excreted virus of some vaccinees. This finding is satisfactory, but the number of observations has necessarily been limited by the number of monkeys which are required for this type of test.

The basic problem we have to consider is the safety of the virus which is excreted by vaccinees and which will probably spread to other members of the community. As stated earlier, there is a broad spectrum of neurotropism among wild polioviruses. From the evidence so far published we do not consider that the virus excreted by some vaccinated subjects in recent trials can be differentiated from the less neurotropic strains of wild poliovirus. This opinion is based on our own interpretation of results from other laboratories, and we realize that not everyone will agree with it. Further work may show that there has been an irreversible change in the vaccine virus and that the excreted viruses are in fact unlike wild polioviruses and are never likely to change sufficiently to become dangerous. At the moment we consider that the irreversibility of the change is not proved.

If we accept that excreted vaccine polioviruses are similar to wild avirulent polioviruses, then how safe are they? Because neurotropic strains of virus have always been isolated from paralytic cases we may presume that the avirulent wild strains are probably safe provided that they are stable and cannot change to a more neurotropic form. Unfortunately there is little information on the stability of wild polioviruses, and for this reason we have been attempting to discover more about the problem by comparing the monkey neurotropism of polioviruses isolated from the faeces of paralytic patients and their close contacts. This method of approaching the problem is open to the criticism that, how-

ever carefully one may select a case and a contact, there is never absolute proof that both were infected with the same virus strain. The results of tests on three pairs of viruses are shown in the Table. Faecal virus was given one passage in monkey-kidney-tissue culture and then inoculated intracerebrally into rhesus monkeys in various amounts.

With two pairs (B and C) the viruses isolated from both the contact and the paralytic case were probably equally neurotropic. But in pair A, though the virus from the paralytic case (D.D.) was highly neurotropic, the virus from the contact (P.B.) was only slightly neurotropic and fell into the group of naturally occurring avirulent strains. The virus from P.B. resembled in monkey neurotropism (as judged by intracerebral inoculation) the virus excreted by subjects vaccinated with SM 100 type I poliovirus vaccine (Dick *et al.*, 1957; Koprowski *et al.*, 1956) and by subjects vaccinated with more highly attenuated poliovirus strains in a recent Minnesota trial (da Silva *et al.*, 1957). If other currently used vaccine viruses had been subjected to the same type of trial that was conducted at Minnesota similar results might have been obtained.

We do not consider that the small piece of circumstantial evidence we have given above is in any way conclusive proof that wild polioviruses are unstable in their neurotropism, but we do think that these preliminary results might serve as a reminder to those planning attenuated vaccine trials of the sort of problems they have to face in evaluating vaccine safety.

The W.H.O. Expert Committee on Poliomyelitis (World Health Organization, 1958), in its review of present knowledge about live poliovirus vaccines and in its recommendations for trials, virtually ignores the problem of spread. It points out "that preliminary tests on attenuated polioviruses in the hands of several investigators have failed to reveal signs of illness or other harmful effects in the vaccinees or their associates" (our italics). Apart from this one oblique reference to spread there is no indication to the reader that it might be important. Whether the committee considered the spread of these vaccine viruses potentially dangerous or not, it was odd that it dismissed the whole problem with such brevity. The uncontrolled spread of poliomyelitis vaccine virus in a community must either be beneficial or potentially dangerous. If spread is dangerous this will be discovered only if field trials are planned with the object of answering this most important question. If spread is beneficial then it would be useful to know this. A new concept in the use of attenuated virus vaccines might be evolved which could be of great value in combating such diseases as influenza, mumps, and measles.

Effectiveness in the Vaccinee

The ultimate test of the effectiveness of attenuated poliovirus vaccines must await controlled field trials if these are in fact possible. In the meantime it seems reasonable to judge likely effectiveness by measuring the levels of neutralizing antibody in vaccinated subjects.

In the trials where virus grown in monkey-kidney-tissue culture has been used the proportion of vaccinees developing neutralizing antibody has usually been over 90%, and the levels of antibody appear to have been satisfactory. With the TN type II rodent-adapted virus we found that a smaller proportion of children developed antibody (77% of 124), but the levels of antibody in children who did so were broadly similar to those reported following vaccination with viruses grown in tissue culture. Information about the persistence of neutralizing antibody comes mainly from trials with strains of vaccine virus no longer in use. Our own follow-up study on children vaccinated with TN type II virus (Dane, Dick, Briggs, and Nelson, 1958) is open to this criticism, but we consider that the results obtained with TN type II virus are likely to be at least as good as, or better than, those which will be found with the less virulent current vaccine viruses that do not undergo such a marked change after growth in the human gut. We found that about two months

after vaccination 77% of children had developed neutralizing antibody at levels comparable to that found by others following two injections of formalized virus (Report, 1957a), and that in a proportion of the children there was a marked decline in antibody level over the next year, which again was like that reported after two injections of formalized virus (Report, 1957b).

Very high levels of neutralizing antibody have been shown to develop following a third booster injection of formalized vaccine (Report, 1957b), and it is doubtful whether refeeding with live virus vaccines would have such a marked effect. Furthermore, in view of the alimentary resistance to reinfection which follows vaccination with live virus vaccine, it would be difficult to predict whether or not, or when, reinfection would occur. This does not mean that refeeding would not be a possible way of maintaining immunity induced by live virus vaccines, but only that certain problems would arise which have not arisen with formalized vaccine.

The alimentary resistance to reinfection which follows vaccination with live virus is often presumed to be some sort of local gut immunity. Little is known about the nature of this immunity or how long it will last, and, although it is of obvious benefit to the individual vaccinee, it may have more far-reaching consequences to the community as a whole.

Effectiveness to the Community

The resistance or comparative resistance of people vaccinated with live attenuated polioviruses to reinfection with these viruses gives hope that they will be similarly resistant to infection with wild polioviruses. If this proves to be the case, then there is a real chance that wild polioviruses might disappear from a community where sufficient numbers had been vaccinated with live virus vaccines. This does not appear to have happened in the U.S.A. following the use of formalized vaccine, but until a high proportion of the susceptibles in a country have been adequately vaccinated with potent formalized vaccine the possibility that the elimination of polioviruses from a community can be achieved with this type of vaccine cannot be excluded. Experimentally, Howe (1957) has shown that there was a significant reduction in the amount of virus excreted by chimpanzees fed a virulent strain of poliovirus if they had previously been vaccinated with formalized virus. Poliovirus infection in chimpanzees is characterized by a greater pharyngeal multiplication than occurs in man, and for this reason a direct comparison may not be valid.

Use and Testing of Current Attenuated Strains

There appear to be four possible uses of attenuated poliovirus vaccines. They could be used (a) instead of formalized vaccines; (b) to supplement formalized vaccines; (c) to halt epidemics; and (d) in countries whose financial resources do not permit the use of formalized vaccines.

In the first case, it seems unlikely that any country with the finances available to undertake a vaccination programme using formalized vaccines would use, or switch to, attenuated virus vaccines until it has been shown that they are as safe as, or safer than, formalized vaccines and produce as good or better levels of immunity.

In the second case, attenuated virus vaccines might be used to supplement formalized vaccines in the hope of eliminating wild viruses from the community. Before undertaking such a programme one would like to know whether virulent polioviruses may not in fact be largely eliminated from communities which are efficiently immunized with potent formalized vaccines. Enough time has not elapsed from the introduction of formalized vaccines, and sufficiently thorough immunization has not yet been achieved to answer this question.

The use of attenuated vaccines to control epidemics at the present time involves the employment of a contagious virus whose safety and effectiveness during non-epidemic periods

has been inadequately studied. It cannot be predicted how avirulent viruses would behave if they were introduced into a community in which conditions are ripe for an epidemic, and in many areas it would be difficult to organize voluntary immunization of a whole population as was done recently in Africa (Courtois *et al.*, 1958). The problems involved in attempting to evaluate the results of vaccinating a community during an epidemic are great enough to deter some authorities from introducing a largely unproved vaccine in this manner.

There remains the possibility that live virus vaccines might be used in countries in which formalized vaccines cannot be afforded. In our opinion carefully conducted trials of attenuated virus vaccines should be undertaken in such countries if there is a genuine need for vaccination, and they should be done during non-epidemic times of the year. The previous epidemic history of poliomyelitis should be available, and should be carefully considered before initiating the trials. Such trials would be the most valuable first step in gaining information in the field, but it must be appreciated that there are great difficulties in planning trials of a vaccine virus which spreads from vaccinees to their contacts. Any trial of safety must take this factor into account and must attempt to evaluate the harm or good which has been achieved by the uncontrolled spread of a living virus. The information so far published about the currently available attenuated vaccines does not suggest that they will necessarily be either dangerous or completely safe. It is important that trials should aim at defining the limits of safety of these vaccines, rather than at sidestepping the possible dangers which accompany the use of a contagious vaccine.

"The meat arriving at Smithfield Meat Market has presumably been inspected at the time of slaughter in this country or abroad. Evidence of disease which has escaped notice at the primary inspection is nevertheless found: in some cases it has been overlooked, in others it has only become apparent when the carcass is cut up. Condemnations of meat at Smithfield are to a considerable extent due not to disease but to deterioration during transport, decomposition, bone-taint, brine-staining, etc. The total amount of meat delivered at Smithfield Market was 422,607 tons, of which 497 tons were found to be diseased or unsound and were voluntarily surrendered."—From the *Report of the Medical Officer of Health for the City of London for the Year 1957*.

VACCINATION AGAINST POLIOMYELITIS WITH LIVE VIRUS VACCINES

5. NEUTRALIZING ANTIBODY LEVELS ONE YEAR AFTER VACCINATION

BY

D. S. DANE, B.A., M.B., B.Chir.

Lecturer in Microbiology

G. W. A. DICK, M.D., D.Sc., F.R.C.P.Ed.

Professor of Microbiology

MOYA BRIGGS,* B.Sc.

AND

ROBERT NELSON*

From the Department of Microbiology, The Queen's University, Belfast

During the first half of 1956 small laboratory-studied trials of TN type II and SM type I oral attenuated poliomyelitis vaccines (Koprowski, Norton, Jervis, Nelson, Chadwick, Nelsen, and Meyer, 1956) were made in Northern Ireland (Dane, Dick, Connolly, Fisher, and McKeown, 1957; Dick, Dane, Fisher, Connolly, and McKeown, 1957). Neither of these vaccines fulfilled what we considered to be the necessary theoretical requirements of safety (Dick and Dane, 1957), but the results of investigations into the duration of immunity following their administration are reported here because they may be of some value in predicting the sort of immunity which is likely to follow the use of the more attenuated virus vaccines now available.

Materials and Methods.—The materials and methods used were as described previously (Dane *et al.*, 1957). Comparative results for levels of neutralizing antibody in any individual are given only when paired sera were titrated in the same test.

Results

Persistence of Neutralizing Antibody After Vaccination with SM type I Poliovirus

A number of volunteers who were fed SM type I virus in 1956 were bled at frequent intervals after vaccination in order to estimate the highest titre of antibody which they would develop. The serum with the highest titre from each of six adult volunteers was tested again with another serum taken about a year later. The results of these tests are shown in Table I.

TABLE I.—Levels of Type I Neutralizing Antibody in Adults at Various Intervals After Vaccination with S.M. Type I Virus

Serial No.	Age	Sex	Pre-vaccination Titre	Weeks After Vaccination	Titre	Weeks After Vaccination	Titre
193	41	M	<4*	7	22	67	<4
218	39	M	<4	6	22	68	11
353	24	F	<4	4	16	68	4
284	20	M	<4	3	179	99	64
212	20	M	<4	5	359	62	89
235	25	M	<4	9	8	72	256

* Reciprocal of serum antibody titre.

The antibody titre had fallen in five of the individuals, but had risen significantly in the other (No. 235). A number of serum specimens taken from No. 235 over the study period were tested in an attempt to explain this rise in anti-

*Technicians paid with grants from the National Fund for Poliomyelitis Research and the Medical Research Council.

body. It was found that between the ninth and the fifteenth month after vaccination he had developed a significant rise in neutralizing antibody to both type I (from 1:4 to 1:256) and type II poliovirus (from <1:4 to 1:96). It appears, therefore, that during this time he had had at least one natural poliovirus infection.

Persistence of Neutralizing Antibody After Vaccination with TN type II Poliovirus

Blood samples from 60 children vaccinated orally with TN type II poliovirus in 1956 were taken approximately one year later. The comparative levels of neutralizing antibody in this specimen and one taken about two months after vaccination were estimated by testing the two sera at the same time. The variation in antibody levels during this period is shown in the Chart.

Individual variation of type II neutralizing antibody titre in 60 children following vaccination with TN type II poliovirus. All the children were without type II antibody at the time of vaccination.

In a proportion of the children a significant antibody rise occurred after the first post-vaccination blood specimen had been taken. It is impossible to prove that the antibody rises in these children were not the result of infections with naturally occurring type II polioviruses, but the most satisfactory explanation is that vaccine virus multiplication in the gut (and therefore the antigenic stimulus) continued in these children beyond the date when the first post-vaccination blood sample was taken (approximately the ninth week after vaccination). We have no laboratory data to support this hypothesis, because the trial was originally planned on the basis of observations by Koprowski *et al.* (1956) that TN type II vaccine virus was excreted in scarcely detectable amounts over a short period, and for this reason collection of faecal specimens was not continued long enough. However, a number of children were excreting faecal virus during the fourth week after vaccination, when specimen collection ceased, and there seems to be no reason why they should not have continued doing so for several months, as was the case in children vaccinated with SM type I virus (Koprowski *et al.*, 1956).

The possibility that some of the rises in type II antibody might have been due to natural infections with heterologous poliovirus types was also considered. Serum specimens taken at the time of vaccination and one year later were tested at a 1:4 dilution against types I and III poliovirus to find out whether any children had developed antibody against

these poliovirus types. Titrations of the paired sera from children found to have developed antibody showed that six natural infections had occurred—three with type I poliovirus and three with type III poliovirus. In the course of another investigation type I poliovirus had in fact been isolated from two of the children who showed serological evidence of a type I infection.

We conclude that heterotypic poliovirus infections could only have contributed to the late rise in type II antibody in these six instances.

After testing the first post-vaccination blood sample (taken after about two months) we reported that only 77% of 124 children had developed neutralizing antibody following vaccination with TN type II virus (Dane *et al.*, 1957). We were able to obtain blood samples one year later from 15 of the 28 children who did not develop antibody. None were found to have developed type II antibody during this interval, thus confirming our original conclusion that the vaccine had failed to "take" in these individuals.

Influence of Heterotypic Antibody on Vaccination with TN Type II Virus

Because of the possibility that previous natural heterotypic poliovirus infections might have influenced the response of children to vaccination with TN type II virus, pre-vaccination samples of blood from 110 children who had been vaccinated with TN type II virus were tested for neutralizing antibody at a 1:4 dilution against types I and III poliovirus. The pre-vaccination antibody patterns found are shown in Table II. Children possessing different pre-vaccination heterotypic antibody patterns showed no significant difference in their response to vaccination.

TABLE II.—Poliomyelitis Neutralizing Antibody Patterns at the Time of Vaccination in 110 Children Fed TN Type II Virus in 1956

Discussion and Conclusions

The neutralizing antibody levels which we found in children one year after vaccination with TN type II virus were of the same order as those reported in non-immune children who had received two injections of formalized vaccine a year before (Report, 1957). A number of the TN-vaccinated children were found to have had a marked decline in their neutralizing antibody level over the year, and our previous finding that 23% of children failed to develop antibody after vaccination was confirmed.

One of the advantages claimed for oral attenuated poliomyelitis vaccines is that they will produce a more durable immunity than formalized vaccines. We can find no evidence that this was true in a proportion of children vaccinated with TN type II virus. Admittedly our yardstick for the measurement of immunity has been circulating neutralizing antibody. Some sort of local gut immunity follows infection with oral poliovirus vaccines, but in the absence of more precise information about this local immunity it would be unwise to assume that it is more durable than circulating antibody.

Further trials of Koprowski's TN type II vaccine have been abandoned because the virus is liable to change its character and become virulent after growth in the human gut. If it can be shown that the recently developed more highly attenuated poliovirus vaccines do not suffer from this drawback, then it would seem desirable to show also that they can produce a reasonably durable immunity in the majority of vaccinated subjects before they are used on a large scale. On the basis of the results reported here we do not think that durability of immunity should be considered as an automatic benefit associated with living vaccines.

We wish to acknowledge grants from the National Fund for Poliomyelitis Research, the Medical Research Council, and the Northern Ireland Hospitals Authority.

The purpose of this small-scale trial of a single strain of living attenuated poliovirus vaccine was to obtain information concerning the capacity of the virus to induce infection in children previously immunized with inactivated Salk-type vaccine, to measure the antibody formation after the feeding of the virus, and to compare the virulence for monkeys of excreted virus with that of the strain composing the vaccine. In addition, evidence was sought concerning the spread of virus from vaccinated children to their contacts. The virus vaccine selected for use was the type III attenuated poliovirus from culture of monkey-kidney tissue developed by Dr. Albert B. Sabin and obtained as virus-containing culture fluid from Dr. J. D. Verlinde at Leyden. The virus was the highly purified Leon strain previously subjected to many kidney-tissue-culture passages and plaque-selection, and designated the 12a,b (KP4) virus (Sabin, 1957). The strain pool was freshly titrated by one of us (A. P. G.) upon receipt and found to have a titre of $10^{7.55}$ 50% tissue-culture infective doses per ml.

Control Period of Study

The test was carried out in a long-stay orthopaedic institution where the children were under treatment for lesions such as those due to Perthes's disease or tuberculous arthritis. A control period of study began in September, 1957, when immunization with two doses of British-type Salk vaccine was given to certain boys whose parents volunteered for their inoculation. Nineteen boys aged 6 to 15 years received vaccine intramuscularly after a preliminary withdrawal of 10 ml. of blood. The second dose of vaccine was given one month after the first dose, and all inoculations were completed by December 4, 1957. A second specimen of blood was obtained two weeks after the second

*In receipt of a grant from the Medical Research Council and the National Fund for Poliomyelitis Research.

dose of vaccine, and the neutralizing antibody contents of the pre- and post-immunization sera were estimated by titration in monkey-kidney-tissue cultures against each of the three types of poliovirus (Tyrrell *et al.*, 1956).

Permission to use live poliovirus as a boosting vaccine was sought from the parents of those who had received Salk-type vaccine and was given in 14 instances. The children were housed in two wards prior to the trial. One of these contained 12 children aged 6 to 8, of whom five eventually went into the trial, while the remaining nine children in the trial came from a second ward of 12 children aged 9 to 15. Faeces were obtained once weekly for 17 weeks from all children in the first ward and for a further three weeks from all children who were to receive live virus in both wards. In no instance was a strain of poliovirus obtained from the faecal suspensions tested in pools of three to four specimens which were inoculated into monkey-kidney-tissue cultures. This preliminary period of testing was considered desirable because patients convalescent from poliomyelitis were nursed in the same hospital. But their wards were in a separate building situated at least 200 yards (180 m.) from the main block of the hospital. Segregation of the patients in the respective sections was complete. The only natural virus strains recovered in Sheffield at any time from September, 1957, to April, 1958, had been obtained by Dr. J. E. M. Whitehead at the Public Health Laboratory, Sheffield, during the acute phase of illness prior to the transfer of patients with poliomyelitis to the orthopaedic hospital. All were of type I poliovirus. No case of type III poliomyelitis was in fact encountered in Sheffield during the entire period of the trial, and the last case of type III virus isolation had been in December, 1956.

Period of the Trial

The 14 boys aged 6 to 15 years who were to receive live virus vaccine were collected together and were the sole inmates of one ward on February 16, 1958. They were attended by nurses who had been previously immunized with two doses of Salk-type vaccine. All but three of the boys were confined to bed, and some were immobilized on frames during the period of observation.

Virus was fed orally in hard gelatin capsules containing a dilution of stock vaccine virus in sterile synthetic medium 199 mixed with polyethylene glycol 400 so as to contain $10^{4.5}$ TCD₅₀ infective doses of virus in a volume of 0.2 ml. A third sample of blood was obtained from each boy prior to virus feeding, which was carried out in two stages.

On February 17 seven boys received capsules containing virus and seven received capsules filled with uninfected culture medium. Faecal specimens were obtained daily or when passed from all the boys during the ensuing weeks, and occasional specimens were obtained from the nurses in contact with the boys.

The second stage of the feeding of virus took place on March 10, 1958, when 11 boys, including all those previously fed dummy capsules, received a capsule containing live virus similar in amount to that previously used. Faecal specimens continued to be obtained at frequent intervals from all children found to be excreting virus, until the specimens were negative. A fourth sample of serum was collected from all the boys on April 1, six weeks after the first virus feeding and three weeks after the second administration of virus. These serum samples, together with the third samples, were titrated for neutralizing antibodies to the three types of poliovirus as before. The results obtained with these sera and also with the faecal specimens are described after details have been given of the technical methods which were used.

Technical Methods: (a) Sheffield

Isolation of Poliovirus from Faeces

Faeces were stored at -25°C . until tested. Emulsions of 10–30% were then made in Hanks's saline, which contained 1,000 units of penicillin and 1,000 units of streptomycin per ml. Each emulsion was centrifuged at 3,000 r.p.m. for one

hour, and 0.5 ml. of the supernatant was inoculated into each of four monkey-kidney-tissue culture tubes containing 1.5 ml. of medium. Trypsinized monkey-kidney-tissue cultures were prepared as described by Balducci *et al.* (1956) from rhesus and cynomolgus monkeys. The maintenance medium consisted of 2% calf serum and 0.25% lactalbumin hydrolysate in Hanks's saline to which three times the normal amount of 1.4% NaHCO₃ solution had been added. Three to six hours after inoculation the emulsion was removed from the cultures and fresh medium added. When specific cytopathogenic changes appeared the medium and cells were harvested and stored at -25°C . If no cytopathogenic change appeared after 12 days' incubation the cultures were harvested and a second blind pass was made. This was also incubated for 12 days, and if any suspicious cytopathogenic effect appeared a third pass was made. The faeces collected during the control period were tested in pools of three or four specimens, and only one pass in monkey-kidney-tissue culture was made unless suspicious cytopathogenic effects appeared. Throughout the period of the trial, when faeces were collected and examined no live poliovirus of any type was used in the Sheffield laboratory and no faeces from other sources were examined. The neutralization tests on the serum specimens were done before and after this period.

Titration of Faeces

Accurate 10% emulsions were made from most of the virus-containing faeces. Tenfold dilutions of these emulsions were made in Hanks's saline, and 0.2 ml. of each dilution was inoculated into each of two monkey-kidney-tissue culture tubes containing the medium as used for isolation. End-points were calculated by the method of Reed and Muench (1938).

Neutralization Tests

Sera previously stored at -25°C . were inactivated at 56°C . for 30 minutes and serial fourfold dilutions made in Hanks's saline. The same pools of virus were used in each batch of tests. They were diluted in Hanks's saline, so that 50 TCD₅₀ were inoculated into each of the tissue-culture tubes. Equal volumes of serum dilution and virus dilution were mixed in screw-capped bottles and allowed to stand at room temperature for one hour. Into each of two monkey-kidney-tissue culture tubes 0.5 ml. of each mixture was then inoculated. The tests were read daily and the end-points calculated for the day after full degeneration had occurred in the control tubes (usually the fifth day after inoculation). The titres were expressed as the reciprocals of the serum dilutions before the addition of virus. The titre was estimated as "2" when the end-point was less than 4 on the final day of reading the test but where some antibody had been detected at readings on earlier days. The titre was expressed as "less than 4" if no neutralization was apparent when a cytopathogenic effect first appeared in the control tubes. However, the technique was not sensitive enough for detection of very small amounts of antibody. The specimens taken before and after Salk vaccination or before and after feeding the live vaccine for each child were tested at the same time. A control serum was included in each batch of tests.

Technical Methods: (b) Beckenham

Virus Titrations

Each virus pool inoculated into monkeys was titrated for tissue-culture infectivity. Trypsinized rhesus or cynomolgus monkey-kidney cultures in roller tubes were used when an abundant healthy monolayer of epithelial cells was present. Cultures were maintained on a protein-free medium devoid of inhibitors which had been shown to be of optimum sensitivity for demonstrating the cytopathic effect of poliovirus; it consisted of 5% horse-liver digest ultrafiltrate in Earle's balanced salt solution (S. E. Smith, personal communication, 1958). Serial tenfold dilutions up to 10^{-8} of each virus were made in this medium, and 0.5 ml. of each dilution was inoculated into 10 cultures each containing

1.5 ml. of freshly changed medium. Cultures were examined up to the seventh day after inoculation, when final readings were taken and the 50% tissue-culture degeneration end-point (TCD₅₀) was calculated by the method of Kaerber (Irwin and Cheeseman, 1939). Each pool selected for virulence study was titrated on the day it was inoculated into monkeys, and again on a subsequent date together with all other virus pools using one tissue-culture batch. Differences between the two titrations varied between zero and 0.5 log₁₀. In Table III the quantities of virus are expressed as TCD₅₀ per ml. of culture fluid and are derived from the mean of the titrations.

The vaccine virus has been titrated four times. It was received frozen at -70° C. and was thawed and titrated; smaller lots were distributed into ampoules and refrozen at -70° C. Three ampoules have been thawed for titration subsequently. The first titration gave a value of 7.55 log TCD₅₀ per ml. Three titrations of the refrozen material gave values of 6.7, 6.8, and 6.9 log TCD₅₀ per ml., indicating a fivefold loss by this procedure. Since twice-thawed material was used for both feeding and virulence tests the value of 10^{6.8} TCD₅₀ per ml. has been used.

Virulence Tests

A test for virulence, semi-quantitative in nature, was done on the vaccine, as fed to the children, and on two samples of excreted virus from each child proved to be a virus carrier. The first and the last virus strains isolated from the faeces during the study period were tested, except in one child where the virus excreted on the second day after feeding was tested because the first-day specimen contained very little virus. Tissue-culture fluids of the first passage from cultures inoculated with faecal suspensions were pooled when a full cytopathic effect was apparent, and these fluids were used for the virulence experiment.

Each virus pool was inoculated undiluted into two or three monkeys and diluted 1 in 100 into two or three monkeys. Normal cynomolgus monkeys, between 1.2 and 2.9 kg. in weight, received 1 ml. of sample intracerebrally under thialbarbitone, 0.5 ml. being placed in each thalamic region (Bodian, Morgan, and Schwerdt, 1950). Monkeys were observed for up to 30 days after inoculation, during which time they were isolated in groups of two or three in cages measuring 3 ft. (90 cm.) high by 2 ft. (60 cm.) square, and were not removed unless obviously paralysed. It became apparent during the experiment that this method of observation had a high threshold; minor grades of paralysis were almost certainly missed through not exercising monkeys in an open run. Monkeys showing severe paralysis were sacrificed immediately; those showing minor paralysis were watched over for one or two days for further spread; one monkey showing only moderate involvement of both legs on the 14th day was kept until the 29th day with a fair degree of recovery. All surviving monkeys were killed between the 28th and 30th days after inoculation. At post-mortem examination, samples of blood and lumbar enlargement of spinal cord were taken for recovery of virus, after which the whole animal was fixed by perfusion with 10% formal-saline. Selected lengths of lumbar, thoracic, and cervical cord were processed for histological examination.

Results of the Trial

Clinical

No clinical reactions which could be related to the administration of the live vaccine were detected in the boys or in their contacts. Virus excretion which was believed to signify actual infection therefore occurred in the absence of those clinical phenomena, such as pyrexia, minor illness, and so on, which may accompany the non-paralytic form of clinical poliomyelitis.

Virus Excretion

Excretion of the virus was detected in 6 of the 14 subjects who received live virus by mouth, and in five cases was prolonged and quantitatively considerable in amount. Virus strains were recovered from 2 of the first 7 boys fed virus and from 4 of the 11 fed virus on the second occa-

sion. Four who were fed virus on two occasions and who did not excrete virus on the first occasion also failed to excrete virus on the second occasion. Nor were viruses recovered from the seven boys given dummy capsules during the first stage of the trial, when two other boys were actively excreting virus, or from nurses at any phase of the trial. No evidence of spread of virus to contacts was thus obtained, but it happened that all the boys who excreted virus were immobilized on Jones frames during the entire period of the trial.

The amounts of virus detected in the stools of five of the six boys who excreted virus are shown in Table I. The

sixth boy (1311) excreted a very small amount of virus for only 24 hours after oral feeding. As this virus was detected only after three tissue-culture passages it seems likely that it represented vaccine virus which had passed through but did not multiply in the intestinal tract. The five boys shown in Table I excreted quantities of virus varying from 1.1 to 5.2 log₁₀ 50% tissue-culture infective doses of virus per gramme of stools. Excretion occurred for periods from 9 up to 30 days including the day on which virus was first detected. It is certain that multiplication of virus had taken place in the alimentary tract of these five children. The viruses recovered from each of two specimens of faeces from each child were typed by neutralization techniques. All were found to belong to type III poliovirus.

Antibody Response

The results of serum neutralization tests on all 14 of the boys in whom the trial was made are shown in Table II. The rise in antibodies after the two doses of Salk-type vaccine were of the same order as those found by other workers (M.R.C. Committee, 1957; Russell, 1958). Good antibody responses were obtained in most of the boys, but one boy (1203) failed to respond to the type III antigen and one (1200) to the type I antigen. After the feeding of the live vaccine children who did not excrete virus and the

one boy with transient excretion showed no increase or a twofold decrease in antibody to type III virus and variations with a twofold increase or decrease in antibodies to the other types. Of the five children who excreted virus for prolonged periods one showed no change in antibody levels and one showed a twofold decrease in antibody to type III virus. The remaining three children all showed a fourfold or greater increase in type III antibody without any significant alteration in antibodies to the other poliovirus types. The two children who showed no antibody response after the live virus vaccine had received the second dose of inactivated vaccine 2½ and 4½ months previously. This relatively short interval of time may have been responsible for their failure to develop a further increase in antibody.

In such a small number of subjects it is clearly impossible to discern correlations between the ability of the oral vaccine to establish infection and the antibodies pre-existing in the blood. Of the five who became infected, two had no antibodies to type III virus before the administration of Salk-type vaccine, and only one of those who failed to become infected was similarly devoid of such antibody. On the other hand, the geometric mean titre of the type III antibodies just prior to feeding was 42.2 in those who developed infection compared with a mean titre of 351.8 in those who proved resistant to infection. Finally, four of the five boys who became infected were among the youngest subjects in the trial, so that it is possible that age is as important a factor in determining the likelihood of infection as is naturally or artificially acquired antibody.

Neurotropism of Excreted Viruses

The comparative virulence for monkeys of the vaccine virus and of the strains of virus excreted by the five boys considered to have developed an alimentary infection is shown in Table III.

None of the monkeys inoculated with vaccine showed either paralysis or other evidence of neurotropic activity. On the other hand, each child in whom the vaccine virus multiplied excreted at some stage a virus of increased virulence. The viruses included in Table III show a graded spectrum of neurotropic activity which bore a distinct relationship to the length of time that the virus had had to multiply after the original feeding. Thus Case 1308 on the first day and Case 1205 on the second day showed viruses of similar behaviour to the vaccine. Cases 1203 and 1202 on the second day showed some slight increase in paralytic activity. Every strain after the second day showed paralytic activity at the lower concentration of virus inoculated. With the exception of Case 1201, in whom the 7th-day and 31st-day virus both showed strains of intermediate virulence, all cases showed an increased virulence in the strain of virus excreted later compared with that excreted in the earlier phase of infection. On the 14th day Case 1203 showed a degree of neurotropism similar to that of field strains of type III virus from paralytic cases. Eight thousand tissue-

culture doses given intracerebrally caused severe paralysis of relatively rapid onset in two monkeys and extensive histological lesions in a third monkey. One monkey had viraemia at the onset of paralysis on the sixth day after receiving the lower dilution of virus.

As will be noted from Table III, the extent of involvement of the spinal cord revealed by histological examinations was greater than that shown by clinical assessment of the monkeys from outside their cages. The lesions in some cases were indeed extensive and severe, as can be seen from Figs. 1, 2, and 3. All the viruses recovered from the spinal cords of these monkeys were type III. No other strain of poliovirus was being used in the unit housing the monkeys during the period of these experiments.

Discussion

The use of living attenuated viruses for immunization against poliomyelitis is now being actively pursued by several different groups of observers. There are, however, few recorded observations concerning the use of such vaccine as an agent for reinforcing the basic immunity acquired by immunization with Salk vaccine. Paul *et al.* (1957) reviewed the argument for such a use of an attenuated live virus vaccine and suggested that it might be desirable to obtain a planned exposure to an attenuated virus by mouth rather than to rely upon natural infection with an unpredict-

able dose of wild possibly virulent poliovirus. They showed (Horstmann *et al.*, 1957b) that a child of 9 vaccinated previously with Salk vaccine was readily infected by live attenuated type III virus (Leon—KP34) fed by mouth. In a later trial of type I virus (L.Sc. strain) under conditions where spread of infection readily occurred to contacts, Horstmann *et al.* (1957a) found that children immunized with Salk vaccine acquired alimentary infection in 10 out of 10 instances after virus-feeding by mouth and in 12 out of 13 instances by natural exposure. These observations are paralleled by the occurrence of alimentary infection under natural circumstances in previously vaccinated children who were family contacts of cases of poliomyelitis (Lipson *et al.*, 1956; Gelfand *et al.*, 1957; Davis *et al.*, 1958). It thus appears likely that children who have received Salk-type of inactivated poliomyelitis vaccine can readily become infected under natural conditions or after deliberate feeding of poliomyelitis virus. Yet the observations of Sabin (1956) and of Horstmann *et al.* (1957a) showed that persons whose blood contained naturally acquired antibodies frequently resisted infection by live attenuated viruses fed by mouth, thus suggesting that the alimentary tract does acquire immunity after exposure to poliovirus.

Our own study has confirmed the fact that it is possible to infect the alimentary tract of children previously immunized with two doses of Salk-type vaccine in spite of the presence of antibodies in the serum at the time of infection. Too few of the children lacked type III antibody prior to immunization with Salk-type vaccine for us to throw any light on the relative protective power of natural versus artificially acquired antibody, though the data suggested that age of the subject may be a factor in this question of immunity. The circumstances of our trial were also too restrictive for the observation that spread of virus did not take place from carriers to contacts to have much significance. No spread of infection was in fact observed by Horstmann *et al.* (1957b) in the study of a similar attenuated type III virus in a ward of 13 mentally defective children and adults. On the other hand, the L.Sc. type I attenuated virus fed in the later study of Horstmann *et al.* (1957a) to mentally retarded children spread widely, so that strain differences as well as the circumstances of the trial may be important in determining whether or not contact infection will occur.

The antibody-boosting capacity of infection with attenuated poliovirus proved less uniform than was expected. One explanation of the failure of two of the five infected children to react may be that the recent boost of antibody consequent upon the injection of Salk-type vaccine had interfered with the capacity of the alimentary infection to raise the antibodies to a still higher level (Sabin, 1957). However, Dick and Dane (1957), who worked with the rodent-adapted type II strain developed by Koprowski *et al.* (1956), similarly recorded a failure of uniformity in antibody response after oral feeding.

Probably the most important of our observations are those relating to the comparative virulence of the vaccine virus which was fed and that of the strains of virus recovered from the stool. Tests on the vaccine virus fully confirmed Sabin's opinion concerning the high degree of attenuation of this virus for the brain and spinal cord of the monkey. However, all the children whose faeces contained virus for several days after oral feeding excreted strains with a capacity to induce paralysis in monkeys inoculated intracerebrally. Sabin (1957) found that the viruses excreted by persons fed attenuated poliovirus strains had an altered neurotropism in that they would sometimes produce paralysis after direct intraspinal inoculation into monkeys. Some increase in intracerebral activity was also

recorded, more frequently for type III than for types I and II, but less consistently and of a lower order than that recorded above. However, the majority of viruses examined by Sabin were isolated early in excretion; in common with our finding, increased neurotropism was found most often at a later stage of excretion. Nevertheless, Sabin considered that such excreted viruses were less highly neurotropic than wild polioviruses disseminated by healthy children during non-epidemic periods.

It is a matter of opinion whether all the viruses excreted by the children in our trial were less virulent than strains encountered in nature. But the degree of alteration from the original vaccine strain appeared to be considerable. In this regard our observations seem to be similar to those recorded by Dane *et al.* (1957) with rodent-adapted type II virus and by Dick *et al.* (1957) with modified type I virus (Koprowski *et al.*, 1956). It will be recalled that Dick and Dane (1957) stated that these virus strains were unacceptable for mass immunization because of their alteration in virulence during passage through the alimentary tract. In spite of the mass use of living attenuated poliovirus vaccine in the Belgian Congo (Courtois *et al.*, 1958) it is our opinion that further research concerning the properties of the viruses excreted by those receiving such vaccines is desirable in order to reconcile the conflicting evidence.

Summary

Fourteen children who were patients at a long-stay orthopaedic hospital were immunized with two doses of British inactivated poliovirus vaccine and were later given living attenuated type III virus vaccine (Sabin) by mouth in gelatin capsules. No adverse clinical reactions were observed. Five of the children developed an alimentary infection, as shown by excretion of virus in the stools for from 9 to 30 days, and in three instances by a further increase in antibody titre. No instance of spread of excreted virus to contacts was detected. The vaccine virus and some of the viruses excreted early in the course of infection did not produce paralytic effects in monkeys inoculated intracerebrally. All five infected children excreted strains of virus possessing enhanced neurotropic properties for monkeys at a late stage of the infective process.

We wish to thank Dr. A. B. Sabin for kindly permitting us to use the attenuated type III virus vaccine. Dr. V. Udall, of the Wellcome Research Laboratories, gave much assistance in the histological examination of the monkey nervous tissue.

COMBINED GASTRIC AND DUODENAL ULCERATION

A SURVEY OF 157 CASES

BY

R. MANGOLD, M.D.

From the Department of Gastro-enterology,
Central Middlesex Hospital, London

From the time Sir David Wilkie (1926) first reported on combined ulceration of the stomach and duodenum there has been a considerable divergence of opinion in respect to its incidence. This is revealed in the recent observations by Feldman (1953) and by Johnson (1955). From their papers it would appear that surgeons as a rule observe a much higher proportion than is found in either post-mortem or radiological studies. Johnson also drew attention to gastric retention as leading to gastric lesions in patients suffering from chronic duodenal ulcer. The present study shows the incidence of combined ulcers as encountered in a general hospital, and gives some additional information on duodenopyloric stenosis causing secondary ulcer of the stomach. It also reveals the increased danger of bleeding, making surgical treatment more advisable than with a single ulcer.

Material

The 157 cases reported here were collected from the files of the in-patient and out-patient clinics of the Central Middlesex Hospital, London. Only cases with combined ulcers first diagnosed in the years 1947 to 1954 were included. Definite radiological, surgical, or post-mortem evidence of chronic ulceration was required. Acute ulcers were excluded. In all doubtful cases the x-ray films were reviewed. While the work proceeded, it became increasingly obvious that cases with antral, prepyloric, and pyloric ulcers were not suitable for analysis. There would often arise considerable doubt about the exact location of the ulcer. Extensive scarring due to prepyloric lesions will sometimes lead to secondary duodenal deformity, particularly after perforation. For this reason, only gastric ulcers at or above the angulus were included.

Incidence

During the eight-year period from 1947 to 1954, 157 cases showing both gastric and duodenal ulcers or ulcer scars were observed. In 139 of these, both ulcers were diagnosed radiologically. During the same period 3,744 duodenal and 1,352 gastric ulcers were detected by x-ray study in the hospital, excluding the combined lesions. Based on x-ray findings, the observed incidence is 2.7%. As mentioned above, cases with prepyloric ulcers were not included in the combined ulcer group. Ihre and Müller (1943) observed 26% of all benign gastric ulcers to be prepyloric. Many authors give figures lying between 15 and 20%, but Gott,

TABLE I.—Incidence of Combined Ulcers Based on X-ray Investigation (Central Middlesex Hospital, 1947–54)

No. of Cases With Single Ulcers	Combined Ulcers (Prepyloric Ulcers Excluded)		Combined Ulcers (Estimated 25% Prepyloric Ulcers Included)	
	No.	Incidence	No.	Incidence
D.U. ... 3,744	139	$\frac{139 \times 100}{3,744 + 139} = 3.6\%$	185	$\frac{185 \times 100}{3,744 + 185} = 4.7\%$
G.U. ... 1,352*		$\frac{139 \times 100}{1,352 + 139} = 9.3\%$		$\frac{185 \times 100}{1,352 + 185} = 12.0\%$
All ulcers 5,096		$\frac{139 \times 100}{5,096 + 139} = 2.7$		$\frac{185 \times 100}{5,096 + 185} = 3.5$

* Including prepyloric ulcers.

Shapiro, and Kelty (1954) found 42% of gastric ulcers below the angulus. If an estimated 25% of prepyloric ulcers are added, the number of combined ulcers would increase to 185 and the incidence to 3.5% (Table I). Thus one in every eight hospital patients suffering from an ulcer of the stomach and about 1 in 30 patients having a duodenal ulcer or ulcer scar may be expected to have an associated ulcer of the other organ as well.

It has been suggested by Johnson (1955) that many combined ulcers may be missed on x-ray examination, thus decreasing their apparent proportion. In this series, 18 cases were not diagnosed by x-ray examination. In six of these no barium-meal study was performed at any time before surgery or necropsy disclosed the ulcers. In most cases an emergency situation such as bleeding or perforation was responsible for this omission. In another six cases the last radiological investigation had taken place two to six years before gastric surgery revealed an additional ulcer not shown before. Judging from the symptoms during the interval, the presence of combined ulcers at the previous examination is unlikely. In only five patients was one of the ulcers certainly missed. There were duodenal scars in four of these patients, and an active duodenal ulcer in one, accompanied by a considerable degree of pyloric stenosis. In addition, one gastric ulcer was possibly not detected two months before it was found at an emergency operation for bleeding. In no case examined radiologically were both ulcers missed. Thus the x-ray findings were incomplete in less than 5%. It is believed that careful x-ray examination provides reliable data for estimating the incidence. The high proportion of positive diagnoses reflects the particular care taken in the hospital's x-ray department in respect of barium-meal studies as well as the awareness of the frequent concomitance of ulcers. In the majority of cases the radiological diagnosis was confirmed by surgery or gastroscopy or both.

Time Sequence of Ulcer Appearance

The sequence is of some importance in aetiological considerations on combined ulceration. Previous observations by Feldman (1953) and Johnson (1955) showed that a proved chronic duodenal ulcer preceded the appearance of the gastric ulcer in most patients. This sequence took place in 91 patients (group 1), of whom 20 were women (Table II).

TABLE II.—Sequence of Ulcer Appearance and Sex Incidence

Group	Sequence	Total	Men	Women	Sex Ratio
1	D.U.→G.U.	91	71	20	3.6:1
2	"Simultaneous" G.U.+D.U.	25	19	6	3.2:1
3	Sequence unknown	20	17	3	5.7:1
4	D.U.→G.E.→G.U.*	13	11	2	5.5:1
5	G.U.→D.U.	8	7	1	7:1
	All groups	157	125	32	3.9:1

* Including one vagotomy without gastro-enterostomy.

In 25 others the ulcer history was remarkably short, rarely exceeding two months. Still the first x-ray examination or surgery performed for complications showed both active duodenal and gastric ulcers (group 2). No sequence could be established in 20 patients with incomplete records or in cases where a long ulcer history preceded the first x-ray study which showed combined ulcers (group 3). Twelve patients underwent gastro-enterostomy for duodenal ulcer 1 to 25 years before a gastric ulcer at some distance from the anastomosis was discovered (group 4). Another patient also included in this group had submitted to a vagotomy without gastro-enterostomy for duodenal ulcer two years before an ulcer of the stomach appeared. Similar cases have been reported by Johnson (1955).

Evidence for a gastric ulcer preceding a duodenal ulcer was obtained in eight patients (group 5). The early x-ray films of these patients were reviewed by the radiologist, and the duodenal cap was found to be normal in the presence of a gastric ulcer in all instances.

Sex and Age Incidence

Of the 157 patients with combined ulcers, 32 were women, giving a sex ratio of 3.9:1 (Table II). This figure lies between the ratios of 2.4:1 in respect to gastric and 6.8:1 in respect to duodenal ulcers found during a somewhat earlier period at the Central Middlesex Hospital (Avery Jones and Pollak, 1945). There was little variation of this ratio in the different age groups in either this or the present study. Deviations in the small groups may be due to an inadequate number of cases.

The age incidence is represented in the lower half of the Chart, which shows the distribution at the time both ulcers were recognized. For comparison, the age distribution of duodenal and gastric ulcers at the same hospital is included in the upper half (Avery Jones and Pollak, 1945). It is readily seen that the age distribution in combined ulcers is very similar to the gastric ulcer group.

In patients with duodenal ulcer preceding gastric ulcer (group 1) the mean age at which the combined lesion was diagnosed was 54 years, with little variation between the sexes. Symptoms of peptic ulcer appeared at the much earlier age of 39 years on the average. However, the diagnosis of duodenal ulcer usually was established much later, after an interval averaging almost eight years. Many of the patients showed no free interval before the gastric ulcer appeared, making it impossible to date the onset of the latter. In some, however, there was either a relapse following a prolonged remission or a definite change in the character of the disease, and in these the interval between onset of symptoms and x-ray or surgical confirmation of gastric ulceration was quite short.

In the other groups the mean age at the time both ulcers were discovered similarly lies between 50 and 55 years. In group 5 the gastric ulcer was diagnosed on the average six years before the duodenal ulcer. Intervals ranged from some months to 14 years.

Characteristics

Activity.—As judged by definite x-ray demonstration of an ulcer crater or by surgery, both ulcers were active together at any one time in 98 of the 157 patients. This incidence of almost two-thirds may reflect the severity of the disease in this series.

Free Interval.—A symptom-free interval lasting more than one year was present in 41 patients. This figure applies to the 112 patients with a known sequence only (groups 1, 4, and 5). In the eight cases showing the gastric-duodenal ulcer sequence (group 5) any free interval was always shorter than one year.

Change in Symptoms.—Most symptoms besides pain were too indefinite to allow investigation. Excluding groups 2 and 3 ("simultaneous" appearance or unknown sequence) as well as cases with incomplete records in this respect, enough notes on pain were available in 89 patients. Some definite change was noted in 42 of these, being a change in character of pain only in 29, a shift in site only in another 3, and a change in site as well as character in 10 patients. It appears

that in a minority only can combined ulceration be suspected on the basis of change in symptoms. The significance of vomiting is discussed below.

Site of Gastric Ulcer.—The ulcer was located at the angulus in 45 cases, at the middle third of the lesser curve in 82, and at the upper third in 30. In the presence of multiple ulcers the lesion appearing first was taken into account. No relation of the ulcer site to either age or sex could be established.

Multiple Ulcers.—These were present in 22 cases, with two gastric ulcers in nine cases, three gastric ulcers in three, and four gastric ulcers in one. Kissing duodenal ulcers were observed in nine instances.

Gastric Retention

With regard to pyloric stenosis, the following groups were established. (A) Occasional or no vomiting; no x-ray evidence of delayed emptying. (B) Frequent but transitory vomiting; little vomiting with considerable loss of weight; no x-ray evidence of delay. (C) Delayed emptying, later followed by normal emptying on x-ray investigation. (D) Pyloric stenosis, predominantly organic in nature, as a rule treated surgically.

Table III shows the respective distribution. Not included among the 131 cases are the patients with a former gastro-enterostomy. In these no delay in emptying appeared to be present, and some factor other than retention might be

TABLE III.—Incidence of Gastric Retention

Presence and Degree of Gastric Retention	No. of Patients	Incidence
A. No or rare vomiting; normal emptying	94	71.7%
B. Frequent vomiting or weight loss; normal emptying	12	9.2%
C. Transitory delay in emptying	13	9.9%
D. Organic pyloric stenosis	12	9.2%
Total (cases with gastric-duodenal sequence and G.E. or vagotomy excluded)	131	100%

responsible for gastric ulcer formation. Also excluded are the eight cases with the unusual gastric-duodenal-ulcer sequence and five cases with insufficient details. In group A gastric retention was presumably never present, and thus would not appear to play any part in the appearance of the gastric ulcer in more than 70% of the series. Even this figure may represent a conservative estimation, because it is by no means certain that frequent vomiting or loss of weight is indicative of decreased emptying. Severe pain and even fear of pain may give rise to both.

Other Complications

Of the 157 patients, 59 had a total of 89 haemorrhages. This incidence has to be considered in relation to duration of the disease as shown in Table IV. In the group of 91 patients with the known duodenal-gastric-ulcer sequence, nine suffered from haemorrhages while they had a duodenal ulcer only, the disease lasting on the average 12½ years. At

TABLE IV.—Incidence of Bleeding in Single and Combined Ulcers Related to Duration of Disease

	No. of Patients	Patients with Haemorrhage		No. of Haemorrhages	Average Duration of Disease in Years
		No.	%		
Duodenal ulcer (Group 1 only*)	91	9	10	11	15 {with haem., 12.5 without haem., 16.4
Combined ulcers (Group 1 only*)	91	27	30	36	1.4 {with haem., 1.1 without haem., 1.6
Combined ulcers (all groups)	157	45	29	64	
Total	157	59	38	89	13

* See Table II.

the time combined ulcers appeared there were 36 instances of bleeding in 27 patients. The haemorrhages then took place in a period barely exceeding one year. The gastric ulcer was proved to be the source of bleeding in 16 of these patients, while the others may have bled from either stomach or duodenum. Thus the incidence of bleeding appears much higher in the presence of combined ulcers in spite of their short coexistence.

In many instances the combined ulcer disease was terminated by partial gastrectomy, often after the first haemorrhage. This would alter the proportion of haemorrhages in respect of time. To obviate this difficulty a special group of 49 patients was investigated. These 49 cases could be followed for a period of at least one year after the diagnosis of gastric ulcer following duodenal ulcer was established by x-ray examination. Six patients suffered from a total of eight haemorrhages while they supposedly had a duodenal ulcer only, the disease lasting 722 patient-years in the 49 cases. On the other hand, during the period of combined ulceration with 130 patient-years, the number of haemorrhages was 12, with 10 patients bleeding. Thus there was one haemorrhage for 90 patient-years with single as compared with one for 11 patient-years with combined ulcers in this group. These findings correspond reasonably well with the data of all patients with the same sequence.

Age was not responsible for an increased incidence of bleeding, the patients with haemorrhages being on the average four years younger at the time both ulcers were discovered.

In all groups taken together there were 89 haemorrhages in the 157 patients, and at least every third patient bled at one time or another. Although in several instances it was difficult to correlate the bleeding accurately with the presence of either single or combined ulcers, in 45 patients at least the haemorrhage took place when both gastric and duodenal ulcers were present. Here again the much higher incidence is apparent, inasmuch as the bleeding took place during a period averaging little more than one and a half years. Some patients, however, may have bled from a lesion other than a gastric or duodenal ulcer, particularly in the group with a previous gastro-enterostomy.

The 24 perforations in 22 patients were with one exception duodenal. There were nine cases of hourglass deformity of the stomach.

If pyloric stenosis is included, 92 of the 157 patients thus suffered from one or more major complications—again a striking proportion. The complications are listed in Table V.

TABLE V.—Complications, Operations, and Deaths in 157 Patients With Combined Ulcers

	No. of Patients	Incidence
Gastric retention { Possible	12*	9%*
Proved	25*	19%*
Haemorrhage	59	38%
Perforation	22	14%
Hourglass stomach	9	6%
One or more complications	92	59%
Operations { Partial gastrectomy	68	43%
All types	82	52%
Deaths	5	3%

* Of 131 patients (see Table III).

Deaths

During the eight-year period there were five known deaths more or less directly due to the ulcer disease. The causes of death were as follows. One patient died from bronchopneumonia after a successful partial gastrectomy for active duodenal and gastric ulcers at the age of 68. Subacute bowel obstruction four months after gastrectomy required another operation, from which the patient did not recover. A second fatality related to surgical treatment occurred in a man aged 53 operated on for both gastric and stomal ulcers

after a gastro-enterostomy established 15 years earlier for duodenal ulcer. Death took place following reoperation necessitated by bleeding shortly after partial gastrectomy. Another patient, aged 69, had well recovered after suture of a perforated duodenal ulcer, but died suddenly from massive bleeding due to chronic gastric ulcer. A fourth male patient with a 30-year history of peptic ulcer died two years after a successful partial gastrectomy. At necropsy, renal disease suggestive of Burnet's syndrome due to prolonged alkali medication was found. The fifth patient, a man of 60, died 24 hours after emergency admission for a bleeding gastric ulcer accompanied by a duodenal scar.

Operation

Of the 157 patients, 82 underwent one or more operations for peptic ulcer, including simple suture for perforation and gastro-enterostomy. Several patients were operated on twice. In 68 partial gastrectomy was performed. In at least eight cases this was done as an emergency measure for bleeding. Forty patients undergoing gastrectomy were over 50 years of age, and, among these, 24 were more than 60 years old.

Gastric Secretion.—The available data on 79 patients could not be compared, because gastric secretion had been assayed by different methods.

Discussion

A radiological diagnosis of combined gastric and duodenal ulcers was made in 2.7% of more than 5,000 ulcer patients in the eight-year period 1947–54. Inclusion of an estimated 25% of prepyloric ulcers would raise this figure to 3.5%. This is in fair agreement with the findings of Morrison and Feldman (1951), who in a special investigation observed clinical and radiological evidence of combined ulcers in 4.2% of 500 peptic ulcer patients. A considerably lower proportion was reported in most general x-ray and post-mortem series reviewed by Feldman (1953). Papers not mentioned by this author include those by Needham and McConachie (1950), Shapiro and Schiff (1952), and Stewart, Sanderson, and Wiles (1952) indicating that 1.8 to 4% of bleeding gastric and duodenal ulcers show combined lesions. Smith, Boles, and Jordan (1953) found a concomitant duodenal deformity in 19.7% of patients with benign gastric ulcers of all sites. Glenn and Harrison (1951) reported 12% and Rauch (1952) 3.2% of combined ulcers in their surgical patients. Johnson (1955) personally observed concomitant lesions in one of seven duodenal and one of four gastric ulcer patients. He suggested a general incidence of about 5%, including asymptomatic cases. There is reason to believe that the higher incidence generally reported by surgeons may be caused by the selection of patients.

No doubt the most reliable figures on combined ulcers are to be found in Watkinson's (1958) analysis of the necropsy findings in the late Professor Matthew Stewart's department at the University of Leeds. The incidence reported here is by far the highest with the exception of Sir David Wilkie's findings in 1926. This is explained by the painstaking care taken in the department in the detection of all ulcers and ulcer scars. Of a total of 1,848 chronic ulcers found between the years 1930 and 1949, 227 were combined gastric and duodenal ulcers, 174 in men and 53 in women. The calculation of the incidence is best based, however, on the findings in patients who died from causes other than ulcer disease. There were 1,232 of these patients, and 142 showed combined lesions. This gives an incidence as high as 11.5%. In the same group there were 799 duodenal and 284 gastric ulcers. The proportion of combined lesions among gastric ulcers (284+142) thus reaches 33.4%, and among duodenal ulcers (799+142) 15.1%. The sex ratio of combined ulcers in patients not dying from their ulcers was found to be 1.58 compared with 1.97 in the duodenal and 1.09 in the gastric ulcer groups, the male patients always predominating. The greatest incidence was found between the ages of 45 and 74 in males and above the age of 75 in females.

Admittedly a study based on hospital in- and out-patients will not allow any conclusions as regards the incidence of the disease in the general population. In hospital patients at least, the incidence is certainly high. As already pointed out by Johnson (1955), this is surprising, because many features of duodenal and gastric ulceration are to some extent mutually exclusive. The differences in gastric secretion between duodenal and gastric ulcer patients are well known. Differences in the motor activity of the stomach and duodenum are not as well documented as the secretory aspects. Most patients with uncomplicated duodenal ulcer are found on gastric biopsy to have a normal stomach mucosa. On the other hand, the incidence of gastritic changes in the ulcer-bearing stomach is high. Such features may appear compatible in cases where the gastric ulcer follows a healed duodenal ulcer after a long interval. However, almost two-thirds of the present cases showed active lesions of both stomach and duodenum. Moreover, in at least eight cases the reverse sequence occurred. On occasion the evolution was quite striking, the gastric and duodenal ulcer appearing to be independent of each other.

Thus in a man aged 40 with a short history of dyspepsia a large ulcer was found at the middle third of the lesser curve. He was successfully treated as an in-patient and four x-ray series did not reveal any duodenal crater or deformity. A few days after he left the hospital he was readmitted for a perforated duodenal ulcer, which was sutured. No active gastric lesion was found at the operation. The duodenal ulcer healed, but the gastric ulcer relapsed within three months. One year later the duodenal ulcer had also recurred, accompanied by two gastric ulcers. When partial gastrectomy was performed after another two months, the gastric ulcers had healed. At no time was there any evidence of delayed emptying. The pattern of gastric secretion did not change markedly when concomitant ulceration followed the gastric ulcer.

That even the pattern of gastric secretion may change is shown in observations reported by Watkinson (1951). In one 42-year-old male patient the healing of a gastric ulcer was followed within five months by the appearance of a duodenal ulcer, both confirmed at operation. In another man aged 33 a gastric ulcer appeared six months after a duodenal ulcer had healed. In both patients there was a definite change in gastric secretion from the gastric ulcer type to the pattern found in duodenal ulcer, and vice versa.

Gastric retention is one factor thought to be responsible for combined ulceration (Johnson, 1955). In less than 30% of the 131 patients analysed in this respect were there any possible signs of pyloric stenosis. Even in cases with delayed emptying it may be questioned whether gastric retention is the cause rather than the effect of chronic gastric ulceration. Retention is present in a similar proportion of gastric and duodenal ulcers. The importance of pyloric stenosis arising from duodenal ulcer may also be questioned on the basis of the sex ratio, which was nearer to the figure found in gastric ulcer. Again the age distribution is more or less the same as in gastric ulcer. It is thought that a factor common to both gastric and duodenal ulcer disease may be at work to cause combined ulcers. Unfortunately, there was insufficient material for a detailed analysis in respect of ulcer inheritance. In several instances, though, the family history was most striking, with proved cases of both gastric and duodenal ulcers in near relatives of the patients. The work of Doll and Kellock (1951), which includes cases with combined ulcers, is most suggestive of a common hereditary background. They observed that 6 out of 11 patients with combined ulcers had near relatives with the same disease.

It is reasonable to expect that combined ulcer disease runs a more severe course than either duodenal or gastric ulcer. Although no conclusive proof can be offered, the present study bears out this impression. The proportion of patients with perforations is not unexpected in view of the findings of Martin and Lewis (1949). On the other hand, the risk of bleeding is certainly high, particularly if

the period before the appearance of combined ulcers is taken as a basis for comparison. According to Balfour (1932) about 25% of peptic ulcer patients followed for an average of 10 years will show one or more episodes of bleeding. Emery and Monroe (1935) found an incidence of 26.7% in patients observed for an average of 3.5 years. Gastric ulcers are thought to bleed more often than duodenal ulcers (Ivy, Grossman, and Bachrach, 1950). However, Martin and Lewis (1949), in their follow-up of peptic ulcer patients for more than 10 years, observed bleeding in 26.8% of gastric and 35.2% of duodenal ulcers. In the present series the incidence of bleeding in 59 of 157 patients—that is, 37.6%—followed for a similar length of time, is somewhat higher. Moreover, three-fourths of the haemorrhages took place during the period which represented on the average one-eighth or less of the total ulcer history. It is therefore not surprising that conservative treatment was abandoned in favour of partial gastrectomy in 68 of these patients. In fact, the present findings would suggest that surgical treatment is indicated more often in combined ulcers than in single ulcer, whether gastric or duodenal.

Summary

The combination of chronic gastric and duodenal ulcers or ulcer scars was found in 157 hospital patients during a period of eight years. Cases suffering from prepyloric gastric ulcer were excluded owing to the uncertainty of location.

The observed incidence of combined ulceration was 2.7% based on x-ray investigation. With the inclusion of an estimated 25% of prepyloric ulcers the incidence would reach 3.5%. Thus about one in every seven hospital patients suffering from ulcers of the stomach and 1 in 30 patients having a duodenal ulcer or ulcer scar will be found to show combined ulcers.

With due awareness of the frequent occurrence of combined ulcers, the radiological examination represents a reliable means of their diagnosis.

Combined ulcers run a higher risk of bleeding, making surgical treatment more often advisable than in either gastric or duodenal ulcer occurring alone.

Pyloric stenosis does not appear to be a major factor in the pathogenesis of combined ulcers.

I wish to thank Dr. F. Avery Jones, Dr. R. Doll, and Dr. T. D. Kellock, in whose department this work was done, for much encouragement and advice. Dr. F. Pygott kindly made his files available and reviewed several x-ray films. I am also indebted to the clerical staff of the Central Middlesex Hospital. The work was done during the tenure of a fellowship of the Swiss Foundation for Fellowships in Biology and Medicine.

RECTAL TEMPERATURE IN THE NEWBORN AFTER BIRTH ASPHYXIA

BY

E. D. BURNARD, M.B., M.R.C.P., M.R.A.C.P.

AND

K. W. CROSS, Ph.D., M.B., M.R.C.P.

Paediatric Unit and Physiology Department, St. Mary's Hospital Medical School, London

In a previous investigation (Cross, Tizard, and Trythall, 1955) it was shown that if normal babies were given 15% oxygen to breathe there was a fall in oxygen consumption which was so large that the energy loss would be greater than the energy gain from any anaerobic metabolism which might be taking place. From this indirect calorimetry it was suggested that energy production fell under these experimental conditions, and this seemed to be confirmed when Brodie, Cross, and Lomer (1957) showed that infants breathing 15% oxygen heated the plethysmograph in which they were placed less than when they breathed air, though a consistent fall in rectal temperature was not found when the 15% oxygen was given for periods up to 50 minutes. Young kittens and puppies show a fall in temperature directly after oxygen consumption is reduced in anoxia (Moore, 1956a, 1956b).

In babies the absence of this immediate fall in body temperature along with their fall in oxygen consumption in an atmosphere of 15% oxygen might be connected with a relative thermal inertia compared with the smaller animals. Vascular reactions might also play a part, since skin pallor was noticed in the babies. The probability that factors such as these influenced the findings in short-term observations is supported by Sjöstedt and Rooth's (1957) report that in full-term babies the temperature is "a little lower than normal if kept in 15% oxygen for a week."

Although suggestive, these results might not apply to the infant showing apnoea or cyanosis at or after birth. While cyanosis is evidence of anoxia, it is unlikely that the natural condition is ever a pure "anoxic anoxia." CO₂ retention will probably, although not necessarily, be present. An investigation which would in some measure test whether naturally occurring anoxia causes a fall in heat production of the newborn infant was undertaken. We wished to make the investigation as simple as possible so that it could be fitted into the activities of a busy maternity unit, and decided to divide the babies into those that did and those that did not show asphyxia at birth, and to follow their rectal temperatures. As it became apparent that maternal sedation was a complication the scope of our investigation had to be widened slightly, and finally four groups of infants were studied, but the general scheme was not made more complex in any other way.

Material and Methods

Babies were delivered at a labour-room temperature of 78–80° F. (25.6–26.7° C.), wrapped in a towel, and, after they had been held by their mothers, were transferred to the nursery after a period that varied from 10 to 30 minutes. Resuscitative measures used after birth were oxygen, which was given for a few minutes at the discretion of the obstetrician or midwife in charge, and 1 mg. of N-allyl

morphine by intramuscular injection if delay in breathing could be attributed to maternal sedation with pethidine; some mothers who had received pethidine were given 10 mg. of N-allyl morphine an estimated 30 minutes before delivery. In the nursery, where the temperature was kept between 70 and 74° F. (21.1 and 23.3° C.) throughout the investigation, the infant was covered with two blankets, and after a further interval varying between half an hour and one and a half hours was bathed and dressed.

The rectal temperature was taken two-hourly for 24 hours by the nursing staff with thermometers graduated from 85 to 105° F. (29.5 to 40.6° C.), the thermometer being inserted an inch (2.5 cm.) beyond the anus. A complete record was not always obtained, as will be apparent from inspection of the individual totals in Figs. 1-3. So far as possible, all the babies born in a four-months period were examined, but at busy times the taking of temperatures had to lapse.

The infants were born at term, or possibly later in a minority. None received any special treatment apart from oxygen for the few minutes before the establishment of normal breathing. Babies who needed oxygen for some hours after birth have been excluded from this report.

Asphyxia in this paper means failure to establish respiration within three minutes of birth. While the observations were being made it became clear that maternal sedation with pethidine was a frequent cause of apnoea, and a division was therefore made into the following groups: A ("normals"), 53 babies whose breathing began within three minutes and the mother had received only chloral; B ("pethidine and apnoea"), 29 babies in whom normal breathing was not established within three minutes, the mothers having received pethidine; C ("pethidine, no apnoea"), 35 babies who were breathing normally within three minutes, all the mothers having received pethidine. Group D ("pure asphyxia") is made up of 15 babies. The need for sedation in difficult labour rendered apnoea after birth without maternal pethidine an uncommon event, and explains the small number of observations in this group.

The dosage of pethidine and the time between administration to the mother and birth varied considerably. In order that an infant should qualify for groups B or C it had to be born within three hours of a single dose of 200 mg. or within five hours after 400 mg. (2 × 200 mg.) or more.

The accompanying charts show the mean temperatures for each group, and the vertical lines indicate the 95% confidence limits for each set of two-hourly observations. When

there is no overlapping of these lines the odds against the difference between means being due to chance are greater than 20 to 1.

Results

In Fig. 1 the means of groups A and D are compared. Asphyxia is seen to result in a significantly lower rectal temperature from the second to the sixteenth hour.

In Fig. 2, group B is compared with the normal, and a significant lowering of temperature over the same period is apparent. In group C, however, the fall in temperature occurred after pethidine without the intervention of apnoea (Fig. 3), and it is for this reason that we were careful to exclude the possibility of a drug effect in collecting the data for Fig. 1.

FIG. 2.—Mean rectal temperatures after maternal pethidine and apnoea at birth. Conventions as in Fig. 1. — Group A (normals), 53 babies. - - - Group B (pethidine and apnoea), 29 babies.

FIG. 3.—Comparison of mean rectal temperatures after maternal pethidine with and without apnoea at birth. Conventions as in Fig. 1. - - - Group B (pethidine and apnoea), 29 babies. — Group C (pethidine, no apnoea), 35 babies.

FIG. 1.—Mean rectal temperatures after normal birth and after birth asphyxia. The vertical lines are the 95% confidence limits of the means. — Group A (normals), 53 babies. - - - Group D (asphyxia, no pethidine), 15 babies.

TREATMENT OF RHEUMATOID ARTHRITIS WITH CHLOROQUINE

BY

H. FULD, M.D., M.R.C.P.Ed.
Consultant Physician

AND

L. HORWICH, M.B., Ch.B.
Medical Registrar
Sefton General Hospital, Liverpool

The fact that there is a significant difference in temperature over several hours between group A and group D suggests that asphyxia causes a fall in oxygen consumption and energy production as in the experiments on pure anoxia (15% oxygen) already quoted. It is worth speculating on the degree of anoxia our subjects had met, as Brodie *et al.* noted no fall in rectal temperature in infants breathing 15% oxygen for 50 minutes. The pronounced fall in heat production suggested by the low rectal temperature points to an incident of considerable severity.

There is no apparent difference between the temperatures of the two groups of babies whose mothers had received pethidine (B and C), whether the babies were apnoeic for three minutes after birth or not. Their pattern of temperature change after birth is very similar to that of babies with pure asphyxia. Either the initial asphyxia or mild persistent respiratory depression from the drug could explain the similarity to the group D babies. A second possibility is vasodilatation, since J. Ginsburg (1958, personal communication) has found an approximate doubling of skin-blood flow in the human subject for periods up to an hour after 100 mg. of pethidine intramuscularly. Thus the temperature of babies after maternal pethidine might be lowered both by diminished heat production and by increased heat loss.

To some extent the absence of a difference between groups B and C may be due to artificial selection, because severely asphyxiated babies who were felt to need oxygen for a number of hours after birth have not been included in the series, although some of them had much lower temperatures and these would have enlarged group B.

When the babies in group C were divided according to whether or not they had received N-allyl morphine, the fall in temperature was the same in each subgroup. While the drug proved a very effective antidote to pethidine in the initiation of breathing (Paterson and Prescott, 1954) it did not appear to have any subsequent effect on the course of the temperature. Roberts *et al.* (1957) similarly found that the reduction of the baby's minute-volume after maternal pethidine was not influenced by this antidote.

We conclude that a somewhat reduced rectal temperature is a natural phenomenon in babies suffering from asphyxia at birth. It seems probable that this lowered temperature is the result of a period of diminished metabolic rate, caused by the anoxia. If this is so, then the lower temperature may have survival value.

Summary

Neonatal rectal temperature was measured at two-hourly intervals in 53 infants after normal delivery and in 15 after birth asphyxia. Asphyxia was found to cause a significantly lower temperature for 16 hours.

The same effect followed the maternal administration of pethidine independently of apnoea at birth.

The reduced temperature appears to be a natural consequence of anoxia in the baby.

We thank Mr. Leslie Williams, Mr. Douglas MacLeod, and Dr. Reginald Lightwood for permission to examine infants in their care, and Sister K. A. Taylor and her nursing staff for their faithful co-operation.

Mepacrine was first observed to have a beneficial effect on the course of rheumatoid arthritis by Page (1951), when treating discoid lupus erythematosus. Two of these patients had associated rheumatoid arthritis, which cleared up under mepacrine treatment. Haydu (1953) two years later published his result of treatment by chloroquine of 28 patients suffering from rheumatoid arthritis. In the dosage of 0.5 g. of chloroquine thrice weekly for six months he found considerable improvement in 21 of the 28 patients with rheumatoid arthritis without encountering toxic symptoms during the trial. Forestier and Certonciny (1954) published a short-term trial of mepacrine in 11 patients and of chloroquine in 17 patients suffering from rheumatoid arthritis for a period of one to six months. Half of the patients in each group responded favourably. Escarpenter-Oriol *et al.* (1955), quoted by Bagnall (1957), treated eight rheumatoid arthritics with mepacrine and 30 with chloroquine, but none of them received more than five months' treatment. Nevertheless, the authors noted an improvement in 29 of the chloroquine cases.

Following an investigation of the unusually high incidence of amoebic infection in patients with rheumatoid arthritis (95% compared with 30% of normal patients in Oregon), Rinehart employed chloroquine together with di-iodohydroxyquinoline ("diiodoquin") in these patients (Rinehart, 1955; Rinehart *et al.*, 1957). He noted improvement in both conditions and attributed most of the antirheumatic activity to chloroquine. Eight out of 11 children showed major improvement of rheumatoid arthritis, and 8 out of 14 adults experienced similar benefit. He followed this series by a "double blind study" of two groups of rheumatoid arthritics (33 in all) receiving either chloroquine or an inert substance. He regarded the improvement in the chloroquine group as statistically significant, more than half the patients on chloroquine deriving and maintaining improvement after two months.

Freedman (1956) observed 66 patients, divided into equal groups of similar rheumatoid disease, half of whom received chloroquine (200 to 300 mg. a day) and the remainder dummy tablets. Small doses of salicylates were permitted during the trial, which lasted 16 weeks in the first instance. Subjective and objective progress was assessed and there was appreciable benefit during this period. Subsequently, 50 patients remaining under treatment received chloroquine and 43 became really

well. Nausea and vomiting and mild dermatitis were the only toxic effects noted in this group, and necessitated some reduction in dosage. Lacapère *et al.* (1954) treated 80 long-standing cases of rheumatoid arthritis with chloroquine in doses up to 600 mg. daily and reported favourable results in two-thirds of these patients.

A much larger number of patients suffering from rheumatoid arthritis have been treated and observed over the long period of four years by Bagnall (1957). He followed up personally 125 private patients, of whom 121 had more than eight months of continued therapy and 25 received treatment for longer than three years. He stressed that no early response to chloroquine was to be expected and that no benefit may be obtained prior to 6 to 12 weeks after the beginning of treatment. To bridge this period, rest, sedation, salicylates, and when necessary glucocorticoid therapy were used. There was a good result in 70% as judged by work performance, sedimentation rate, and haemoglobin level. Six patients relapsed on premature withdrawal of the drug but benefited when treatment was resumed. Only minor toxic symptoms were encountered. 10% were unable to continue the drug. He concluded that "chloroquine comes closer to the ideal for a long-term safe control of rheumatoid arthritis than any other agent now available." Scherbel *et al.* (1957, 1958)

Literature on Antimalarial Drugs in 1,092 Cases of Rheumatoid Arthritis

Author	No. of Patients	Length of Treatment	Drugs	Results
Page (1951)	2	1-3 months	Mepacrine	Improvement in both cases
Haydu (1953)	28	6 "	Chloroquine	75% considerable improvement
Forestier and Certonciny (1954)	28	1-6 "	11 Mepacrine 17 Chloroquine	50% improved
Lacapère <i>et al.</i> (1954)	80		Chloroquine	60% improvement
Escarpenter-Oriol <i>et al.</i> (1955)	38	Up to 5 months	8 Mepacrine 30 Chloroquine	97% improved in chloroquine group
Rinehart (1955), Rinehart <i>et al.</i> (1957)	25		Chloroquine + diodoquin	65% improvement
Freedman (1956)	50		Chloroquine	86% improvement
Bagnall (1957)	125	30% less than 6 months; 97% from 8 months to over 3 years	"	70% considerable improvement
Scherbel <i>et al.</i> (1958)	716	Up to 3 years	Hydroxychloroquine Chloroquine	58% major improvement (157 patients)

administered chloroquine phosphate or hydroxychloroquine sulphate to 716 patients suffering from rheumatoid arthritis over periods up to three years. They have so far reported their results in 157 patients. A major improvement occurred in 58%. The Table represents a summary of the results of chloroquine treatment of rheumatoid arthritis published up to April, 1958.

Present Series

Our own experience of chloroquine in hypersensitivity states and collagen diseases dates back to July, 1953, when one of us (H. F.) first tried the drug in systemic lupus erythematosus followed by other collagen diseases and hypersensitivity states (1958). In 1954 we began to treat cases of active rheumatoid arthritis with chloroquine, but were quite sceptical about any possible benefit, and it was not until 1955 that we were convinced that chloroquine influenced the course of the disease, and it was from then on that we followed these cases up regularly. Thirty-nine patients (29 female, 10 male) were observed between May, 1955, and August, 1958, the longest for up to four years and the most recent patients for only three months. The

average duration of symptoms prior to the commencement of chloroquine treatment varied between several years in almost half the cases to a few months in three patients. No patient with "burned-out" arthritis was treated. The indications for chloroquine therapy were painful joint swellings and muscle spasm accompanied by a raised E.S.R. and low-grade pyrexia. With few exceptions our patients had had previous treatment elsewhere, including gold injections, steroid hormones, and phenylbutazone, and one patient had had deep x-ray therapy for ankylosing spondylosis. None of these measures gave lasting relief.

We soon found that no benefit from chloroquine could be expected for some three weeks from the start of treatment, and almost all patients therefore received other therapeutic measures soon after admission. These comprised the following. (1) Salicylates in the form of calcium aspirin for symptomatic relief. (2) Complete bed rest for several weeks or until the E.S.R. returned to normal. (3) Artificial fever by means of intravenous T.A.B. vaccine in four doses starting with 25 million and increasing to 100 million organisms at intervals of three to four days. Thirteen patients received the full course. (4) Weekly transfusions of 1 pint (570 ml.) of fresh blood in 11 patients over a period of three to four weeks. (5) Injection of hydrocortisone acetate into single joints to overcome deformities by relief of muscle spasm. (6) Graded physiotherapy after acute stage.

One of us (H. F.) has used this regime of treatment of active rheumatoid arthritis for many years; quite often satisfactory remissions followed, but relapses occurred in most cases sooner or later. Chloroquine was started on admission to the ward or at the end of induced fever treatment. The initial dosage was 600 mg. daily, and was reduced only when gastric irritation made it necessary.

Of the 39 patients, all but five still take a maintenance dose of chloroquine 200 to 400 mg. daily. Two discontinued the drug because of lack of benefit and three could not tolerate prolonged treatment on account of gastric upset.

Results

The results were assessed in four grades: grade 1, full remission; grade 2, major response; grade 3, minor improvement; grade 4, no improvement.

A full remission in rheumatoid arthritis is defined as a state of excellent general health without any joint complaint, normal E.S.R., normal blood count, and being able to lead an active, unrestricted life. Major response (grade 2) comprises a group of patients who had greatly benefited by chloroquine treatment, but who still had minor handicaps—for instance, limited range of movement of a single joint or incapacity to walk beyond 3 miles (5 km.). The few patients who had improved slightly but remained considerably handicapped in their daily lives were placed into grade 3. Grade 4 is self-explanatory.

In 12 patients a full remission was obtained, with weight gain and return of E.S.R. to normal. A major response (grade 2) was observed in 19 patients who take salicylates from time to time but are leading active lives. Minor improvements occurred in four patients and four failed to benefit at all. About 80% of our cases derived a full remission or major benefit by treatment with chloroquine. The failures (grades 3 and 4) include patients with active rheumatoid arthritis of many years' duration as well as patients with quite recent development of joint lesions. On the other hand, some of the best results occurred in long-standing cases (eight years' and five years' history of rheumatoid arthritis in two of our series). Secondary degenerative joint changes with irregularities of joint surface and narrowing of joint spaces remained unaffected, but remineralization of osteoporotic bones took place under treatment. We have not observed relapses in patients after an initial response to chloroquine and whilst taking not less than 400 mg. daily. Bagnall recorded 18 relapses (less than 1.5% of his series). The difference between our results and those of Bagnall may be explained by the different dosage employed. The therapeutic dose given by us was 450 mg.

of chloroquine alkaloid, whereas Bagnall prescribed only 150 mg. base. Our maintenance dose was 300 mg. base daily.

Discussion

If antimalarial drugs, chloroquine in particular, have a beneficial effect on the disease process of rheumatoid arthritis, the question of its mode of action arises. Haydu investigated the effects of chloroquine as an adenosine triphosphatase inhibitor in rheumatoid arthritis. He regarded the high tissue requirements for adenosine triphosphate and the lack of corticoid support—for example, during infection and mental stress—in certain constitutional types as the basis of rheumatoid arthritis. Kurnick (1956) found that chloroquine combined with desoxyribonucleic acid and thereby prevented its depolymerization. This breakdown of the molecule is the preliminary to sequestration of the nuclear material and to phagocytosis, which represent the L.E.-cell phenomena. In other words, the addition of chloroquine *in vitro* to a system otherwise positive for the L.E.-cell phenomena will prevent the reaction taking place.

Experience gained in treating and following up 39 patients suffering from rheumatoid arthritis up to four years does not justify sweeping statements about the effect of a new drug. It was our original intention to publish a five-year review of our observations, but the recent interest aroused in chloroquine as a potentially useful drug in the management of rheumatoid arthritis has induced us to publish this report.

The assessment of any new treatment of rheumatoid arthritis is not easy, as remissions—some of them permanent—may occur at almost any stage of the disease. It is unlikely, however, that anyone experienced in the management of rheumatoid arthritis would attribute a maintained state of remission in over two-thirds of cases under observation to the natural course of the disease. The *Lancet* (1958) dealt with prognosis in rheumatoid arthritis based on observations in the Rheumatic Unit in Edinburgh between 1948 and 1951. 43% of cases admitted in the first year of illness but only 10% of those admitted between the fifth and tenth years were free from any restriction in activity six years later. Hospital treatment comprised bed rest, plaster splints, salicylates, and physiotherapy. These "sound and uncontroversial methods" and ancillary measures (induced pyrexia and transfusions) have in the past failed to bring an arrest of the condition in the majority of cases. The best results have been achieved by long-continued chrysotherapy, using small weekly doses. Gold failed, however, quite frequently even in cases with a short history of illness. Chloroquine does not seem to distinguish between old and recent cases so long as the disease process is active. We have given up corticosteroids for systemic treatment of rheumatoid arthritis altogether and use them only as hydrocortisone acetate for local injections into single joints to achieve mobility and overcome contractures during the first few weeks, until chloroquine takes effect.

It is too early yet to know how patients with rheumatoid arthritis treated with chloroquine will fare after five to ten years. Long-term maintenance treatment with chloroquine has been planned for the patients under review until the day when the enigma of rheumatoid arthritis has been solved and a more specific and radical cure has been discovered.

In the meantime, we believe that further trials of chloroquine in the treatment of rheumatoid arthritis are justifiable in view of the results achieved so far and the lack of dangerous side-effects of the drug.

Summary

The literature on the use of chloroquine in the management of rheumatoid arthritis is reviewed.

Results in treatment and following up 39 patients from three months to four years are described.

Complete remission of the disease process was obtained in 30% of cases, a major improvement occurred in 50%, and insignificant or no benefit was noted in about 20% of the patients.

The drug proved harmless and was well tolerated in larger doses than used by other authors. Relapses whilst on chloroquine were not observed in our series.

We recommend a regime of treatment consisting in bed rest, induced pyrexia, blood transfusions, and salicylates during the first three weeks of treatment, and tablets of chloroquine sulphate, 200 mg. t.d.s., throughout the treatment or immediately after induced fever—this dose of chloroquine to be continued until a remission has been obtained, when the dose may be decreased to 400 mg. daily (equals 300 mg. base). The maintenance therapy may be required for 12 months or longer.

UNCONTROLLABLE POST-OPERATIVE HAEMORRHAGE AFTER INCOMPATIBLE BLOOD TRANSFUSION

BY

JAMES M. MOORE, F.R.C.S.Ed., F.R.F.P.S.
Senior Registrar, Hairmyres Hospital, East Kilbride

It has often been reported that a defect of coagulation may occur in obstetrical conditions and in pulmonary and prostatic surgery. For example, it has been noted in accidental haemorrhage, amniotic fluid embolism, intrauterine foetal death, and missed abortion (De Lee, 1901; Dieckmann, 1936; Moloney *et al.*, 1949; Schneider, 1951; Reid *et al.*, 1953; Barry *et al.*, 1955), following pulmonary lobectomy (Soulier *et al.*, 1952), and in metastatic carcinoma of the prostate (Tagnon *et al.*, 1952; Swan *et al.*, 1957). One of the features of these cases has been hypofibrinogenemia.

That abnormal bleeding may occur as a transfusion reaction is not so well known, although it has been recorded by American authors on a number of occasions since it was mentioned by Drinker and Brittingham (1919). Muirhead (1951) found nine cases, while Friesen *et al.* (1952) investigated 11. Other examples are given by Wiener (1954) and Stefanini and Dameshek (1955). Krevans *et al.* (1957) studied two instances, and in a survey of the literature found 11 additional reports. No report of a case has been traced in British literature, although Mollison (1956) refers to the condition.

It is the object of this paper to give a clinical account of such a case which had a fatal termination.

Case Report

The patient was a single woman aged 25 suffering from a chronic gastric ulcer. In the past she had undergone appendicectomy and tonsillectomy, and no excessive bleeding had been noted. Menstrual blood loss had been normal. There was no history suggestive of any allergic upset.

Operation.—A Billroth I partial gastrectomy was carried out, and it was uneventful. The anaesthetic consisted of

thiopentone sodium, tubocurarine chloride, gallamine triethiodide, and nitrous oxide, and a pint (540 ml.) of carefully matched homologous group O rhesus-negative blood was given. The operation was completed at 12 noon.

A second bottle of blood was started at 12.30 p.m. When examined 15 minutes later the patient was rather pale, with a slight cyanotic tinge, and there was a little staining from a stab drainage wound. There was little change during the next two hours. At 2.45 p.m., when about two-thirds of the second bottle of blood (360 ml.) had been given, it was discovered that it was in fact group A rhesus-positive blood which had inadvertently been transfused. Immediately, carefully matched blood of the correct group was substituted and 1 pint (540 ml.) of 50% dextrose given in an attempt to minimize renal complications.

At 4 p.m. it was noted that venous blood sent for further cross-matching would not clot, and by then there was considerable fresh bleeding from the stab wound. Only a small amount of altered blood had been aspirated from the gastric tube during the afternoon, but at 6 p.m. there was 15 oz. (450 ml.) of fresh blood and the main wound had started to ooze. The patient became weaker despite continued transfusion, and another laparotomy was carried out at 7.45 p.m.

Second Operation.—About 4 pints (2 litres) of blood was found in the peritoneal cavity with a few clots. There was a general ooze from many areas involved in the previous operation. On opening the stomach more blood escaped, but again this arose from numerous areas, many not at the suture lines. Despite all attempts at haemostasis the ooze continued. The supply of matched blood for transfusion was temporarily exhausted during the operation, and 2 pints (1 litre) of 6% dextran in saline ("dextraven" and "intra-dex") was given. As nothing further of benefit could be done, the stomach opening was repaired and the abdomen closed with two drainage tubes.

It was now obvious that the patient had developed an abnormal haemorrhagic tendency.

Treatment.—4 ml. of "adrenoxyl" (1.5 mg. of adrenochrome monosemicarbazone dihydrate) and 100 mg. of vitamin K analogue ("synkavit") were given intramuscularly. 10 ml. of 10% calcium gluconate was given intravenously and a rapid transfusion of matched group O rhesus-negative blood continued. After consultation with the director of the regional transfusion centre at 10 p.m. the patient was given 4 pints (2 litres) of fresh dried plasma alternating with blood, and 2 g. of concentrated fibrinogen fraction. At this stage there appeared to be a slight temporary decrease in the rate of blood loss. Fresh frozen plasma was requested for her, but her condition deteriorated and she died at 1.45 a.m. on the day following operation, before it could be given.

She had received a total of 17 pints (9 litres) of blood, 3 pints (1.5 litres) of processed plasma, and 2 pints (1 litre) of dextran, as well as the 4 pints (2 litres) of fresh dried plasma and fibrinogen mentioned above. In all, this represents the administration of approximately 20 g. of fibrinogen, of which half had been given after the haemorrhagic defect had been recognized. In spite of this, up to the time of death, bleeding continued from the drainage tubes in the abdomen and from the gastric tube.

Relevant Post-mortem Findings

There was a large amount of blood and clot in the peritoneal cavity. The stomach was filled with a well-formed clot equivalent to about a pint (0.5 litre) of blood. No open vessels were identified, but there appeared to have been diffuse haemorrhage from the gastric mucosa, in which there were numerous slit-like defects several millimetres in length apparently communicating with submucosal haematoma. The liver and spleen were normal. Histological examination of kidney showed amorphous eosinophilic material, and desquamated epithelial cells in a few convoluted tubules. The lungs appeared oedematous, but there

were no histological changes, and selective staining showed no significant intravascular deposits of fibrin.

Blood Examination.—A specimen of venous blood taken at 3.30 p.m. on the day of operation failed to clot in 24 hours, even after the addition of thrombin in excess, indicating afibrinogenemia. Marked haemoglobinemia was noted soon after withdrawal, proving rapid destruction of the incompatible blood. A similar specimen taken two days before operation clotted normally.

Investigations at the regional transfusion centre confirmed that the patient was group O, rhesus negative, and that she had received group A blood, which had been rapidly destroyed. The pre-transfusion serum of the patient contained an anti-A haemolysin, and it was considered that this was responsible for the rapid haemolysis of the incompatible cells.

Discussion

The patient undoubtedly developed a haemorrhagic defect associated with afibrinogenemia. The development of hypofibrinogenemia has been described by Stefanini and Dameshek (1955). Among the conditions mentioned as leading to the syndrome are haemorrhagic shock and haemolytic transfusion reactions. The patient's condition was good immediately after operation, which had not been associated with significant loss of blood. Therefore, even if haemorrhagic shock can produce such a syndrome, it seems unlikely that it was initially responsible for the onset of the fibrinogen deficiency in this case. The trigger mechanism was almost certainly the transfusion of blood of the wrong group.

Acquired hypofibrinogenemia might theoretically result from (a) defective formation of fibrinogen; (b) intravascular clotting following the entrance of thromboplastic material into the circulation, with consumption of fibrinogen; or (c) depletion of fibrinogen by fibrinolytic or proteolytic enzymes in the blood. In this case it is unlikely that there was any defect in the formation of fibrinogen, as there was no evidence of impaired liver function. It is possible that intravascular clotting was the cause of the haemorrhagic state, because Quick *et al.* (1954) have demonstrated the thromboplastin-like activity of lysed red blood cells. However, there was no evidence histologically of abnormal fibrin deposition in tissues; nevertheless a fibrin deposit could have been destroyed by fibrinolytic enzymes, the presence of which has been reported in some cases of this syndrome.

The response to treatment was disappointing although there was post-mortem evidence of clotting. Stefanini and Dameshek (1955) suggested that the average amount of fibrinogen required in treatment was 2–4 g., but mentioned that 8–20 g. might be necessary. Barry *et al.* (1955) recommended 2–6 g. of the fibrinogen fraction in the treatment of hypofibrinogenemia of pregnancy, but if this was not available found triple- or quadruple-strength raw plasma equally effective (1 pint (0.5 litre) of the latter strength yielding 4.4 g. of fibrinogen). In this case approximately 10 g. of fibrinogen was given after the haemorrhagic defect had been recognized, but it is possible that this amount might have produced a greater effect if more of the fibrinogen had been in a concentrated form and had been administered over a shorter period. However, the failure of the patient to respond suggests that there may well have been additional factors involved.

Other coagulation elements may have been absent or diminished—for example, prothrombin, Factor V, and platelets (Greenwalt and Triantaphyllopoulos, 1954). Krevans *et al.* (1957) studied two patients after 500 ml. of incompatible blood and in both found hypofibrinogenemia, hypoprothrombinemia, and thrombocytopenia, with reduction of Factor V activity in one. (Incidentally, they could find no evidence of increased fibrinolytic activity, and favoured intravascular coagulation as a probable cause of these changes.) In treatment they advised fresh whole blood supplemented by fibrinogen. It may be that the fresh frozen plasma, containing some of these factors, would have been of benefit.

Two pints (1 litre) of dextran 6% in saline was given when matched blood and plasma were temporarily unavailable. In retrospect it is clear that this was inadvisable, as a number of reports have incriminated dextran as a cause of a haemorrhagic tendency (Carbone *et al.*, 1954; Scott, 1955; McKenzie and Langlands, 1956). The mechanism of the process is not clear, and suggestions made include interaction of dextran with fibrinogen, haemodilution, production of thrombocytopenia, and prolongation of the bleeding time. The patient, of course, had developed abnormal bleeding before the dextran was given, but it is possible that the dextran aggravated the haemorrhagic tendency.

Friesen *et al.* (1952) described similar cases in which post-operative bleeding occurred as a result of a haemolytic transfusion reaction, when over 250 ml. of incompatible blood had been given. They felt that fibrinolysis was an important factor, but considered that a "heparinoid disturbance" was present. Toluidine-blue dye, given intravenously to two patients in a dosage of 15 mg. per kg. of body weight, apparently corrected the bleeding tendency. Such treatment might be worthy of a trial in any refractory case.

Treatment with corticotrophin (200 units intramuscularly) or cortisone (400 mg. intravenously) has been recommended, in addition to fibrinogen, by Stefanini and Dameshek (1955).

If the possibility of a bleeding state after incompatible transfusion had been known, the second laparotomy would probably not have been carried out, and appropriate treatment might have been started earlier.

Summary and Conclusions

A case is described in which there was fatal post-operative bleeding, associated with afibrinogenemia, following a haemolytic transfusion reaction.

Treatment is discussed, and the following points may be of value in controlling such a condition: (1) early recognition of the fact that a haemorrhagic state has developed; (2) administration of large amounts of the fibrinogen fraction—for example, 2–6 g., repeated if necessary—or the use of quadruple-strength concentrated raw dried plasma if fibrinogen is not available; (3) fresh frozen plasma, or fresh blood, if there is a poor response to adequate fibrinogen; (4) avoidance of dextran; (5) corticotrophin, cortisone, or toluidine-blue dye intravenously, if not responding.

I am grateful to Dr. John Wallace, the director of the West of Scotland Regional Transfusion Centre, and Dr. A. S. Douglas for their assistance and advice. I should like to thank Mr. K. I. Macrossan for permission to publish details of this case.

THE ISOLATION OF TRYPANOSOMA RHODESIENSE FROM A BUSHBUCK

BY

R. B. HEISCH, M.D.

J. P. McMAHON, O.B.E.

AND

P. E. C. MANSON-BAHR, M.D., M.R.C.P.

From the Division of Insect-borne Diseases, Medical Research Laboratory, Kenya

It has long been believed that an animal reservoir of Rhodesian sleeping sickness exists, but only one serious attempt has been made to isolate polymorphic trypanosomes from game animals and to test their pathogenicity in man. This was done recently by Ashcroft (1958), who killed 74 animals of various species in two endemic areas in Tanganyika and inoculated blood from them into rats. One polymorphic strain was isolated from a Coke's hartebeest (*Alcelaphus cokei*) near Babati in the Mbulu District and inoculated into man with negative results; this strain was presumably *Trypanosoma brucei*. It must be stressed that the only sure way of differentiating *T. rhodesiense* from *T. brucei* is by the inoculation of man. *T. rhodesiense* infects man while *T. brucei* does not: both trypanosomes are morphologically identical.

The present experiment was carried out on Utonga Ridge, a small peninsula projecting into Lake Victoria about 40 miles west of Kisumu in the Nyanza Province of Kenya. This area was chosen because not only were a few natives suffering from Rhodesian sleeping sickness found near by but because *T. rhodesiense* had been isolated from *Glossina pallidipes*, which is now the predominant tsetse fly on the ridge. Between April and August, 1958, 24 animals, which included 13 duikers, 10 bushbucks, and one serval cat were shot and their blood inoculated into rats. The serval cat was negative, but a strain of polymorphic trypanosomes and *T. congolense* were isolated from the duiker, and two polymorphic strains and two strains of *T. congolense* from the bushbuck. The polymorphic strains were inoculated into human volunteers and one of those from the bushbuck (*Tragelaphus scriptus* Fall.) was pathogenic to man (see below). This strain, which is highly pathogenic to rats and produced numerous posternuclear forms, is presumably *T. rhodesiense*. This is the first time that *T. rhodesiense* has been isolated from animals and establishes finally that Rhodesian sleeping sickness is a zoonosis.

The bushbuck strain was inoculated into the forearm of Mr. C. A. W. Guggisberg, mammalogist on our staff. The inoculum was heavily infected and consisted of 25 ml. of blood from a subinoculated rat with numerous trypanosomes in its blood (over 100 per oil-immersion field). On the seventh day there was a hardish lump at the site of the inoculation and trypanosomes were seen in material aspirated from the swelling. On the eighth day scanty trypanosomes appeared in the blood and the temperature rose to 103° F. (39.4° C.). On the ninth day the arm was very swollen, with a hard inflamed area about 3 in. (7.5 cm.) in diameter on which was a blister about the size of a half-crown. Fluid from the blister contained about three trypanosomes per oil-immersion field. At 11 p.m. the temperature rose to 106.9° F. (41.6° C.) and the patient felt very ill. At 11.45 a.m. he was given his first injection of antypol. Response to treatment was dramatic and recovery uneventful. Rats inoculated on the ninth day with exudate from the blister and blood taken from an earlobe became infected.

The technique employed is considered of great importance. It is essential to inoculate enough blood (30 ml. at

least) from the animal killed into enough rats (six at least), otherwise light infections can easily be missed. In our opinion Ashcroft inoculated too little blood into too few rats; this may be the reason why he isolated so few strains from such a comparatively large sample of animals. Experiments of this kind must be designed with a broad sweep on a large scale and may have to be continued for a considerable time.

Although the isolation of *T. rhodesiense* from a bush-buck is important, it would be interesting to repeat the experiment in areas where *G. morsitans* and *G. swynnertoni* are vectors of sleeping sickness to discover whether the same or other species of animals are acting as reservoirs. This note gives only a brief account of our work; detailed results will be published elsewhere.

We are much indebted to Messrs. Harvey, Harmer, and Highton for their enthusiastic work in the laboratory and the field.

SECOND BACTERIOLOGICAL STUDY FROM A MATERNITY HOSPITAL

BY

FRANK MARSH, M.D., D.T.M.&H.

Director of Pathology, Epping Hospitals Group

The measures used in a maternity hospital to check the growth and build-up of pathogenic micro-organisms in lying-in wards and nurseries have already been described (Marsh and Rodway, 1954). That paper covered a period of some 38 months, and the methods used were described in some detail. The present paper extends the study for a further four years—to nearly eight years in all.

Floors were treated with "marinol D." After the discharge of a patient, disinfection of a ward was effected by spraying chlorhexidine 1:5,000 from a "microsol" disperser. Blankets were washed in "lissapol N" (1:200) and disinfected with "fixanol C" (1:200). For a while "cirrasol O D" was used, but fixanol C was preferred. Blankets of the mothers were treated every two to three weeks; blankets of the babies every 10 days. Mattress sterilization was by Sparkhall, each time a new occupant used the bed. The rubber or sorbo mattresses of the infants were treated by wiping with a dilute solution of "dettol," "roccal," or chlorhexidine. The pillows were at first disinfected with formalin, but later this treatment was abandoned and plastic covers were used for the pillows. Since May, 1955, hand cream has been supplied for the nursing staff and also for the mothers, after they had washed their hands. Chlorhexidine and roccal were incorporated in the hand cream, 50% of each; the two compounds seemed to be equally effective.

Results

Records were kept of 211 blood-agar plates exposed in the wards during periods of activity. No colonies of *Staphylococcus aureus* were observed. Numerous colonies of *Staphylococcus albus* were identified. On two occasions a few colonies of *Streptococcus haemolyticus* (Lancefield group A) were found on a plate. A total of 477 swabs (nasal 243, eyes 165, and umbilical 69) from infants were examined. *Staph. aureus* was isolated from 58.8% of nasal, 48.4% of eye, and 55% of umbilical swabs taken between the eighth and the tenth days of life. (Penicillin-resistant staphylococci were found in 75 to 90% of the earlier (pre-1954) series, and in 65 to 80% of the present series (1955-7).

Infection among 4,919 infants (1955-7) was 2.5% (respiratory infections 0.2%, minor skin lesions 1.3%, eye infections 0.18%).

A total of 309 swabs from mothers were examined (110 nasal, 124 throat, and 75 nipple). *Staph. aureus* was isolated from 23.6% of nasal, 6.5% of throat, and 47.9% of nipple swabs. (*Staph. aureus* was insensitive to penicillin in 75% positive swabs in 1955, and in 65% positive swabs in 1957.) From January, 1950, to December, 1953, among 4,830 patients (including 64 admitted after delivery) there were 5.3% puerperal pyrexia cases. In 1953 three cases of breast abscess occurred; there were none in 1955-7. (A few post-natal women—a week or two after discharge—developed a breast abscess.) A total of 310 swabs from nursing staff were examined (150 nasal, 111 throat, and 49 hand). *Staph. aureus* was found in 34% of nasal, 4.5% of throat swabs, and in one hand swab. Of these strains 90% were resistant to penicillin.

During the second four-year period, 22 midwives and nurses and 202 pupil midwives were employed. Infections occurred in 75 individuals (33.6%). Four-fifths were minor respiratory cases, mainly tonsillitis and influenza. Other cases included minor skin lesions, boils, and furuncle of the ear (3.5%), eye infections (styes) 1.8%, gastro-enteritis 0.27%, and one case of glandular fever. *Staph. aureus* was not isolated from exposed plates—that is, from air-borne settles—but the micrococcus was isolated from the nasal, eye, and umbilical swabs. Of 255 neonatal deaths, respiratory infection was found in 2.3%.

The methods evolved for the prevention of cross-infection show some success; but *Staph. aureus* implanted in the noses of infants did not seem to be unfavourably affected.

It is thought that *Staph. aureus* confined to the noses of infants may not be harmful unless some means of dissemination occurs.

I thank Miss Helen Rodway, consultant obstetrician, Thorpe Coombe Maternity Hospital, London, for collecting the data and for enlightened supervision of the fight against cross-infection; and Dr. H. Caplin, director of pathology, Forest Hospitals Group, for undertaking many of the swab examinations.

Medical Memorandum

Acute Haemolytic Anaemia in a Case of Infantile Gastro-enteritis Treated with Oxytetracycline

Anaemia of mild or moderate degree following infantile gastro-enteritis is not uncommon, and is usually thought to be due to a toxic depression of blood formation, often in association with a nutritional deficiency. It is not known whether haemolysis plays any significant part. By infantile gastro-enteritis we mean a specific disease due to a number of serologically distinct types of *Escherichia coli*: an acute severe haemolytic anaemia following this condition has not been seen before in this unit. The following case is reported because other workers may have had similar experience and may be able to shed further light on its aetiology.

CASE REPORT

A male infant aged 6 months was admitted to hospital on December 5, 1956, with a five-day history of diarrhoea with some vomiting. His temperature was 98° F. (36.7° C.), pulse 134, and respirations 32. He was an ill child, with moderate dehydration and sore buttocks, but otherwise clinical examination was negative. He had not had any previous illness and there was nothing relevant in the family history. Glucose saline (2.5% glucose in 0.3% sodium chloride) was given by mouth, and after two specimens of

faeces had been obtained oxytetracycline, 50 mg. six-hourly, was begun. After 24 hours his condition had much improved and there was no dehydration. Subsequent progress was uneventful, and oxytetracycline was discontinued on December 11 after a five-day course. At that time he appeared very well, the stools were normal, and the feeds had been increased to full-cream National dried milk.

On December 5 and 6 a pure culture of a smooth type of *E. coli* was isolated from the faeces. It was, however, an anaerogenic strain and was not typable with our sera (O26, O55, O86, O111, O114, O119, O125, O126, O127, and

O128 sera are used routinely). On December 12 only rough *E. coli* were isolated. The haemoglobin on December 7 was 12.6 g./100 ml. (85% Haldane); the Chart shows the further levels.

On December 12 the child was noted to be rather pale; his temperature was 99° F. (37.2° C.). Next day the pallor was marked and there was a subconjunctival haemorrhage in the right eye. The sclerotics showed a suspicion of icterus. He became progressively more ill and on the 15th there was marked air hunger. A small transfusion of about 200 ml. of compatible group A Rh-negative blood was given. The haemoglobin rose slightly on the 16th, but fell again next day. From December 22 there was a steady rise in the haemoglobin value. From December 12 to 22 the bone marrow was very active, but was only able to maintain the haemoglobin at a constant level. The circulating red cells showed an astonishing degree of anisocytosis. Many macrocytic cells were present together with about 5% normoblasts and a maximum reticulocytosis of 23%. The white-cell count increased, reaching a peak of 24,100/c.mm. with many myelocytes and metamyelocytes.

On December 14 the serum bilirubin was 1.3 mg./100 ml. and the liver-function tests were normal. Next day the direct Coombs test was negative on two specimens of blood. On the 19th the test for occult blood in the faeces was negative. The faecal stercobilinogen content was 130 mg./100 g. of moist stool; this figure was thought to be too low for a patient suffering from haemolytic anaemia until it was realized that in an infant's stool most of the pigment was likely to be in the form of bilirubin. There was insufficient material for a quantitative assay of bilirubin in the stool, but qualitative tests showed a very large quantity to be present. On December 21 the faecal stercobilinogen content was less than 20 mg./100 g. of moist stool; bilirubin amounted to 400 mg./100 g. of moist stool. A week later

the bilirubin content was 250 mg./100 g., and the stercobilinogen content 10 mg./100 g. of moist stool. Assays of the bilirubin and stercobilinogen contents of the stools from two infants of the same age who had just recovered from infantile gastro-enteritis showed 50 mg. and 110 mg. of bilirubin and 15 mg. of stercobilinogen per 100 g. of moist stool. The levels found in the patient were obviously greatly in excess of these, indicating that the anaemia was haemolytic in origin.

Red-cell fragility on two occasions was normal. During the period of acute anaemia there was no recurrence of diarrhoea. The stools were of an orange colour, and this was clearly due to the large amount of unaltered bilirubin present. The reduction of bilirubin to stercobilinogen may be imperfect in infants, and the removal of the normal flora by the action of oxytetracycline undoubtedly slowed down the process. Repeated stool examinations did not show any pathogenic organisms. Apart from the small blood transfusion mentioned, no other treatment was given except for several injections of vitamin B₁₂ on the basis that a great deal of blood regeneration was necessary to compete with the haemolysis that was occurring. Between December 11 and 17 there was pyrexia of 99 to 101° F. (37.2 to 38.3° C.), but from the 17th onwards he remained afebrile.

From December 22, when the haemoglobin rose steadily, there were no setbacks, apart from a cross-infection with *E. coli* type O127 which led to a mild gastro-enteritis on January 3, 1957. The blood count was unaffected, but on this occasion the patient was treated with neomycin. By January 7 the haemoglobin had risen to 12.3 g./100 ml. (83% Haldane) and the red cells appeared normal. Follow-up on February 12 showed exactly the same figures.

COMMENT

From the history and clinical examination the case appeared to be one of infantile gastro-enteritis. A smooth *E. coli* was isolated from the stool which was not a recognized pathogenic type, but which might nevertheless have been a pathogenic strain. This has occurred not infrequently, and some strains have been identified by Dr. Joan Taylor, at Colindale, as identical with those causing gastro-enteritis from other areas.

A severe haemolytic anaemia developed about 10 days after the onset of the illness. Haemolysis continued, and in spite of a very active marrow no rise in haemoglobin was recorded for about 10 days. The red-cell fragility was normal and no circulating antibody was demonstrated by the Coombs test. The nature of the haemolysis remains unknown. At the time of onset of the haemolytic anaemia the child appeared to have recovered from gastro-enteritis and there was nothing to suggest a source for the circulating toxin.

The acute haemolysis occurred after a course of oxytetracycline. Thrombocytopenic purpura following this antibiotic has been described by Welch *et al.* (1954) and Beckett *et al.* (1955). The former mention the occurrence of other blood dyscrasias, but make no direct reference to haemolytic anaemia. A search of the literature has not revealed a previous case; nevertheless, oxytetracycline remains a possible cause.

Cross-infection later with another known pathogenic type of *E. coli* (O127) led to a mild gastro-enteritis on January 3, but the blood count was unaffected. This infection was treated successfully with neomycin. Subsequent follow-up has not shown any abnormality in the blood picture.

Reviews

SOCIAL WELFARE IN SCOTLAND

Scottish Social Welfare, 1864-1914. By Thomas Ferguson. (Pp. 609+xi; illustrated. 42s.) Edinburgh and London: E. and S. Livingstone Ltd. 1958.

This account, by Professor Ferguson, of the Scottish social welfare services is comprehensive and well documented. It is full of facts and figures supported by apt quotations. The 50 years covered show the evolution from primitive conditions to the beginnings of the Welfare State. Though the book is long, it is a pity that it stops at 1914, and it is to be hoped that a further volume, to bring it up to date, is contemplated.

The early chapters describe in considerable detail the housing, earnings, diet, and general environment of the people, ranging from the slum-dwellers of the great cities to the lonely crofters and cottars of the Highlands and Islands living, along with their animals, in "black houses." Then there are over 120 pages on the relief of destitution, and all the controversies about rates of relief and whether any relief should be given to the able-bodied. This is followed by chapters with a greater medical flavour on the infectious diseases, cholera, smallpox, typhus fever, tuberculosis, and certain zoonoses; on the care of the sick, domiciliary and institutional; and on the welfare of mothers and young people.

The half-century saw the beginning of the famous Highlands and Islands Medical Service, and the establishment in 1894 of the Local Government Board, which incorporated the functions of the Board of Supervision and retained for long the latter body's Poor Law outlook with its fixed principle of discouraging idleness and imposture. It saw in 1865 the highest death rate and in 1868 the high-water mark of pauperism. The living conditions described are so degrading as to be almost unbelievable. Quotations show that Professor Matthew Hay, of Aberdeen, wrote that typhus fever was spread by body vermin. This was in 1904, and several years before the role of the louse in this disease was generally accepted.

Scotland is well known for its housing problems, but it is not so well known that at the census of 1871 32.5% of the houses had only one room and that 5% of those living in them consisted of families of ten or more. The reader is brought up against the decline in the purchasing power of money when told that in 1906 the pay for unskilled labourers was 5½d. an hour, and that house rents in the country districts were about £1 to £3 a year.

In a serious book such as this it is a relief to come across a lighter touch, as is the account of the formal opening by Royalty in 1903 of the Colinton Fever Hospital in Edinburgh. The guests arrived early. By inadvertence the doors of the refreshment rooms were opened too soon, and by the time the ceremony was due to start "the tables had been literally swept of all vestige of food."

The book deals not only with purely medical matters, but also with those, now comprised in the term "social medicine," which lead to, or are at least associated with, ill-health. It can be highly recommended, and there is a full bibliography for those who wish to gain even further information.

ALLEN DALEY.

A GREAT MEDICAL EPOCH

The Medical World of the Eighteenth Century. By Lester S. King, M.D. (Pp. 346+xvii; illustrated. 43s. 6d.) Chicago: University of Chicago Press. London: Cambridge University Press. 1958.

The author of this interesting monograph, looking forward as well as backward from the viewpoint of the eighteenth century, finds that a study of this epoch will enable us to understand better "our mature present-day medical structure." He begins his survey by a rather lengthy account of

the feud between physicians and apothecaries which exercised so potent an influence upon medical progress, and he seasons his remarks by quoting from Sir Samuel Garth's poem, "The Dispensary." The second chapter deals with "Quack and Empiric," from the common-sense John Wesley and his popular work, *Primitive Physick*, to Sir William Read, the royal oculist in the time of Queen Anne, and from Berkeley's tar-water to Joshua Ward's drop and pill.

As might be expected, considerable space is devoted to Hermann Boerhaave, by far the greatest physician of the eighteenth century, who strove to blend old and new facts and theories into a well-organized system. His theories were "by no means models of lucidity." So the author tells us, but it is disappointing to find that his own attempts to explain Boerhaave's "gluten," "acrimony," and the like leave the reader more mystified than ever. It is a relief to pass from Boerhaave to the more readable description of the eighteenth-century view of fevers.

"Similia Similibus" is the title of a long and illuminating account of Hahnemann and his homoeopathy. The word suggests infinitesimal dosage, but the prescribing of one drug at a time, and the belief that a drug which produced certain symptoms in health would cure disease marked by the same symptoms, were ideas of equal importance in this system, which arose as a reaction against the barbarous therapy of the day. It was during the eighteenth century that the nomenclature of disease was closely studied, under the stimulus of Linnaeus, whose classifications of plants, or taxonomy, was extended to diseases and called nosology. Emphasis is laid upon the pioneer work of François Boissier de Sauvages, the title-page of whose book is reproduced, entitled *Nosologia Methodica* and dated 1768. About this period William Cullen turned his brilliant talent towards nosology, but it was not yet possible to separate symptoms from diseases, and it is not surprising that Benjamin Rush affirmed that "diseases anastomose" and cannot be classified.

Other leading phenomena of the eighteenth century were the development of medical ethics and of the modern outlook in pathology. John Gregory's lectures "On the Duties and Qualifications of a Physician" were followed by Thomas Percival's important work which coined the term "medical ethics" and was the forerunner of all modern ethical codes. In pathology Morgagni's *De Sedibus et Causis Morborum* in 1761 inaugurated a new era, although the forgotten work of Lieutaud also deserves attention. The concluding chapter, which might well have been longer, describes the rise and fall of inoculation against smallpox and the ever changing attitude in medical practice.

This interesting account of a great epoch deserves to be studied and pondered. Sir Robert Sibbald is not Sibbald (pp. 26 and 27), nor was he appointed professor "early in the century," but in 1685. Again, "empire" on page 34 should be "empirics." These, however, are trivial errors. The bibliographic notes on each chapter are of value, and show that the author has been careful to draw his information from the original sources. It is perhaps a pity that so little mention is made of recent books and articles on the same topic. There are an excellent foreword by Professor Ilza Veith and an adequate index.

DOUGLAS GUTHRIE.

REHABILITATION IN THE U.S.A.

The Handicapped and Their Rehabilitation. Edited by Harry A. Pattison, M.D., F.A.C.P. Introduction by Major-General Melvin J. Maas, U.S.M.C.R. ret. (Pp. 944+xxxii; illustrated. £5 12s. 6d.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1957.

This book is a mixture of sermon, encyclopaedia, training manual, and synopsis of medical practice. Forty-four authors contribute, and all save one are from the United States of America. Section I—the sermon—contains full extracts from the writings of leading American authorities on rehabilitation such as Kessler and Rusk. Section II deals with specific handicaps, diseases, and age groups. The American public is more informed medically than most, but

it is difficult to believe that they, and for that matter the trained medical auxiliaries, could follow and understand the significance of the technicalities referred to in Chapter 5. Medical practitioners will, on the other hand, find the chapter most rewarding. Another chapter (Chapter 10), entitled "What is Being Done for the Aged," will be very useful for reference to anyone unfamiliar with the work in this field. The majority of the chapters in this section contain full and sound advice and indicate the scope and the basic principles of rehabilitation, stressing always the needs of the individual. Occasional references to the problems of medical diagnosis as already indicated seem to imply that the book is written for the medical graduate. This confusion as to whom the book is designed for is possibly resolved on page 401, where it is stated: "The responsibility for assisting the physician in charge by co-ordinating the activities of the rehabilitation team and for developing on the staff a rehabilitation consciousness are phases of the work of a new profession in the medical field, whether we call the position Rehabilitation Counsellor, Rehabilitation Co-ordinator or Executive Assistant." Section III is a résumé of the role, and occasionally of the training programme, of the different members of the team, and Section IV deals with American practice. The latter affords an excellent survey of the development of rehabilitation services in the U.S.A., both Federal and State and also in industry. This section will be of value to all interested in rehabilitation problems and procedures. Apart from these aspects, the book is essentially designed for the members of the rehabilitation team in the United States of America and thus has a very limited appeal to readers in Western Europe.

R. E. TUNBRIDGE.

STUDY OF BODILY FUNCTION

Taschenbuch Klinischer Funktionsprüfungen. Edited by Arthur Gitter and Ludwig Heilmeyer. Fifth edition. (Pp. 484+xx; illustrated. DM. 18.) Jena: Gustav Fischer Verlag. 1958.

This handbook on clinical procedures by Dr. A. Gitter and Professor L. Heilmeyer deals with the study of function in various organs and systems. The fact that it has reached its fifth edition within four years is some indication of its popularity and usefulness to the German clinician, although the British reader will be conscious of some confusion between detail and repetition. The aim of this book is to describe those practical procedures which determine minor or major abnormalities of function where these are of diagnostic value.

Experimental methods in clinical medicine at the bedside are becoming increasingly important. Recent advances, particularly during the past decade, in all branches of general medicine demand the closest liaison between laboratory procedures and the basic principles of sound clinical methods—to wit, good history-taking and clinical examination of every system (with particular attention to the system currently involved). An adequate knowledge of basic principles in radiology, applied physiology, and pathology has for some years been included in the armamentarium of the practising clinician. To-day clinical laboratory procedures include applied physiological, biochemical, and haematological disciplines which must all be integrated with clinical medicine and brought to the bedside. Only in this way can the physician assess the value and limitations of such investigations.

In the sphere of thoracic medicine, the applied physiology of respiration with special reference to the mechanics of ventilation, disturbances of gas exchange in blood and alveoli, tests of pulmonary function, and methods of study by spirometry and bronchospirrometry, and the like; in the cardiovascular system, angiocardiology, cardiac catheterization, and methods of investigation of the arteries by oscillometry and arteriography; and skin and muscle investigations of blood supply, are among many other features outlined. Tests of renal and liver function and those concerned with endocrine and metabolic disorders are all reviewed; in fact, no system is neglected, and some are

D

dealt with in even greater detail than the average reader would consider necessary. There is a very full bibliography, but one could wish that this bibliography had a more international flavour. The book is well produced in a most convenient form, and is, for myself, among the few books I have seen from the presses of East Germany.

PHILIP ELLMAN.

RECTOSCOPIC APPEARANCES

Principles of Rectoscopy. By Karel Herfort and Zdenek Maratka. (Pp. 254; illustrated. 42s.) London: Constable and Co., Ltd. 1958.

The objective of this book, originally written in Czech but with triple translation into Russian, German, and English contained in the one volume, is to describe the technique of proctoscopy and sigmoidoscopy and to record pictorially certain lesions of the anus, rectum, and colon. The author describes his preferred knee-elbow position for sigmoidoscopy and concerns himself with certain of the difficulties and hazards of the examination, but this section has nothing to add to the routine description of the procedure contained in any monograph devoted to proctology. The volume is copiously illustrated, but without reference to the captions I have found it difficult to recognize some of the lesions portrayed in the colour photographs. Two illustrations show the formation of a perineal colostomy and an artificial anus. But the suggestion that a surgical stoma is well sited when placed in these positions will not find general approval amongst English and American surgeons. The multiple artists' drawings of the sigmoidoscopic appearances in the normal and in the diseased bowel are beautifully prepared, but, as in all such illustrations of endoscopic appearances, they tend to be impressionistic rather than realistic. The beginner in sigmoidoscopic examinations may well find initial difficulty in correlating what he visualizes during instrumentation with appearances represented in these colour drawings, but with additional experience they should provide him with considerable help.

Combined with an adequate practical training in the specialty of proctology and the interpretation of sigmoidoscopic appearances the book can play a part. But coloured illustrations, however beautifully prepared, can never replace the experience gained by the detailed and direct observation of the changes accompanying disease processes affecting the rectum and colon.

STANLEY AYLETT.

A bibliography of the publications of W.H.O. from its inception to the end of 1957 is now available (*Publications of the World Health Organization 1947-1957*; 128 pp., H.M. Stationery Office, 17s. 6d.). It lists all articles published in the *Bulletin of the World Health Organization*, all numbers of the *Monograph Series*, the *Technical Reports Series*, and the *Official Records*, and selected material from the *Chronicle*, the *International Digest of Health Legislation*, the *Epidemiological and Vital Statistics Report*, and the supplements to the *Weekly Epidemiological Record*. Certain occasional publications of W.H.O. are also included. The items are serially numbered and grouped alphabetically under subject headings; author and country indexes are provided. The bibliography is also available in French.

In the sixth edition of his *Forensic Medicine* (London, A. and C. Black, 1957; 30s.) Professor Douglas Kerr has made a general revision of the text and has rewritten the section on the treatment of barbiturate poisoning. Mention is made of the B.M.A. report on the *Recognition of Intoxication*, 1954, but the original memorandum published by the Association in 1927 has been retained in the book as being more suitable for teaching purposes, although a table based on data in the later report has been included to show blood alcohol percentages in relation to amounts of beer or spirits consumed.

The Metabolism of Sulphur Compounds, by Professor Leslie Young and Dr. G. A. Maw (pp. 180; Methuen and Co., Ltd., 16s.), deals with various organic and inorganic compounds of sulphur in higher animals and in micro-organisms. Cysteine, cystine, homocysteine, methionine, and other compounds of especial interest are discussed in detail. Each chapter is followed by an extensive bibliography.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY NOVEMBER 15 1958

ENVIRONMENT AND BLOOD PRESSURE

Environmental factors in the production of chronic disease have recently been given increasing attention. The Pneumoconiosis Research Unit in South Wales has been in the forefront in this work, and its interest has not been restricted to respiratory diseases. Recently workers there have been studying levels of arterial blood pressure in the general population, and W. E. Miall and P. D. Oldham¹ have described a study of samples of the population of the Rhondda Fach, a mining valley, and of the Vale of Glamorgan, an agricultural area. The samples, chosen at random, were assumed to be representative of the general population in these two districts and were used as the index cases (propositi) for inheritance studies in which measurements were also made for all the first-degree relatives living within 25 miles of the centre of each area. These relatives comprise parents, siblings, and children. The measurements were made under standard circumstances by one observer.

The results from the samples have been used for fitting curves relating arterial pressure with age, and these show that there is no material difference in the relationship in the two populations despite their strikingly different environments. In further analyses of environmental factors the data from both districts have accordingly been pooled. Comparisons of the arterial pressure of individuals is not possible without standardizing for age and sex. A system of scoring devised by M. Hamilton and his associates² has been followed to allow for these variables so that direct comparisons may be made. In this way a number of environmental factors were shown to have a considerable influence on arterial blood pressure. Occupation, either directly or indirectly through economic factors, appeared to affect pressure. People in light work with less expenditure of energy, higher incomes, and higher standards of living had higher pressures. Heavy manual workers with higher expenditure of

energy, lower incomes, and lower living standards had lower pressures. There was a steady trend between these two extremes, the intermediate groups having intermediate pressures. These differences were not due to differences of arm girth or weight. Furthermore, the effects of occupation were most obvious in bachelors and in men over 50 years old. The authors point out that these are the two groups of people who most truly reflect occupational differences in income and energy expenditure.

These observations do not entirely agree with those reported in some other studies. In a survey in Birmingham³ higher pressures were found in Social Class V than in Social Class I, but no real trend with the physical demands of occupation was noted. In Bergen⁴ a study has shown that persons occupied in heavy labour have the highest systolic pressure, while those with independent and responsible positions have the lowest blood pressure. The reasons for these discrepancies are not clear, but it may be noted that in the South Wales survey the blood pressure was taken in the individual's own home after a rest of five to ten minutes. The Birmingham records were made without any previous period of rest. In Bergen each person attended at a centre at a time most convenient to himself. It is therefore not perhaps surprising that the labourer coming straight from his place of work presented a higher systolic blood pressure than the sedentary worker.

An investigation of the effect of family size on blood pressure produced some interesting, and at first sight surprising, results. Pregnancy may provoke the appearance of hypertension in some subjects who develop toxæmia, and in some the rise of blood pressure may persist.⁵ Accordingly, it might be expected that multiparous women might have higher pressures than nulliparous women. However, on the contrary, an inverse correlation was found with family size—the larger the family the lower the pressure. A similar trend was reported in the women of the Bergen survey.⁴ Even more surprising was the finding in the South Wales survey that family size influenced blood pressure in a similar way in the male. The trend for systolic pressure in men aged 15–50 years is almost as marked as in young females, though it is absent in diastolic pressure measurements. Single men had higher systolic pressures than the married, and the fathers of small families higher than those of large families. The influence of family size eventually becomes less obvious in the elderly.

Speculation on the explanation of these environmental effects is tempting but unlikely to be fruitful without further investigation. The fact that the pressures in both males and females are related to family

size suggests that the relationship is probably not a direct physiological effect of pregnancy or lactation. Though women with high pressures may be advised to limit the number of children, this advice is rarely given to hypertensive fathers. The factor which associates high fertility with low blood pressure cannot yet be clearly defined, and several possible explanations come to mind. Clearly, a large family brings financial problems and certainly increases energy expenditure, and in this way may diminish some of the distinctions between the social classes. The findings of this application of epidemiological techniques to the study of hypertension will undoubtedly stimulate much further inquiry.

COMPENSATION FOR INJURY

Workmen's compensation attracts the eye of the public, and undoubtedly press reports of accidents and compensation are widely read by employer and employee. It has often been questioned whether changes in the law have been beneficial to the claimant and have facilitated the task of the doctors concerned with his case. The duties of the certifying surgeon and the medical referee were stated in the Workmen's Compensation Act of 1906, when the previous Acts of 1897 and 1900 were repealed. As time went on further changes were made, and a departmental committee on workmen's compensation issued a report¹ in 1920 (the Holman Gregory report) which influenced the trend of further legislation and practice. In 1946 the National Insurance (Industrial Injuries) Act provided regulations governing the constitution of medical boards and medical appeal tribunals. The appointment of medical assessors in connexion with local appeals tribunals was recognized. One of the consequences of all this is that a group of doctors now deal with these cases and not one or two holding a special and permanent position.

These legal changes may have made the work of the claimant's solicitor easier, but they have merely altered rather than simplified the medical procedure. Sometimes all the claimant's family doctor can do is to provide certification and sedatives—perhaps knowing that the provision of both is necessary but may be harmful—while the medical aspects of the claim pass into the hands of a practitioner or group of practitioners whose main occupation is to prepare

reports on medico-legal matters. They obtain specialist opinion from consultants, particularly neurologists, psychiatrists, and orthopaedic surgeons. There is little evidence that the frequent medical examinations are of benefit to the litigant, and many observers consider that they are detrimental to him and misleading to the lawyers. In fact it can be argued that the present system of long-drawn-out negotiation sometimes tends to demoralize patients, helping to induce a traumatic neurosis, and robbing their doctors of all opportunity to prevent the onset of this clinical condition, so well known to the courts.

Emotional reaction after injury has been recognized for many years, and circumstances have provided labels for types, such as railway spine and shell shock. Sir Francis Walshe,² discussing the subject recently, has observed that some non-medical factor operates to determine the development of traumatic neurosis. The aetiology of the condition has been considered particularly by Farquhar Buzzard,³ J. Collie,⁴ and L. Brahdy and S. Kahn,⁵ as well as Walshe, to name only a few. Their observations show emotional symptoms are more likely to arise after an injury resulting from war or earthquake, or from accidents on the railway or in industry, and particularly in the course of gainful employment, than from injury received on the rugby football ground, hunting field, racecourse, or in childhood. Indeed, traumatic neurosis is rarely found in childhood, though parents suing on behalf of a child may present symptoms of a neurosis. The patient's pretraumatic personality is not necessarily other than normal, but accidents of a particular type or to certain areas of the body are more apt to produce manifestations of traumatic neurosis. If the injury is emotional rather than physical—such as a fright—then headache, fear, vertigo, tremor, and insomnia may develop, though these may also develop after physical injury. Such symptoms are well known after injury to transverse processes of vertebrae, coccyx, head, and neck. In these circumstances it can be difficult to determine if the claimant is a sick man seeking adequate compensation, or a malingerer. Walshe concludes that "trauma by itself does not give rise to neurosis, but when a claim for compensation can be made in respect of an accident or injury, this factor allows, if it does not actively induce, the neurosis. In its absence neurosis does not ensue upon injury." And it is commonly observed that settlement of a patient's claim to his satisfaction usually leads to an improvement or cure, temporary or permanent, of the traumatic neurosis. The remarkable benefit that follows settlement has attracted attention in the courts of many countries. Lump sums have always been popular with the work-

man. Now that treatment is provided by the State this is of less importance, but it is worth noting that they are prohibited in many foreign countries, and evidence⁶ from the Ministry of Pensions was that they had not proved successful in cases of war neuroses.

To help the judge decide whether a litigant's condition is legally directly or indirectly the result of injury, the doctor has a duty to state what he finds, and, if asked, he will give his opinion on whether the symptoms result from the injury. Hence it is not for him to decide if there is malingering or fraud, but the doctor can be of great assistance to the court if he can say the man is genuine and he considers him to be as disabled as he claims⁷ to be. Walshe draws important conclusions on the enormous loss to industry of the complications, particularly neurosis, after injury, and the distress to the injured person. He points out that the process of negotiation is often not only interminable but of such a nature as to aggravate the emotional condition of the litigant. Are doctors sometimes at fault in writing pessimistic reports? Are lawyers sometimes blind to the advantages for the claimant of an early settlement? In the end the injured person's recovery is likely to mean more to him than any financial award.

LIVE POLIOMYELITIS VACCINE

An Expert Committee¹ of the World Health Organization, reporting earlier this year, had this to say about living attenuated poliomyelitis vaccines: "Tests on hundreds of thousands of people will be necessary to establish whether the theoretical expectations of safety can be confirmed in actual practice." "Tests" of this magnitude are already in progress in different parts of the world, and a preliminary report on one of them, involving 244,596 persons vaccinated in the Belgian Congo and Ruanda-Urundi, has already been published.² Three articles in this issue focus attention on "the theoretical expectations of safety" of the living attenuated poliomyelitis vaccines so far available. Professor C. H. Stuart-Harris and his colleagues in Sheffield (p. 1188), using Sabin's attenuated type III polio virus, designated 12a₁b (KP₁), in a rigidly controlled trial on 14 boys first immunized with two injections of the formolized vaccine, found that virus isolated from all five of the boys in whose intestines it multiplied regained its power to paralyse monkeys inoculated intracerebrally. Virus isolated from one case on the

fourteenth day after ingestion of the vaccine "showed a degree of neurotropism similar to that of field strains of type III virus from paralytic cases." It is unlikely that any of the strains isolated from boys in this trial was a "wild" strain accidentally picked up, because "no case of type III poliomyelitis was in fact encountered in Sheffield during the entire period of the trial, and the last case of type III virus isolation had been in December, 1956." In another article (p. 1187) Dr. D. S. Dane and Professor G. W. A. Dick and their colleagues in Belfast record neutralizing antibody levels in 60 children vaccinated orally a year previously with living attenuated type II TN virus. Their earlier report³ had shown that this virus regained its cytopathic power and some power to paralyse monkeys in its passage through the human intestine, a result which led to universal agreement² that, on grounds of safety, the TN strain is unsuitable as a vaccine. The Belfast workers now show that the level of neutralizing antibody in the same children a year after vaccination is "of the same order as in children a year after vaccination with two injections of formolized vaccine." This result is disappointing, since one of the expected advantages of living vaccines, chiefly because of the experience with yellow-fever vaccination, was that they would give a more durable immunity. However, as the authors observe, neutralizing antibody titres may not measure immunity, especially as they take no account of possible local immunity in the intestine.

The third paper on live virus vaccines in this issue (p. 1184) is a balanced review of the present position by Professor Dick and Dr. Dane. Thousands of people have been vaccinated with live attenuated virus, and experience shows that there is little likelihood that the vaccinated subject will himself suffer any ill effect: none so far are known to have done so. The possible danger is to contacts, who may become infected from the vaccinated. That contact infection with the live vaccine strains occurs has been repeatedly shown. If such strains remain attenuated, contact infection, by disseminating them among the population, might supplant wild virulent strains and raise the general immunity; but if on passage the vaccine strains regain appreciable virulence, then they might lead to paralytic cases of poliomyelitis among those to whom they spread.

Although their discussion does not take account of the Sheffield experience, Dick and Dane emphasize the importance of defining the limits of safety of living attenuated vaccines as the immediate aim of further trials. Much remains to be done before any firm assumption on the safety of widespread use of live virus vaccine is justified. Under the more or

less controlled and special circumstances of laboratory study, the level of neurotropic virulence can be varied in either direction, or held approximately steady. It is not known whether attenuation is a process of mutant selection, as the plaque-picking technique assumes, or whether it is a phenotypic change induced by environment, of the kind seen with encephalomyocarditis, another R.N.A. virus.⁴ Nothing is known of the nature of the annual change in poliomyelitis which, in temperate countries, brings on the polio season in summer and autumn. It is possible that in nature strains of virus change their virulence in either direction as freely as they do in the laboratory. Dick and Dane record an interesting and highly pertinent observation on the high virulence to monkeys of virus isolated from paralytic cases compared with the much lower monkey virulence of virus presumably of the same strains isolated from contacts of these cases.

Many different pieces of circumstantial evidence seem to indicate that the power of the polio virus to paralyse is a most unstable characteristic, that fluctuations in this power occur in nature for reasons which are entirely unknown, and therefore are unpredictable. The "theoretical expectations of safety" can, in the opinion of some authorities, hardly be said to be firm enough to justify any trials on human beings other than those made on small numbers of volunteers in circumstances such that the spread of the virus can be closely watched and effectively controlled. Such trials are wholly practicable, and are needed to shed further light on this difficult and complex problem. At this stage "trials on hundreds of thousands of people" may or may not be carried through without ill effect. It is difficult to see how they can tell us much about the protective power of the vaccines; and to attempt to apply the results observed in tropical countries with an initially high incidence of poliomyelitis virus to temperate or other countries where the disease behaves differently might, for all we yet know, prove disastrous. The whole history of poliomyelitis vaccination has a tendency to run at a pace decided by politics and the press: in this respect it is very different from the history of diphtheria immunization, which did not become general until the scientific basis of it had been fully worked out. The best chance of achieving a sound assessment of live poliomyelitis vaccines lies in a continuation of careful small-scale studies like those discussed in the three articles in this issue and the many which have been made in the United States by the American workers who have pioneered in this field.

WILD GAME AND SLEEPING SICKNESS

In the Croonian lectures of 1915 Sir David Bruce¹ described the isolation of polymorphic trypanosomes from 14 wild animals out of 180 examined in Nyasaland. He was of the opinion that the organism was identical with the one responsible for Rhodesian sleeping sickness, and that wild game animals must constitute a dangerous reservoir of the infection. Further isolations were made by British and German workers, but all these observations, including Bruce's, were based on the assumption that a single species of trypanosome was concerned; we now know, on the contrary, that two species exist, identical in appearance, one of which is infective to man and animals (*Trypanosoma rhodesiense*) while the other is infective to animals alone (*T. brucei*). The only way of distinguishing the two species is by inoculating them into man, in whom *T. rhodesiense* alone will take. This essential test was not applied by the early workers, and their isolations may have been of either species. The same doubt shadows the experiments of H. L. Duke² in Uganda, where he reported the presence of *T. gambiense* in the sitatunga (swamp bushbuck). Nevertheless, epidemiological evidence was accumulating that game was indeed a reservoir of the human parasite: repeated examples occurred of hunters going into game country totally uninhabited by man and returning not only with the trophies of the chase but with Rhodesian sleeping sickness. Shortly before his death, C. H. N. Jackson³ summarized his experience in Shinyanga and came to the conclusion that wild animals must form a reservoir of the disease in nature, basing this both on the history of cases and on the isolation of true *T. rhodesiense* from tsetse flies caught in the bush.⁴ The susceptibility of antelopes to *T. rhodesiense* was proved beyond question by J. F. Corson, H. Fairbairn, and K. C. Willett, working at the Tinde laboratory of the East African and Trypanosomiasis Research and Reclamation Organization, and the strain was maintained in these animals by blood or fly passage continuously for ten years, at the end of which time it proved to be still infective to man.⁵

Many people were satisfied with this circumstantial evidence, but final proof was still lacking, and two attempts have recently been made to fill the lacuna. M. T. Ashcroft⁶ in Tanganyika inoculated the blood of 47 wild animals into rats and recovered a polymorphic trypanosome from a single hartebeeste; this proved to be non-infective to man. In this issue of the *Journal* (p. 1203) R. B. Heisch, J. P. McMahon, and P. E. C. Manson-Bahr report the actual presence of *T. rhodesiense* in wild game. Using thirty times the quantity of blood that Ashcroft employed and with the resources of the experienced Division of Insect-borne Diseases of the Kenya Medical Department at their disposal, they obtained from a bushbuck a polymorphic trypanosome which was later inoculated into (and infected) a member

of their staff who had remained behind in Nairobi, far from any endemic zone of the disease. The main story of sleeping sickness in Africa is thus brought to a conclusion, though many details still await clarification. It is a paradox that this successful experiment was performed in a region where *T. rhodesiense* was absent until 1940, when it overflowed into Kenya, in the human form, from the epidemic raging in Uganda; wild animals must have become infected later, and once more we have an example of a zoonosis *hors de ligne*.

Confirmation that wild animals are a reservoir of sleeping sickness should not provide to-day ammunition for the bloodthirsty exponents of game destruction for the control of the disease. The facilities offered by the synthetic insecticides, the subtle introduction of sterile male tsetse flies,⁷ or prophylaxis with the new drugs, render this crude approach as unnecessary as the removal of a population. The beautiful African fauna should remain undisturbed.

CARDIOLOGY IN THE N.H.S.

A year or so before the N.H.S. came into being in 1948 a committee on cardiology of the Royal College of Physicians of London reported on the training of cardiologists and on the practice of cardiology in hospitals and in the Health Service that was to come. This month the College has issued a report of another committee on cardiology appointed in 1957 "to review and consider the implementation of the report of the Committee on Cardiology of April, 1947." Of the eighteen members of the later committee nine served on the earlier one. That there is some dissatisfaction about the place of cardiology in the N.H.S. might be assumed from the present report. Many well-trained young cardiologists, it states, are not in a position to use their skill, and this is already deterring the best young men from seeking appointments in cardiac departments. This leads to the suggestion that "the Ministry of Health could with advantage give the same official recognition to cardiology as it does to neurology and certain other specialties." Because a large proportion of the work of physicians in the N.H.S. is concerned with circulatory disablement in some form, the committee regards the investigation and treatment of cardiovascular disorders a necessary part of the work of general physicians, who should, however, always be able to call upon a fully equipped specialist department to help in difficult and complicated cases.

The report gives the committee's recommendations on the training of cardiologists and on the establishment and staffing of cardiac departments. Five years is suggested as the minimum period of training after the conclusion of the trainee's junior hospital appointments: two years of this period should be spent as a registrar or junior teacher in a department of general medicine, two years should be spent in a cardiac department, and one year in research. There should be a department of cardiology at one of the main teaching hospitals of each

medical school, and outside the teaching hospitals a cardiologist should be appointed to every major hospital centre and to every hospital where surgery of the heart is performed. As to the smaller hospital centres, the report urges that a first-class opinion should be available for every patient with a heart disorder needing expert advice: "this means that in every area where access to a major hospital centre is not easy, one or more cardiologists should be appointed among the physicians working in this area." The report is not without glimpses of the obvious: for instance, it outlines the ways in which the department of cardiology should establish liaison with departments of cardiac surgery, child health, and obstetrics, and in its recommendations on accommodation it states that "there should also be adequate room for patients waiting." But, in general, the report gives the Ministry clear guidance on how to provide the best possible cardiological service within the N.H.S.

SPEEDING THE TAN

A tanned skin has come to be regarded as a sign of vigorous health and, lately, as a social asset, for it commonly betokens a visit abroad to those parts of Southern Europe where the sun is less sparing with his favours than in Britain. The cosmetic manufacturers have therefore provided numerous preparations designed to permit tanning while reducing the risk of sunburn, and others which attempt with suitable pigments to simulate a natural tan. Now a drug which increases and accelerates tanning may soon be introduced¹ in the United States.

The drug, methoxypsoralen, has an interesting history. Extracts of the plant *Ammi majus*, containing this substance, were employed in Egypt as an ancient folk remedy for vitiligo. Reports of the first scientific investigation of the photosensitizing properties of extracts of *Ammi majus* appeared in 1947² and the active ingredients were isolated and identified. The first clinical trials were soon carried out, and encouraging results were claimed in the treatment of vitiligo. The psoralens have since been prescribed in dermatological clinics in many countries. There is no doubt that these substances applied topically or taken by mouth before the skin is exposed to ultra-violet light will induce formation of pigment in some areas of vitiligo. However, the response in the individual case is unpredictable; treatment has to be prolonged and is extremely time-consuming; and even if re-pigmentation is achieved it may not be permanent. It has been estimated that only one in seven patients treated obtains satisfactory re-pigmentation. A. Jarrett and G. Szabo³ showed that a pigmentary response is obtainable only in those areas in which some melanocytes remain, and this may explain the many failures. The incidence of unpleasantly severe inflammatory reactions to the topical application of the

⁴ Sulzberger, M. B., and Lerner, A. B., *J. Amer. med. Ass.*, 1958, 167, 2077.

psoralens is so high that this treatment has been generally abandoned. Oral administration produces less spectacular side-effects, but nausea, diarrhoea, headache, and depression are not uncommon. Though no better treatment for vitiligo is available, most dermatologists would now agree that the psoralens should be reserved for selected cases treated under close supervision and that these drugs are mainly of value in research.

While the psoralens will induce a much more consistent pigmentary response in normal skin than in vitiligo, it is neither completely constant nor predictable, and the risk of side-effects is equally great. M. B. Sulzberger and A. B. Lerner⁴ point out that we do not know whether prolonged or repeated ingestion of psoralens exposes the subject to other hazards. We do not know, for example, what effect, if any, these drugs may have on the development of chronic solar degenerative changes, including carcinoma. After critical review of the available evidence it is impossible at present to justify the use of the psoralens merely to acquire an impressive South of France tan in an average English summer.

DETECTION OF OVULATION

Since the human ovum does not survive after ovulation for more than a few hours—less than twelve, it is generally believed—conception is unlikely to occur unless coitus takes place within a short time of it. Couples seeking advice on infertility are always told to have sexual relations during the fertile phase of the menstrual cycle, but to define that phase, except in rather general terms, has proved none too easy. The most commonly used adjunct has been the basal temperature record, which characteristically shows a mid-cycle rise and post-ovular plateau caused by the progesterone secreted by the corpus luteum. The temperature rise, "thermal shift," to use the current transatlantic expression, is usually described as being immediately preceded by a temperature drop—the "ovulatory dip"—but this is exceptional and probably fortuitous, though often said to indicate the precise day of ovulation. The inconsistency, if not irrelevance, of the ovulatory dip, and the fact that the thermal shift occurs *after* ovulation (as has been shown most elegantly by the hormone-excretion studies of J. B. Brown and colleagues¹), make the basal temperature record no more useful for detecting the day of ovulation—except in retrospect—than would measurement of the daily output of urinary pregnandiol, which also reflects progesterone secretion. Detection of the urinary oestrogen peak at ovulation would be more precise but is obviously not a practical proposition. Nor, scarcely, is the daily collection and examination of vaginal smears, though by this means it may be possible to pin-point the day of ovulation. The rat-ovary hyperaemia test of Farris,² which, in the hands of

its author, has facilitated precise prediction of the day of ovulation, is also far too cumbersome for general practical use; moreover, some other workers have not had the same success with it.

In view of the shortcomings of these methods of detecting ovulation, much interest attaches to the observation of C. H. Birnberg, R. Kurzrok, and A. Laufer³ that by inserting into the vagina daily a strip bearing glucose oxidase, which detects the presence of glucose ("tes-tape," the British counterpart of which is "clinstix"), the day of ovulation can be detected by a sharp rise in the concentration of glucose in the cervical secretions. J. B. Doyle⁴ has modified this procedure so that the woman can carry it out herself and so select the day of ovulation without any medical intervention. That this change in glucose concentration really indicates the occurrence of ovulation would seem to be attested by Doyle's finding freshly ruptured follicles in two women subjected to laparotomy (for entirely independent reasons) on the day of maximum "tes-tape" colour, and by the prompt occurrence of conception in 23 out of 27 women subjected to A.I.D. by Birnberg and colleagues on days chosen in the same way. For control of fertility by the "rhythm" method, detection of ovulation by this technique would seem to offer an important advance in safety and precision to the patient who chooses to use it.

TRAVELLING SCHOLARSHIP FOR GENERAL PRACTITIONERS

In the Association Notices this week (*Supplement*, p. 212) particulars are given of a scholarship for which competition among general practitioners is likely to be keen. The trustees of the Claire Wand Fund are offering a travelling scholarship of a maximum value of £600 to a general practitioner prepared to spend 6–8 weeks in the U.S.A. and Canada and to attend the Second World Conference on Medical Education in Chicago early next September.¹ The Claire Wand Fund was established in memory of the wife of Dr. S. Wand, the present Chairman of Council, and the capital sum from which the Fund's income is derived was contributed mainly by general practitioners in recognition of the outstanding services rendered to the medical profession by Dr. Wand and Dr. D. P. Stevenson during the negotiations leading to the Dankwerts award. The income of the fund is applied "for the purpose of further education of medical practitioners who are predominantly engaged in general practice," and the award of the travelling scholarship now announced is to enable a general practitioner to study what is done for the further education of general practitioners in Canada and the U.S.A. In submitting their applications general practitioners should describe what studies they propose to undertake in North America: applications should be submitted to the secretary of the Fund at B.M.A. House not later than January 31, 1959.

certify as mentally defective children in need of special education. In considering the question of mental defect in young children, therefore, we are concerned only with low-grade cases—that is, with idiocy and imbecility. The school medical officer may, however, also be concerned with the question of educational retardation and the need for special education.

I understand that the position in the area with which I am here concerned is that special schools are not available for the educationally subnormal (E.S.N.) until they reach the age of 7 years. An adjacent local authority, on the other hand, has taken the step of providing a nursery school for the E.S.N. Let me say at once that there is a question of expediency here. From a practical point of view, and faced with pressure of social circumstances, it may be easier to help a supposedly backward child in areas where special facilities are provided from an early age. So far as principle is concerned, however, a decision regarding special schooling at the age of 7 years seems much more desirable. By that age it will have been found by experience what the child's capabilities in the way of learning really are, and some form of assessment of his probable future progress will be possible. It seems very undesirable that a child should be classed at the age of 2 or 3 years as E.S.N. or even occasionally as feeble-minded, since an analysis of the total situation in such cases will more often reveal a disturbed background than a disturbed child (Hilliard and Kirman, 1957). Adverse social factors play a major part in causing such cases to be considered retarded (Craib and Woodward, 1958; Kirman, 1958). It is particularly important to remember that once such a decision has been made the label tends to stick to the child throughout his subsequent career regardless of all provision for reassessment.

Anatomical Basis for Mental Defect

Tests are of value only if they predict subsequent attainment, and the predictive value of tests of ability under the age of 5 is limited (Vernon, 1955). If, therefore, we are attempting to assess in the case of a particular young child whether or not he is mentally defective on the basis of unusual behaviour it seems desirable to confine our attention to gross defect. It has long been considered that in most cases of gross mental defect there is a corresponding gross abnormality of the brain. Berry (1938) noted the marked reduction in weight and size. Recent work (Crome, 1954) on a big series of unselected cases has confirmed that obvious lesions are usually present. Figs. 1 to 5 illustrate some of the abnormalities observed. This being so, it will be found that in a considerable number of cases a detailed history and a careful physical examination will provide evidence of abnormality to supplement the story of abnormal behaviour. This applies equally to cases due primarily to genetic factors (primary amentia) and to those ascribed to environmental influences (secondary amentia). In a proportion of cases, however, the cerebral abnormality is discovered only after death, and during life there were no neurological symptoms and no history of illness or untoward event which might have produced the abnormality. In these cases the only symptoms of the cerebral defect are those which are summed up as "mental defect."

First Symptoms Noted By Parents

The data shown in the accompanying Table are derived from the social histories of 233 patients admitted to hospital, usually under the age of 5 years, as mental defectives. In each case the leading symptom complained of by the parents is taken. In some instances there was no specific complaint, merely a general statement that the child was

slow in developing, but in the majority more specific information was available. The symptoms leading to the first recognition of the mental defect have been shown at the time at which they came to the notice of the parent. In

FIG. 1.—Hydrancephaly. Very little functioning brain cortex. Complaint of constant screaming and taking no notice at 3 months.

FIG. 2.—Pachygyria with very poor development of sulci. Convulsions at 3 months followed by regression.

FIG. 3.—Frontal lobes not separated. Did not suck well. Difficult to feed from birth.

many cases this was when the parents first felt sure about the defect: they had often had a vague suspicion previously that all was not well. This was particularly so, for example, in the case of twins where the normal child was available for comparison. In many histories additional details have been supplied, but it was thought that a clearer picture would emerge if only the first symptoms which arrested the attention of the parent were recorded.

Table Showing Time of Appearance of First Symptoms of Mental Defect in 233 Children

Symptom	Age in Months							Total
	Birth	Under 3	3-5	6-11	12-23	24-35	36-48	
Physical features	25	18	8	5	4	1	—	61
Eye defect	4	5	9	5	4	2	—	29

FIG. 4.—Atrophy of brain. At 6 months child did not seem to see or hear.

FIG. 5.—Same case as 4, showing lipoidosis. A case of cerebro-macular degeneration.

The biggest single group of cases was recognized by the parents or by their medical advisors on the basis of physical abnormalities, and this was also the group most readily recognized at birth, as might be expected, since the range of behaviour of the newborn baby is so limited. The commonest of the physical abnormalities recognized in this way was mongolism, but the group also includes such conditions as microcephaly and hydrocephalus. Another big group of cases was noticed early on account of "eye defect." Some of these children were blind, but more often they seemed blind to the parents at this early stage. Their eyes did not follow a light or they failed to fix objects with their eyes, or, slightly later, failed to turn their heads towards objects displayed. The groups which first came to attention because of feeding difficulties, quietness, or cerebral palsy were smaller, and the next big group is that merely classed as generally slow. This is obviously a residual collection due either to failure of the parent to particularize or simply to realization of the fact that this was indeed the most accurate description of the position, that the child was slow in all his accomplishments.

In the "not taking notice" group the emphasis is on the lack of emotional response, whilst the big "not sitting" group begin to worry the parents because of failure to reach this important and well-recognized "milestone" at the appropriate time. A smaller group of parents had suspended judgment until the child failed to walk at the normal time, and only five had delayed still further until the child had reached the appropriate time for beginning to talk. Five patients were noticeable because of restlessness and single cases because of other symptoms.

In glancing through the list of symptoms perhaps the most striking thing is that most of them are negative—that is, simply a statement that a child failed to do a certain thing at a certain time. Only 18 cases drew attention to themselves because they did something which was unusual. Perhaps a more correct statement would be that they persisted in doing something after the time for this form of activity had gone by; this applies, for example, to the fine repetitive movements of the fingers which are normal in a young baby but which are later described in imbeciles and idiots as "digital mannerisms." These patients with positive symptoms included the "screaming" group, those with "peculiar movements," restlessness, head banging, and destructiveness. The majority, then, exhibit simply a quantitative defect or retardation of behaviour development which may be given a quantitative expression on the basis of any of the recognized scales of norms.

Psychosis or Mental Defect?

Difficulties may arise in the interpretation of the abnormal behaviour noted in both the majority and the minority groups. For example, it is well known that on occasion a child who fails to sit, stand, or talk at the usual time may yet prove to be above average in intelligence. It is, however, the minority group whose leading abnormality consists of qualitatively abnormal behaviour who are most difficult to understand. On the one hand the symptoms may simply be evidence of retardation. This may be true of restlessness. Normal children are restless, but they are usually capable of being trained to some extent, so that the expression of the restless tendency can sometimes be limited by parental influence. This implies, however, capacity to respond to "atmosphere," to adult approval or disapproval, and to other factors in the social environment. Very backward children are slow in acquiring this capacity, and the abnormality is not so much that they are restless as that they are inappropriately and persistently restless in an unmodifiable manner.

On the other hand such symptoms as restlessness or "peculiar movements" are also characteristic of children with psychotic and neurotic illnesses. It is often a matter of extreme difficulty to distinguish between simple mental defect and psychosis in a young child. To some extent the distinction is one of definition. In any considerable group

of mentally defective children there is a small minority who might more aptly be described as psychotic. They function socially at idiot level and fail to co-operate in standard tests to such an extent as to secure a very low rating. On the other hand, careful observation may lead to an impression that the child has considerable capacities which are unused or are utilized in a negative manner. For example, a child who attracts attention by head banging may display other forms of negativistic behaviour. This behaviour may be nicely timed in such a manner as to indicate considerable discernment of social situations. The appearance of a stranger or any other slight derangement of the usual order of events may be followed by refusal of food or by a display of head banging. Obsessional tendencies in such patients may likewise indicate extreme nicety of perception.

The position is still further complicated by the fact that it is not rare for a backward child to develop superimposed psychotic features. Similarly, withdrawal and "autism" may be seen in children who are known to suffer from epilepsy or to have good evidence of structural abnormality of the brain.

It should also be pointed out that in psychotic children simple failure to carry out normal activities may also be a conspicuous part of the picture. The commonest form of infantile psychosis is of the schizophrenic type with poverty of social contact, and an important feature is often muteness, though such children may speak in complete sentences on exceptional occasions.

It follows that there are three possible interpretations of such abnormal features as head banging, restlessness, destructiveness, peculiar movements, and screaming. In the first place, any one of these symptoms taken alone may be merely a passing phase in the life of a child and may have no serious significance. It may represent a natural reaction to some set of unfavourable circumstances such as a sudden alteration in the amount of parental attention available. Secondly, these symptoms may be the manifestation of a profound abnormality of personality in a childhood psychosis. In the present connexion I am using the term psychosis to cover a serious prolonged mental illness in which there is no evidence of gross organic brain damage and in which there is an impression of retention of a potentially normal mental capacity: fortunately such conditions are relatively rare in young children. Finally, these symptoms are by no means uncommon as part of the picture of simple mental defect.

At this point I would like to emphasize something which may be thought obvious—this is, that backward children, like ordinary children, react to their environment, though at a more infantile level. If that environment is conducive to the development of emotional disturbances then they may well develop and complicate the picture of straightforward defect. An investigation by Dr. M. Woodward (in press) showed that there was a correlation, significant at beyond the 0.001 level, between disturbed behaviour after admission to a mental deficiency hospital and a mentally adverse home background prior to admission, using objective criteria.

In order to illustrate the vexed question of infantile psychosis and mental defect a film was recently prepared by Dr. E. J. Anthony, of the Institute of Psychiatry, including some studies of typical mannerisms and movements. Two photographs illustrating this subject are reproduced here (Figs. 6 and 7) showing the mannerisms commonly seen in idiocy. Mannerisms of this type are described in such conditions as phenylketonuria, but they are in no way specific to this condition and may be seen in idiocy due to any cause. It is also very difficult to differentiate such mannerisms from those which may be seen in psychotic children. The distinction must be made on the basis of the general picture rather than of the individual symptom. In idiocy the child has not advanced beyond the level of repetitive manipulation, whilst in psychosis he may regress to that level. A clear history of previous normality is sometimes valuable in

making the distinction, but there are reservations to this. In a minority of cases severe defect, perhaps amounting to idiocy, develops after some cerebral catastrophe—for example, post-inoculation encephalopathy or status epilepticus from whatever cause.

Limited Significance of Individual Features

It is extremely hazardous to make any definite forecast on the basis of a single defect or abnormality in the behaviour of a child.

The question of mannerisms may be used to illustrate this point. Persistent head rolling is such a mannerism, and may be seen quite frequently in both idiot and psychotic children. It is also, however, by no means uncommon in normal children. It may, at one stage in the development of an otherwise quite normal child, seem to be an essential preliminary to sleep, when it appears to serve a self-hypnotic role. In normal children these circular activities of very limited scope tend to be broken as the child develops more complicated behaviour patterns and responds to a greater variety of stimuli. In idiots this does not happen, or happens only very slowly and as a result of intensive training. As with normal young children, idiots will tend to resort to repetitive self-hypnotic behaviour when there is little else to attract their attention or when they are bored. It is clear, then, that the presence of such a mannerism cannot in itself be the basis for a diagnosis of defect or of serious maladjustment.

Similar considerations apply to delay in any one accomplishment, though the reasons for this may be somewhat different from those which apply in the case of mannerisms. Urinary incontinence illustrates the problem very well. All young babies are incontinent of urine, as are most idiots, but it is well known that urinary incontinence, especially nocturnal, may persist into adult

FIG. 6.—This boy aged 10 years was thought to be normal up to the age of 3½ years but deteriorated rapidly. He now functions at imbecile level. He shows a variety of mannerisms.

FIG. 7.—An idiot aged 8 years suffering from phenylketonuria.

life in a great variety of conditions apart from mental deficiency. A proportion of these cases are obviously neurotic in that they have other obvious features of neurosis, such as excessive anxiety, night terrors, shyness, timidity: others have some physical abnormality such as paraplegia to account for the weakness. In many children, however, this lack of sphincter control seems to be a solitary abnormality, and one is tempted to think in terms of delayed maturation of the apparatus responsible for the establishment of control. To base any far-reaching conclusions on the existence simply of urinary incontinence at, say, the age of 5 years is improper.

A word may also be said about the need for similar caution in interpreting normal behaviour in very young children. The older views about cerebral localization have come in for a good deal of criticism lately, and, while there is still a lack of general agreement on the subject, there is a tendency to a more dynamic concept of cerebral function which visualizes the central nervous system acting as a whole. None the less, it seems reasonable to suppose that activities such as breathing, coughing, and sucking, which are early developed, are more directly dependent on the integrity of the lower centres, while functions such as the use of logarithmic tables demand a certain amount of normal cortical tissue. The acquirement of skills such as sitting up independently and walking occupies an intermediate position. Most commonly, in severe mental defect the whole range of capabilities is affected in a fairly even manner. Even such elementary functions as coughing and swallowing may be seriously impaired, and breathing may be difficult to establish in a child with a severe brain abnormality. However, from time to time a case is encountered in which early development seems fairly normal in regard to the more vegetative functions and to early motor development. This may apply to children with a severe degree of tuberous sclerosis who may yet sit and walk at a normal time but prove eventually to be of idiot level. The most obvious explanation of this phenomenon would appear to be the fact that in severe mental defect there is a tendency for the higher centres to be more severely damaged than the lower. Similar considerations would apply to the case recently demonstrated by Professor Illingworth in which an infant with gross microcephaly passed the first "milestones" at the correct time.

A parallel with the phenomenon mentioned above may be found in cases of athetosis due to rhesus incompatibility. These children may seem fairly well after recovery from the acute illness (Crome *et al.*, 1955), and athetosis manifests itself only when the child reaches the stage of development at which co-ordinated purposeful movements are attempted.

Advantages and Disadvantages of Early Attention

I have avoided using the term "diagnosis" in this connexion, since mental defect is not a disease entity but rather a legal and social convention. As more light is thrown on the cause of deviation from the normal it becomes increasingly valuable to direct attention to young children who exhibit unusual or retarded behaviour. There is a small group of conditions which are amenable to direct treatment, such as cretinism, phenylketonuria, hypoglycaemia, galactosaemia. Some cases of petit mal associated with backwardness may also derive benefit from treatment. There is a whole group of children who are backward in certain respects whose prospects may be improved by careful study and advice. The most obvious of these is the group of deaf or partially deaf, but many other physical disabilities produce a similar effect. The deaf child is often regarded as mentally defective and frequently finds his way into a mental deficiency hospital, where he may develop a superimposed psychosis. It is essential that such a child should have expert advice and attention from an early age, and in his case the presenting symptom may be failure of speech development, inattention, and naughtiness, contrasting with a good level of attainment in some directions.

On the negative side, too much attention to delayed development at an early stage may distress the parent, may lead the doctor into unwise predictions, and may have a deleterious effect on the child's subsequent career. It is usually quite unjustifiable to ascertain a child under the age of 5 years as ineducable, and it is most undesirable that legal formalities such as certification as mentally defective should be undertaken at this stage. It is to be hoped that when new legislation is devised the present provision for the certification of young children as mentally defective will be replaced by a different arrangement for the care of such children, leaving it to the initiative of the parent to place them in hospital if this seems necessary. This should make it easier for the doctor to study the development and the needs of the individual child without the necessity to arrive at an early decision for purely statutory reasons.

Summary

It is seldom possible to predict accurately mental abnormality in a young child on the basis of specific behaviour disorders. Simple retardation of development is commoner than disturbed behaviour. In regard to mental deficiency it is possible to recognize only severe mental defect at an early stage. Often it is an adverse social background, not mental defect as such, which is the problem. Decisions regarding mental defect are often best postponed. The predictive value of tests under the age of 5 years is very low. A detailed history and physical examination are essential to assessment. Only 8% of 233 imbeciles and idiots drew their parents' attention by disturbed behaviour. The others were simply retarded. Disturbed behaviour of identical pattern may be found in idiots, in psychotic children, and, transiently, in normal children. The distinction must be based on the general picture, not on individual symptoms. Defectives are responsive to the environment and may develop a psychotic overlay in unfavourable circumstances. Even in severe defect early accomplishments are sometimes normal for the age. Early assessment and attention are important, especially where there are conditions which can be treated or complications such as deafness, but expediency should not be allowed to precipitate a rash decision which will prejudice the future of the child.

SOCIAL WORK IN GENERAL PRACTICE

BY

MADGE DONGRAY, B.A., A.M.I.A.

*Social Worker, Darbshire House Health Centre,
University of Manchester*

Considerable interest to-day is focused on the treatment and management of stress and strain and emotional disturbance in general practice. Opinions vary regarding the extent and importance of this problem, but few would deny that the family doctor, whether he likes it or not, is faced with a variety of social and emotional problems on which patients seek his advice and help. This raises the question of how far, in his capacity as medical adviser, he is concerned with them, and, if he feels rightly concerned, the question of what sort of help he can be expected to give. Here again opinions differ, ranging from the few doctors who consider these problems still outside their scope to those who consider the general practitioner should "do it all." The abundance of articles and correspondence on the subject, however, suggests that many family doctors feel a need for some sort of help in dealing with this aspect of their work, and some have written interesting accounts of the particular form of help they have chosen or have been able to find (Balint, 1957; Saville, 1957; Davis, 1957; Chalke and Fisher, 1957; Backett *et al.*, 1957).

At Darbshire House, Manchester University Health Centre, it was decided in June, 1955, for good or ill, to attach a trained social worker to the group of four family doctors practising from the centre and serving approximately 12,000 patients in a closely populated city area. I would like to say a little about this experiment.

First Steps

Experiment it certainly was, as the doctors had not worked directly with a social worker before and I had not worked in general practice. At the outset none of us had any clear idea of the sort of work which might be necessary or possible. The doctors knew that I had been a hospital almoner and had had some experience of child guidance, and it was agreed that in the first place they should refer to me any problems presenting social or emotional factors with which they thought or hoped I might be able to help.

During the first few months, which were largely spent in getting to know each other and learning to appreciate each other's points of view, two difficulties confronting the busy practitioner became steadily clearer; one was connected with the rapid advance in scientific medicine over the past 20 to 30 years, and the other with the growth of the social services over the same period of time.

The first difficulty is best illustrated by an account by one of the doctors of the tremendous change which the introduction of antibiotics had made in the management of pneumonia within his lifetime. Twenty years ago there was little the doctor could do but wait and hope until the crisis passed and then watch over a long, slow convalescence. Now the illness is usually arrested by a few injections, which take a minute or two to give and which can sometimes be delegated to the nurse. The relief from a heavy burden of responsibility in the doctor can readily be appreciated, but his personal contact with the patient and family is immeasurably curtailed and treatment tends to become a service rendered by the doctor rather than an experience lived through with the family. One suspects that the doctor may feel less helpless, but not the family. The mother who said, "We liked the old doctor; he used to talk to us

about Johnny; the new one just sticks needles into him," was, I think, voicing her feeling that she no longer had any significant part to play in the treatment of her child. This does not, of course, mean that the new and the old approach cannot be combined, but perhaps they tend, at present, to remain distinct and are often kept so by the pressure of present-day practice and perhaps for other less obvious reasons.

The second difficulty concerns the rapid growth in the social services and revolution in social legislation over the same period of time. This often makes the doctor feel that management of his cases in a truly personal way has been taken out of his hands. With the best will in the world he could not be expected to be fully conversant with this side of the picture as well as keeping abreast of development in the medical sphere.

Thus doctors and patients alike tend to complain of a dwindling sense of responsibility and consideration towards each other in an age when pain and suffering are no longer accepted passively as the inevitable lot of man, and there is a general feeling that for any misfortune whatever there must be a remedy somewhere in somebody's hands.

Our experience at Darbshire House has, I think, shown that in both these spheres a social worker can give useful assistance to the doctor.

Using the Social Services Effectively

Part of the social worker's basic equipment is a sound knowledge of the social services, both statutory and voluntary. In addition it is her duty to know clearly how these services actually operate in the district in which she works, so that she can interpret and explain them to the doctor and patient, both of whom tend to find them confusing. She can then assist the doctor to choose the agency most likely to help his patient, and can also help him to prepare and assist the patient to make good use of the facilities offered.

Take the simple example of advising a patient to attend a Ministry of Labour rehabilitation unit. It is important that the doctor distinguishes this service from Government training schemes, otherwise there is a danger of raising false expectations in the patient; it is useful to be able to answer some of the patient's questions about the allowances he will receive and to understand that he will not be guaranteed a job on completing the course, although the Ministry of Labour will do everything in its power to place him. It is helpful to understand the sort of experiences he may expect during the first few weeks at the unit: for the timid or truculent, for example, the aptitude tests can be a source of anxiety or irritation which may bring the patient back to complain at the surgery.

A patient who undertakes such a course free from avoidable misconceptions regarding its purposes is likely to make better use of the opportunity and to feel more confidence in the doctor who suggested it, and the social worker can often detect the hidden misconceptions which prevent patients from using the appropriate social service. For instance, a widow was found to be afraid to apply for National assistance because her husband had at one time drawn assistance under false pretences and she feared she would be penalized for his sins. A girl would not take out an affiliation order, believing that the court would send her to Borstal for having an illegitimate child while she was still under 21.

Doctors can attend lectures, read pamphlets, and pay visits of observation, but these time-consuming activities are, we think, no substitute for the opportunity to learn from repeated application and practice in collaboration with a social worker directly attached to the group.

Understanding Family Relationships

The social worker can often supplement the doctor's knowledge and understanding of family problems with her special skills in interviewing and understanding of personal

relationships. In an area such as ours it is not possible for the doctor to know all his patients and families intimately. Families move into and out of the district, split up, and come together again with surprising frequency. The doctor may be called suddenly to attend a family about which he knows nothing but where he senses underlying problems. Sometimes only one member of a family is registered with him, which makes it difficult to get a clear picture of the family as a whole; or the patient may be living alone, often as a result of intolerable conflicts with his family. In such cases an unhurried interview in which the patient does most of the talking and the social worker most of the listening, or a home visit to meet other members of the family, can illuminate the situation and enable the doctor to adopt the most helpful attitude towards the patient and family.

Young Mrs. X had been registered with the doctor for a few months, during which she had appeared repeatedly at the surgery seeking help with trivial ailments in herself and her baby daughter. The doctor was disturbed by her seemingly unreasonable demands on his time and patience, and asked me to see her.

She told a story of a grossly deprived and insecure childhood, and finished by saying, "The doctor is really a nice fatherly soul, isn't he?" This suggestion that she was seeking from the doctor a relationship which she had never had from her parents helped us to come to terms with our own attitude towards her.

Although her basic need for a good parent could never be fully satisfied by the doctor or anyone else, it was helpful that the doctor could understand this need and could tolerate and accept her demands without anxiety. It would have been no good to lecture her on being overanxious, but by accepting her anxiety as real and understandable he could give her a measure of reassurance and security which she should be able to communicate to her child, and, in a slight degree, prevent this child suffering as severely as she had done herself.

This sort of help may also be needed by families who have been registered with the doctor for some years and whose contact with him has been slight because they are seldom ill and send for him only in a crisis or because the management of the ill member of the family is in the hands of a hospital or other organization. This was the case with Mrs. Y, who had a spastic child, Jane, aged 2, and a normal healthy boy, John, aged 7 months. Mrs. Y had attended hospital regularly with Jane ever since she was a baby, and she also went to the child welfare centre with John, and she rarely sent for the family doctor. However, he was called in when John had bronchitis, and noticed that Mrs. Y spoke about Jane in such a way that he asked me to call and assess the situation, mentioning that the undesirable housing conditions made the problem of looking after Jane very difficult.

During my visit I gradually realized that Mrs. Y really had little idea of what to expect from Jane and did not seem to have grasped the implications of her condition. She held Jane up to show me her scissor gait, then put her on the floor, saying, "Look, she won't sit up." She put Jane in a chair with John, an extremely robust and vigorous child, and got annoyed with her for flopping over on to him. Mrs. Y was a young immature woman, but not by nature callous or unkind.

I discussed this with the doctor and suggested it would be helpful for someone to explain the child's condition to the mother and, if possible, to the father also, since Mrs. Y did not strike me as being capable of passing on to her husband, without distortion, whatever the doctor might tell her, and since any mother with a severely handicapped child needs the utmost support from her husband and this is more likely to be fostered by including him in consultations. Mrs. Y must certainly have received considerable information and advice already, but she had clearly been unable to accept and comprehend the nature of Jane's disability while she was still a baby, until John, at 7 months,

had started to outstrip the 2-year-old Jane. It was then the family doctor to whom she voiced her anxiety.

The housing problem did undoubtedly add to her difficulties, but, in spite of application to the housing department, there was no hope of an early solution. However, after a long discussion with the doctor, Mr. and Mrs. Y thanked him for his help, and we learned a little later that they were saving a deposit for a new house.

Long-term Casework with Families

The foregoing examples mainly illustrate help I was able to give to the doctor; the next example is a little different in that the help was given more directly and continuously to the family.

Mrs. Z had been unfortunate with her children. After carrying her first baby eight months she was delivered of a macerated foetus; her second child, Paul, was a mongol; her third child, Douglas, developed epileptic fits at 2½. When I first met them Paul was 5 years old and attending an occupation centre daily; Douglas was 4, and Mrs. Z was complaining of his excessive temper tantrums and destructiveness.

During a visit to the home I saw both parents, who spent much time demonstrating to me, in the presence of Douglas, what a terrible child he was, with the natural result that he behaved accordingly. The mother was sure he was going to be delinquent; the father certain he was "mad" and would never allow his teachers to teach him anything if they succeeded in getting him to school at all. The father said, half provocatively, that friends had advised him to take the child to a psychiatrist, and the mother said that, although she had great faith in the doctor, they had never had "specialist" advice—she seemed to favour a medical or neurological consultation. In fact, the child's attacks were well controlled with phenytoin sodium and phenobarbitone, and he had only an occasional fit.

I suggested that, if the family doctor agreed, we could refer them to the psychiatric department of the children's hospital, where there was a close liaison with the neurological department. They were obviously in two minds about this, but agreed I should consult the doctor. From their manner it seemed to me that these two highly anxious, ill-informed, and guilty parents were unlikely to make good use of this offer without further help and encouragement. The mother poured scorn on those who had already attempted to help her with Paul, and the parents clearly felt threatened by the idea that anyone could do better with their children than they. On the other hand, I felt that behind all this display of aggressive anxiety was considerable positive feeling.

A report was sent to the hospital, and, pending an appointment, I visited the mother fortnightly, seeing her for about an hour. At first she was aggressively casual, but on the third visit this attitude collapsed as she told me how difficult it was to be the mother of the only two children in the street who were "queer"—how she felt people criticized her for being too severe or too lenient with them, making her feel she ought not to have had them at all or should have put them in a home. Gradually she was able to discuss her wish to reject her children and her guilt about it, as well as her wish to cherish them, and how both she and her husband wondered why this had happened to them and who was to blame. She had rather resentfully given up work when Douglas started having fits and had taken to minding three normal children under 3 years of age from 8 a.m. to 5 p.m. five days a week in a house which was barely big enough to hold her own family. She denied emphatically that Douglas could feel jealous of these children, although he was often aggressive towards them; nor could she admit any rivalry between Douglas and Paul, as "she treated them both alike although Paul was worth ten of Douglas." Gradually, however, she began to watch Douglas's behaviour towards the other children and to admit its meaning; and she also began to realize that it was impossible

to treat a mongol child and an intelligent epileptic one exactly alike and to see that it must be difficult for Douglas to have an older brother who will remain a baby while he has to grow up.

Mrs. Z attended the psychiatric department in due course and obtained some satisfaction from learning that Douglas was of normal intelligence and some measure of reassurance about handling his tantrums and understanding of his type of epilepsy. She would not agree to attend more regularly than at three-monthly intervals, and, after consultation with the psychiatrist and his social worker, I continued to visit the home, extending the intervals between interviews as the situation improved.

The family was helped to tackle its housing problem, and there is a definite hope of removal within 18 months. This seems to have spurred the father on to get a better job, but the mother has begun to talk about loneliness on a new estate. Facing a new set of neighbours may well arouse some of her old fears, so we will try to keep in touch with her for a while round the removal time.

It is not possible to give an account of all that has been discussed or has happened during the 12-months association with this family, but certain changes have occurred: medication for Douglas has been reduced and he has not had a fit for nine months; and he started school recently without undue disturbance.

The precise reasons for these changes are open to dispute, although this is not the only case in which a gradual reduction in the need for medication has followed a combined attempt by the doctor and social worker to understand the emotional stresses in a family in which the patient has been diagnosed as having epilepsy. The situation is by no means stable even now, but the mother often speaks of Douglas as "really a very good boy" and the relationship between them seems calmer and warmer. We have yet to see if the improvement will last, as my visits become less frequent and we cannot definitely claim to have prevented more serious and chronic trouble later, although, judging from the accounts we often hear about the distressing early experiences of adult epileptics with disturbed personalities whose families do not appear to have had similar help, we hope that some lasting benefit has been given in this case.

The tensions in this family had been building up for a long time—at least from the shock of Mrs. Z's first disastrous pregnancy. The problem centred in feelings of failure and inadequacy in having produced three damaged children—an extremely difficult situation for any couple to face, much less Mr. and Mrs. Z, who had themselves both suffered considerable emotional deprivation in their own childhood. Many workers had attempted to help them piecemeal with these problems, but what the family most seemed to need was a steady relationship with one person who could accept and tolerate the situation at its most explosive and encourage them to talk freely without fear of criticism or coercion; someone, moreover, who could act as a focusing point, helping them to integrate the separate experiences with the doctor, psychiatrist, health visitor, and teacher, and with relatives and neighbours.

This sort of relationship, I suggest, could not have been supplied by the doctor even though the problem in this case was directly associated with medical care, but it was most appropriately handled by someone working in close co-operation with the doctor.

Conclusions

In conclusion I would like to summarize some advantages which appear to belong particularly to a setting in which a social worker is attached directly and exclusively to a group of family doctors.

1. Accessibility

Help is available on the spot whenever the doctor is puzzled or disturbed by a particular problem, and consequently he tends to seek it more readily than if this were

to involve considerable time and effort in seeking it elsewhere. This is particularly so where the problem does not fall easily into a case for referral to any of the well-known social agencies, but where the dominant need is for an assessment of the situation on which to base a plan of help.

2. Participation in Group Discussion

Informal group discussion over morning coffee will often centre in a particular patient or family; more often it will concern the wider aspects of social care such as housing or employment policy, care of handicapped children or old people, or such perennial points of dispute as "malingering," use and abuse of the Health Service, the "unreasonable" patient, the "problem" family. The social worker can often bring a fresh perspective to bear on these subjects or provide information in the light of which judgments can be confirmed or modified.

3. Interpretation of the Aims and Limitations of Social Work

During the early months of my appointment the attitude of the doctors to me (as a social worker and not as a person) swung from scepticism about the value of social work in general to completely unrealistic demands on my resources. My own feelings were naturally coloured by the anxiety of working in a new setting, but it seemed to me that I was expected as "a nice motherly soul" to perform miracles which the psychiatrist had failed to produce; as a "strong right arm" to the doctor to wrest from the authorities houses for all the ill-housed, jobs for all the unemployed; as an "expert" to clean up and re-educate problem families of long standing; in short, to relieve the doctor of all those painful situations in which he felt unable to be effective in his own right. Those who complain most loudly that social workers spoon-feed their clients and sap their sources of self-help and initiative sometimes demand just this from workers with whom they come in contact.

It was only gradually that we saw that the doctor and social worker must pool their resources and think about their work together in terms of the achievement of reasonable expectations and limited aims. We had to distinguish between what the doctor and social worker might want and what the patient wanted; to examine the values and principles which guided our work and to ask whether disappointing results arose from inadequacies within ourselves, the families, or the social system, or from factors about which we still have little knowledge. To cure sometimes, to relieve often, and to comfort always could then be accepted as applicable to social work as it is to medicine. The more realistic conception of social work aims and methods achieved through daily discussion and experiment can then be transferred to the relationship between the doctor and other social workers outside the group whom the doctor may wish to contact on his own initiative.

4. Exploration of the Role of the Social Worker as Colleague of the Doctor

Patients who consult the doctor on social or emotional problems or who present symptoms which appear to be connected with such difficulties may, I think, be said to have chosen the doctor as a source of help rather than anyone else. They are therefore likely to have strong feelings about any attempt on the doctor's part to suggest they look elsewhere for aid even though they may clearly be asking for the sort of assistance the doctor does not feel qualified to give. If the doctor's own conception of social work is not clear he will hesitate to redirect his patients but remain uneasy at being unable to help them. To have acquired an informed attitude towards social work as described in the last section is therefore helpful, but the strength of the patients' feeling towards the doctor has also to be reckoned with. Too hasty a referral to the social worker may be interpreted as a rejection, and we have learned from experience that it is only when the patient feels assured that the doctor has taken his trouble seriously that he can

tolerate the idea of discussing it with someone else, whom the doctor can then introduce as a colleague, supplementing and not supplanting the aid he offers. In other words, the social worker becomes a sort of extension of the doctor, and patients are then able to accept her as an integral part of the service.

The patient's loyalty almost inevitably remains with the doctor. I well remember the slight shock I experienced when a patient whose problem had been satisfactorily resolved said to me, "the old 'Doc' worked jolly hard on that problem"—my own contribution had been apparently incidental. Our close association has made both the doctors and me very much more aware of the feeling content of the doctor-patient relationship and consequently able to use it more effectively.

5. Discovering Unmet Need in General Practice

It has been shown from the examples quoted in this article that some of the patients and families were already in touch with other workers. Mrs. Y, for example, was known to the staff at the welfare clinic, to the specialist, the physiotherapist, and possibly the almoner at the hospital; Mrs. Z was being visited at intervals of three to six months by the health visitor responsible for the care of children under 5 and by another who supervised the baby-minding; she was also known to the school health and education department in respect of the mongol child. The needs of the family as a whole, however, had either not been recognized by the other workers, each of whom gave particular help with particular problems, or, if they were recognized, it had not been possible, for one reason or another, for them to give the overall help needed. Particularly in the case of Mrs. Z there was a need for one person to undertake the job of standing alongside the family, co-ordinating their experiences in seeking help with their problem; and this sort of need appears to us to occur more often than suspected in general practice. This was also recognized during a survey of a general practice carried out by the Social Medicine Research Unit of the Medical Research Council in 1953 (Backett *et al.*, 1954). "This is not just a question of better co-ordination of the services . . . the need is for a person, someone with professional training and skill, who can help people by means of a casework relationship to use their own and the community's resources in tackling their problem" (Shaw, 1954).

6. Opportunities for Preventive Work

The family doctor is often in a unique position for observing the earliest signs of social and emotional breakdown. Particularly in the case of mothers and babies, he witnesses early signs of anxiety and stress which, left unrelieved, may have serious repercussions in their emotional development and future happiness. Each time the doctor and social worker collaborate in analysing and assessing family needs and tensions the importance of relieving early signs of stress becomes more apparent. Until recently, at any rate, social workers have been made more aware of this in their training than medical students in theirs, but I think it is clear from the examples quoted here that unless both the doctor and the social worker appreciate the importance of this aspect of family care on equal terms little can be achieved.

Hence, for the time being at least, there is much to be said in favour of providing the general practitioner with an opportunity of working with a social worker in closer relationship than has hitherto been the custom.

RHEUMATIC DISEASE AND INDUSTRY

[FROM A SPECIAL CORRESPONDENT]

A joint meeting of the Empire Rheumatism Council and the Association of Industrial Medical Officers was held at the Royal Society of Medicine on October 30 as part of the latter society's 84th meeting. The Chairman, Dr. W. S. C. COPEMAN, opening the discussion, drew attention to the importance of the rheumatic diseases in industry. This group of diseases was second only to respiratory illness as a cause of absence from work.

Field Surveys

Professor J. H. KELLGREN, director of the Rheumatism Research Centre of Manchester University, said that the study of rheumatic diseases had in the past been greatly hampered by the lack of diagnostic definitions—from the eighteenth-century belief that most musculo-skeletal pains were gouty to the nineteenth-century concept of rheumatic fever as an all-embracing rheumatic process. Two recent developments had been of the greatest importance here—radiology and serology. Radiology had enabled rheumatoid arthritis to be distinguished from what he preferred to call osteoarthritis; and, later, other polyarthritides such as spondylitis, Reiter's disease, and psoriatic arthropathy had come to be defined. Serological work had shown that rheumatoid arthritis is associated with a macro-globulin which appeared to be specific, and that this might be associated with visceral, vascular, and cutaneous manifestations of the disease. Biochemical techniques might well add further knowledge. These developments had enabled field workers to gather accurate information about the prevalence and incidence of various forms of chronic rheumatic disease. Professor Kellgren then described the procedure used in some of these surveys, emphasizing the difficulties of relying on only clinical diagnostic criteria. Many of these difficulties did not arise in radiological and serological studies. Radiological surveys had the advantage that standardization could be achieved, observer-error studies could be carried out, and the films could be kept as a permanent record. Serological studies had also produced results of great value. He cited the familial aggregation of the rheumatoid serum factor as an example, and suggested that this might be analogous to the hyperuricaemia of gout. From the epidemiological standpoint there were two main groups—those with the generalized changes of osteoarthritis and disk generation, the most important numerically, and, secondly, those with inflammatory polyarthritis. For both of these groups we now had the techniques and equipment to study them in industry. Interesting variations in prevalence had already been noted—for example, as between rural and urban populations in South Wales.

Dr. J. S. LAWRENCE, director of the Empire Rheumatism Council's mobile field unit, said that industry was concerned not only with direct environmental factors but also with absenteeism due to rheumatic diseases generally. With an ageing population the latter would become increasingly important. He quoted National Health Insurance statistics for 1953-4, which showed an annual loss of 28 million man-days from rheumatic disease alone. After reviewing the role of the rheumatic diseases in various industries, he described a survey designed to investigate the prevalence of rheumatism in miners. This showed a clear association between the severity of x-ray changes in the lumbar spine and the complaint rate of back-hip-sciatic pain. A further survey had then been conducted to study possible occupational factors, and this had shown an association with back strain, other postural factors, and exposure to damp conditions. He believed that the heavy toll of rheumatic disease in miners was largely preventable, mainly by increased mechanization, which need not, as it was inclined to do at present, involve the use of still heavier equipment. Turning to rheumatoid arthritis, he said there were evidently considerable regional differences. This disease affected 3.3%

of adults in Leigh, Lancashire, but only 2% in Pittsburgh, U.S.A. These differences became even more marked after correction for the different age-structures of the population. Dr. Lawrence had also studied the value of routine physiotherapeutic measures in the treatment of rheumatic disease, and produced data to show that recovery could be hastened quite appreciably and rendered more complete by appropriate physiotherapy, active and sometimes passive movements and heat being of value, but massage appearing to have no detectable effect on recovery rates.

Variants of Rheumatoid Arthritis

Professor E. G. L. BYWATERS, director of the Medical Research Council's special unit for juvenile rheumatism, then discussed unusual variants of rheumatoid arthritis. The definition of the usual in a disease of unknown aetiology was difficult enough, and, although dogmatic criteria could be and indeed had been agreed upon, many cases fell into the "probable" and "possible" categories. The variant might be hard to distinguish, especially at the onset, even in those cases which eventually developed all the classical features of the disease.

He then went on to describe some of the more unusual presentations of rheumatoid arthritis, including those that began with involvement of a particular joint such as in the big toe, which were often labelled as "gout"; those with fever, pericarditis, and a migratory polyarthritis, mislabelled "rheumatic fever"; cases which remained limited to one particular joint for a long period of time, usually treated as tuberculous unless the clinician was aware that rheumatoid arthritis not infrequently presents in a single joint. The disease might be confined to bursae and tendon sheaths, in the foot producing "metatarsalgia," or oedema without obvious joint involvement; palindromic rheumatism, with recurrent attacks of pain and swelling in numerous joints over many years, each lasting about 24 hours and then returning completely to normal. These were illustrated by a series of cases, as was the so-called "anarthritic" rheumatoid arthritis. Finally he mentioned cases presenting with iritis, pericarditis, or as a pyrexia of unknown origin. They should be on guard against regarding this disease—or any disease—as a real entity; by providing a specific name we implied that a disease had as much real existence as an elephant or a giraffe. Rheumatoid arthritis should be thought of as a reaction pattern to perhaps a number of different factors. Study of the variants might eventually give some clue to the nature of these factors.

QUEEN MOTHER AT KING'S

Paying her first visit to King's College Hospital since becoming Chancellor of London University, QUEEN ELIZABETH THE QUEEN MOTHER opened a new extension to the Medical School on November 4. One of the pleasures of being Chancellor, she said, was that it brought her frequently into touch with institutions with which she was already familiar. The University's medical ramifications were a constant source of interest, and she had noticed particularly that association with the University, especially in the case of the medical schools, did not mean dull uniformity: each school had its own individuality based on the history and traditions of which it was rightly proud. It might be, however, that with the passage of time some traditions became less important. For example, the liberal attitude which King's had adopted towards the admission of women medical students was no longer distinctive, since all the other medical schools in London had followed suit.

No one could predict what the future held, but it was wise of the School to put its house in order and to see that its facilities for teaching and research kept pace with the ever-increasing demands that were likely to be made upon them. It was from this point of view that the new extension was so timely. "I wish," she added, "there was in sight an equally satisfactory solution to that great problem which

faces both the Hospital and the School: the need for more beds."

In his address of welcome to Her Majesty, the chairman of the Medical School, Mr. R. A. HORNBY, said the reason why it had been necessary to add to the buildings of a medical school which had no present intention of increasing its students was that, with the advance of medical science, it was essential to provide accommodation and equipment to keep pace with it.

Dr. VERNON F. HALL, dean of the School, said the total costs of the extension had been some £205,000, of which well over half had been generously contributed by the University Grants Committee. The remainder had been found from the School's own funds, including a bequest by Dr. Harold Wiltshire, a former member of the staff. The extension housed the new medical and surgical units and a considerable addition to the department of chemical pathology; there was a large practical pathology classroom and a clinical lecture theatre designed for showing cases to small groups of students. The other facilities included a clinicopathological demonstration room in which all aspects of selected diseases could be displayed for varying periods, accommodation for the Clubs and Societies Union, a mixed common room for students, and a council room. Unfortunately, it had not been possible to establish a chair in medicine as there were not sufficient beds to satisfy the needs of a professorial unit, but part-time directorships had been established in medicine and surgery. The medical unit was under the direction of Dr. Clifford Hoyle, and the new surgical unit under Mr. Harold Edwards. The extension to the department of chemical pathology provided a suite of nine research laboratories which would be a valuable addition to Professor C. H. Gray's overflowing department.

Her Majesty then inspected the new building and unveiled a plaque commemorating her visit.

HEBERDEN SOCIETY

At a meeting of the Society at Stoke Mandeville Hospital on October 11 Dr. M. SARTY GOOD reviewed his series of 20 patients with temporal arteritis. Headache had been a prominent feature in every case; tender and thickened temporal arteries in 19; constitutional illness, anorexia, and fever in 16; pain and stiffness of the jaws in 9; painful neck in 9; and pains in the muscles and limbs in 10. Twelve had developed eye involvement, of whom three not treated with cortisone had become suddenly blind. The average duration of disease after biopsy in the patients not receiving steroids and in eight patients receiving steroids was 5.4 and 2.5 months respectively. His experience and that of others suggested that early biopsy for diagnosis, followed by cortisone treatment, could shorten the disease and prevent blindness.

Dr. A. R. HORLER and Dr. MALCOLM THOMPSON (Newcastle) had found instances of pleural effusion complicating rheumatoid arthritis in 8 out of 52 men and one out of 128 women, as against only one in 180 control patients without this disease. In 5 men the pleural effusion was an inaugural event in the development of the arthritis. Dr. C. J. BARFORD (London) reported the case of a woman with rheumatoid arthritis who developed fever and pericarditis and a positive L.E.-cell test after five years of prednisolone therapy. She also had unusual nodules at the lung bases, which proved to be tuberculous at necropsy.

New Steroids

Dr. H. F. WEST (Sheffield) opened a discussion on the new steroids triamcinolone and dexamethasone. Twenty-eight patients with rheumatoid arthritis on prednisolone were allocated at random either to continue with this steroid or to change to triamcinolone, on a roughly "tablet-for-tablet" basis. Those who changed had fared slightly but not significantly better, but the average dose (9 mg.) of triam-

(Continued at foot of next page)

To-day's Drugs

With the help of expert contributors we publish below notes on a selection of drugs in current use.

Dolviran (Farbenfabriken Bayer A.G.; distributors, Levmedic Ltd.).—Each tablet contains acetylsalicylic acid 0.2 g., phenacetin 0.2 g., codeine phosphate 0.01 g., caffeine 0.05 g., phenobarbitone 0.025 g. The valuable analgesic effects of combinations of aspirin, phenacetin, and codeine are well known. Caffeine is a stimulant of the central nervous system and phenobarbitone is a depressant of the central nervous system. It would seem to be illogical to prescribe them together. The quantity of caffeine in this preparation, however, would have a negligible effect, as it is about a third of what would be contained in a small cup of tea. This preparation is about three times as expensive as compound codeine tablets B.P.

N.H.S. basic price: 10 tabs., 2s. 2d.

Robaxin (A. H. Robins Co. Ltd.).—This is 2-hydroxy-3-o-methoxyphenoxypropyl carbamate (methocarbamol), and is one of the derivatives of mephenesin which have been tested in an attempt to find a more effective drug for the relief of skeletal muscle spasm. It has a more prolonged action than mephenesin and has been reported to be effective in treating acute muscle spasm associated with injuries and in treating orthopaedic conditions, but is of only limited use in treating spasticity and rigidity caused by lesions of the central nervous system. It often causes slight drowsiness and dizziness, but serious toxic effects have not been reported. It is supplied in tablets of 0.5 g., and the dose suggested by the makers is 4-9 g. daily, depending on the severity of the spasm.

N.H.S. basic price: 50 tabs., 21s. 8d.

(Continued from previous page)

cinolone was probably on the high side and was apt to produce excessive side-effects. In another group of patients steroid hypertension was not altered by change to triamcinolone. The new drug had been useful to some patients who were excessively wakeful on prednisolone, but its tendency to reduce appetite and cause loss of weight and weakness was a disadvantage. Other speakers reported that triamcinolone caused excessive loss of muscle tissue in some patients, giving the clinical appearance of a myopathy. Experience of dexamethasone was limited, but it seemed an effective drug. Caution was needed, since it had been reported that dexamethasone could suppress the adrenal cortex in sub-therapeutic doses, a finding so far not confirmed.

Dr. J. F. BUCHAN (London) had treated 38 ambulatory patients suffering from rheumatoid arthritis with chloroquine sulphate. In a double-blind trial, objective assessment of disease activity and joint involvement at three and six months showed chloroquine sulphate to be clearly, but weakly, effective in this disease. Stainable bone-marrow iron had been studied by Drs. A. G. S. HILL and C. L. GREENBURY (Stoke Mandeville). It proved to be absent or scanty in 56%, and excessive in 22%, of 120 patients with rheumatoid arthritis, but there was no correlation with circulating haemoglobin. Remissions of disease induced by steroids were accompanied by rise of haemoglobin and disappearance of excess concentration of marrow iron. Dr. J. J. R. DUTHIE (Edinburgh) had confirmed that large doses of intravenous iron (up to 5 g.) induced remission in a controlled trial in rheumatoid arthritis. As part of the remission there was an improvement in the accompanying anaemia. Dr. W. R. M. ALEXANDER (Edinburgh) described experiments in purifying the rheumatoid agglutinating factor.

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

Iproniazid Jaundice

SIR,—The three articles concerning the toxic effects of iproniazid ("marsilid") (*Journal*, November 1, pp. 1067, 1068, and 1070) are valuable. In view of the reports that iproniazid administration is sometimes associated with jaundice, this case report of a patient who received iproniazid 100 mg. daily for five months and died from hepatic coma may be of interest.

Miss C. Y., aged 70, attended the department of cardiology, Edinburgh Royal Infirmary, as an out-patient on March 11, 1957, because of effort angina of nine months' duration. Although there was no clinical history of myocardial infarction, an electrocardiogram showed old transmural posterior and anteroseptal myocardial infarcts. Glyceryl trinitrate and restriction of her activities were advised. She was next seen one year later on March 13, 1958, at a routine follow-up clinic, when it was noted that her angina was less incapacitating and that she was able to walk half a mile (0.8 km.) without stopping. In April her family doctor prescribed iproniazid 50 mg. twice daily, with subsequent reduction of the incidence of angina and of her requirement of glyceryl trinitrate from 8 to 1 or 2 tablets of 1/130 gr. (0.5 mg.) daily.

On August 8, 1958, her sister noticed that her conversation was muddled and that she was slightly confused. She complained of vague ill-health, and two days later visited her family doctor, who noticed that she was slightly jaundiced and discontinued iproniazid. Her confusion continued, and during the night of August 14 she was found wandering in the garden of her house, shouting and disorientated. On the evening of the following day she was admitted as a certified patient to a mental hospital. Jaundice was present and there was tenderness in the right hypochondrium. Her confusion fluctuated until the third day after admission, when she became semicomatose and deeply jaundiced.

She was then admitted to the Edinburgh Royal Infirmary under the charge of Dr. Rae Gilchrist on August 18. Jaundice was marked. There was no history of any contact with infective hepatitis or of any venepuncture as a possible source of homologous serum jaundice. There was guarding in the right hypochondrium, but no detectable hepatic enlargement. There was no splenic enlargement or ascites. Temp. 97° F. (36.1° C.), pulse 76 mm./hr. B.P. 110/60, Hb 97%, W.B.C. 5,300, E.S.R. 6 mm./hr. The urine contained bile and urobilinogen. Serum bilirubin 6.3 mg.%, alkaline phosphatase 19 K.-A. units, zinc and thymol turbidity 8 units each. Serum sodium 128 mEq/l., serum potassium 3.54 mEq/l., serum chlorides 105 mEq/l. Prothrombin activity 36%. Blood urea nitrogen 19 mg.%. Total proteins 5.8 g.%. Electrophoresis of serum proteins showed that 45% was albumin, 8% alpha₂-globulin, 7% alpha₁-globulin, 10% globulin, and 30% gamma-globulin. The patient became progressively more disorientated and required paraldehyde for sedation. Incontinence developed after three days. Serial liver function tests showed little significant change. She was treated with intravenous 5% glucose saline or 50% glucose with added potassium chloride. Her serum potassium and sodium were controlled at a steady level until the eleventh day, when her serum potassium dropped to 2.76 mEq/l., from 3.34 mEq/l. Despite the administration of more potassium chloride, her serum level remained low and was 2.76 mEq/l. when she died in coma on September 5.

At necropsy, the liver was flabby and slightly smaller than normal (1,070 g.). Its capsule was normal and on section the parenchyma was soft, diffused, and brownish yellow. The intra-hepatic bile ducts showed no macroscopic abnormality. The gall-bladder contained concentrated bile and was normal. The common bile duct was patent and healthy. Histological examination revealed subacute and extensive necrosis of the liver: the lobular pattern was partly destroyed and large numbers of polymorphs and round cells were present in the bile ducts and periportal tissue. The heart showed left ventricular hypertrophy and the myocardium had marked focal fibrosis with widespread patchy necrosis. Although the coronary ostia was patent, the whole coronary arterial tree was markedly involved with atheroma.

Middleton, Lancashire.¹ One day an article might be written where some mothers' refusal to breast-feed is attributed to a belief that artificial feeding is just as beneficial with fewer side-effects. My wife's experience, having her first baby earlier this year at University College Hospital, London, was a very pleasant one. At the antenatal clinic and in hospital she stated her views in favour of artificial feeding. After some discussion her views were respected and no breast-feeding occurred at all. In some hospitals this would be unheard of, but I feel they would do well to follow suit.—I am, etc.,

LEO GOLDSTONE,
Statistician, Essex County Council,
Chelmsford.

Thoracic Outlet Compression Syndrome

SIR,—The case histories of two patients under my care whose cervical ribs and upper dorsal ganglia had been removed for symptoms of arterial occlusion in the fingers make me less optimistic that these procedures will prevent the progress of the disease than Professor G. C. Rob and Mr. A. Standeven appear to indicate in their article on the complications of the thoracic outlet syndrome (*Journal*, September 20, p. 709). A further patient whom I have recently treated for blockage of the first part of the subclavian artery, and hope to describe in detail, presented with symptoms which previously would have been ascribed to compression of the artery at the thoracic outlet. The Seldinger technique of aortography permits demonstration of the branches of the aortic arch with minimal upset and danger to the patient. I suggest that until the patency of the appropriate vessels at their origin has been proven by aortography peripheral external pressure of any kind ought not to be considered as a cause of abnormal vascular symptoms and signs in one upper limb.

Case 1.—Female: At the age of 32, 1946, for three months attacks of numbness and whiteness in left ring and middle finger when cold. Rounded pulsatile swelling above left clavicle. Left radial pulse abolished when shoulders braced back and arms raised above head. Thick tendinous scalenus anticus divided and cervical or anomalous first rib removed, and two months later upper dorsal ganglionectomy was performed by Sir James Learmonth because frequent vasospastic attacks persisted in the hand. Relief was temporary but the condition not disabling until 1957, when a sudden attack of pain in the whole arm, forearm, and hand, together with coldness and weakness, occurred. No major pulse was now palpable distal to the bifurcation of the brachial artery. The aneurysm which Sir James had found at the first operation starting behind the lateral border of the scalenus anticus was excised.

Case 2.—Female: At the age of 21, 1957, pain and colour changes in the left hand were produced by cold. A left cervical rib was removed in Galway, but the symptoms persisted and were relieved by upper dorsal sympathectomy performed by Professor P. A. Fitzgerald a year later. Sympathectomy for similar symptoms appearing in the right hand and feet in 1952 was similarly successful (H. S. S.). In 1956 the patient suffered pain in the left forearm and hand of sufficient severity to prevent her working. The hand was pale and the radial pulse absent. An aortogram by the Seldinger method showed blockage of the second part of the subclavian artery with some filling of the axillary artery. Treatment by thromboendarterectomy or insertion of a bypass graft is contemplated.

Case 3.—Female: At the age of 46, 1956, small patches of superficial venous thrombus occurred and resolved on the left upper limb. Pain and colour changes in the fingers of the left hand when cold for eighteen months. Persistent pain and early gangrene of finger-tips for six months. Thrill and bruit over left subclavian artery, radial pulse present. Blood pressure—right arm 180/95 mm. Hg; left arm 140/75 mm. Hg. Aortogram showed incomplete blockage of the first part of the left subclavian artery. Thromboendarterectomy of the first part of the subclavian artery, the occluding plaque being removed by direct arteriotomy after exposure of the area by resecting the left fourth rib. All pain was relieved, normal blood pressure was restored, and the gangrene is resolving.

—I am, etc.,

Leeds, 1.

H. S. SHUCKSMITH.

Antibiotics in Acute Tonsillitis and Otitis Media

SIR.—I was extremely interested in Dr. John Fry's contribution (*Journal*, October 11, p. 883) on the use of antibiotics in acute tonsillitis and acute otitis media. It is of the greatest interest to see the "opinions" which many of us have formed from "impressions" checked in this way by a general practitioner in a scientific manner.

I should be very glad if Dr. Fry could check another impression which I have formed, quite without scientific corroboration—namely, that recurrences of acute tonsillitis and acute otitis media occur more frequently in those patients who are given penicillin at the first onset of the illness than in those who receive no antibiotics. I have delayed or withheld penicillin in the treatment of many cases of acute tonsillitis, particularly in children, in recent years (unless other reasons for giving it were present), believing that the untreated patient can build up an immunity.—I am, etc.,

Birmingham, 14.

M. BARROW.

Halothane Concentration

SIR.—Please allow us to comment on some points raised by Drs. P. J. C. Burton and F. R. Gusterson (*Journal*, September 27, p. 799).

(1) It is stated that the Coxeter-Mushin Mark I unit is unsuitable for use with closed-circuit halothane because of "relatively large areas of dead space." This statement simply does not make sense. There can be no dead space in a circle system save that between the system and the patient's alveoli. A moment's reflection will show that the charge of gases in the system is moved onward with each respiration of the patient, and that in the Coxeter-Mushin unit each inspiration supplies the patient with a gas mixture which has passed twice through the carbon-dioxide absorber and once (in part) through the halothane vaporizer, irrespective of the contained volume of the system. We have had Coxeter-Mushin units (both Mark I and Mark II) in daily use with halothane for nearly a year and can detect no difference in the clinical results obtained.

(2) The writers state, "Work is in progress which will demonstrate clearly . . . that, in a true circle system with halothane, the carbon dioxide build-up with low minute volumes is very slight and of no clinical significance." Surely this forecast of results before the completion and publication of research can only cast doubts upon the impartiality with which the work is being carried out, thus bringing to naught the laudable desire of Drs. Burton and Gusterson to further the use of closed-circuit halothane.

(3) Drs. Burton and Gusterson are "perturbed . . . that an anaesthetist might be content these days to use an unknown concentration of halothane." We on the other hand are perturbed to find anaesthetists of their experience so obsessed with mathematical symbols. Surely it must be clear by now that the only reliable indication of vapour strength of any inhalation anaesthetic in clinical use is the condition of the patient. In closed circuit anaesthesia far too many variable factors affect the concentration of the anaesthetic vapour to allow of any accurate calibration by percentage, and, as for fabricating a vaporizer to deliver a "safe" concentration of halothane, we believe that no vaporizer has any clinical application unless it can deliver a vapour strong enough to produce third plane anaesthesia in the most resistant patient. Administration of such a concentration to a feeble emaciated individual would quickly produce respiratory arrest. For which type of patient is the projected "safe" vaporizer to be calibrated?

(4) Drs. Burton and Gusterson refer to our recently published articles¹ as authority for the statement that halothane is certain to ruin the ether vaporizer of the B.O.C. circle unit. They seem to have misunderstood our statements. If they will reread the articles in question we hope it will become quite clear to them: (a) That only the Boyle II machine in its present form is temporarily "ruined" by halothane. The lesion produced is "gumming" of the vaporizer drum caused by combination of the lubricant with metallic salts formed by the action of halothane on the alloy of which the machine is made. The resultant thick paste prevents movements of the control drum. (b) That the Coxeter-Mushin machines can be easily and rapidly fitted with plastic washers and gaskets which make them absolutely halothane resistant. We have had about a year's trouble-free service from four such units in this hospital group.

(5) The great danger of sudden increases in vapour concentration is described when B.O.C. circle units are used with halothane.

We can only say that in a series of some 2,000 cases using the circle absorber units of the Coxeter-Mushin (Marks I and II) and the Boyle II machines we have encountered no such danger in any case. In our experience each setting of the vaporizer control produces a fixed stable level of anaesthesia in a given patient. This level can be maintained hour after hour once the appropriate setting has been found to suit both patient and surgeon.

It is hard to see how any anaesthetist who has a Coxeter-Mushin unit at his disposal could honestly justify the purchase of a new apparatus for use with closed-circuit halothane when for a few shillings his present machine can be satisfactorily and safely modified for this purpose.—We are, etc.,

Sweet Tooth and Decay

SIR.—I was very interested to read in the *Journal* of September 6 (p. 638) Mr. F. T. Ranson's impression that sugar-cane chewing is beneficial to teeth. My practice is sugar-cane chewing is beneficial to teeth. My practice is in the largest sugar-cane-growing area of this island. It has never been my misfortune to see such a lot of decay in the incisors, and I had been wondering whether the chewing of sugar-cane, in which the incisors would be used much more than in eating other types of softer sweet foods, could have anything to do with it. I have been thinking of doing a small survey and comparing it with a survey in another part of the island where cane is not readily available, but have not got round to it. I would be very interested to know if such a survey has been done elsewhere and with what results.—I am, etc.,

St. Vincent, B.W.I.

V. M. USBORNE.

"Flat on Your Back"

SIR.—I have discovered an interesting reaction made by patients during routine examination. On making the request, "Please lie on your back," the patient almost invariably rolls over into the prone position, making it completely impossible to examine the abdomen. In a fairly unselected series, I have found this response in about 80% of patients. It does not seem to depend on the apparent intelligence of the subject. I have noticed that the correct position can invariably be obtained by asking, "Please lie flat on your back."

Can anyone explain the psychology of this different response?—I am, etc.,

Birmingham, 29.

K. G. BLAND.

Children in Hospital

SIR.—James Robertson (*Journal*, August 2, p. 275), of the Tavistock Clinic, has done a great service by bringing to the notice of the profession the great harm which can result from the admission of the under-4-year-old to hospital. His booklet and film² are full of stimulating ideas which would be well worth study by all connected with the admission of children to hospital.

I feel that much can be done to make the stay in hospital of the older child a less unpleasant experience. Such simple matters as the time of admission, and the mother being encouraged to give the child its first bath, can make a tremendous difference to the child. I would like to see children allowed to have their own night clothes. These points are brought out in a film I made some years ago. When making that film I found that a child's greatest objection to a stay in hospital was "needle pricks." This led me to work out a premedication avoiding injections. I use "elixir of oblivion" (methylpentynol) in which hyoscine is dissolved. Since my original work I have increased the dose of methylpentynol and now use 1 drachm (3.5 ml.) of the elixir for each stone (6.4 kg.) in weight. The dose of hyo-

scine varies from gr. 1/150 (0.43 mg.) for children up to 3 years, to gr. 1/100 (0.65 mg.) for children over 4 years old.

These children are induced with a sleep-dose of thiopentone, of which they have no recollection. Another important modification in this technique is the addition of gr. 1/200 to gr. 1/100 (0.33 mg. to 0.65 mg.) of atropine to the thiopentone, as some of the children are not quite "dry" with the hyoscine alone. It is also important to remember that methylpentynol has no analgesic properties, so that some analgesic should be given as soon as the child recovers its vital reflexes. I have used nepenthe for this purpose, but am at present investigating the value of D.F.118 (dihydrocodeine).—I am, etc.,

Worthing.

F. R. GUSTERSON.

Costs of Notification

SIR.—Last year (*Journal*, May 25, 1957, p. 1241) we wrote to you to draw attention to the remarkable expenditure of money in the notification of infectious diseases. In particular, we mentioned measles as a prime example of a disease whose notification we think to be of no value whatever. We were surprised at how little response our letter evoked. In the past five years 2,162,826 cases of measles have been notified. The cost in notification fees alone for this amounts to over £270,000. Can you, or anyone, tell us to what purpose—other than the provision of pocket money to G.P.s? And what good has come of the notification of acute pneumonia, scarlet fever, or whooping-cough, cases of which total 871,097 at a cost of nearly £110,000?

Enthusiastic G.P.s have in the past five years notified 3½m. cases of infectious disease. It is impossible to assess the cost of the collection, collation, and correction of these figures in terms of paper, postage, and pay-packets, but it can be stated categorically that the notification fees in England and Wales have totalled £406,437. How much longer must this pathetic situation continue?

We do not claim that notification of all infectious disease is useless, and it might be argued that value would arise from the notification of rubella, rheumatic fever, and acute otitis media. We are saddened, however, to think that the £1m. or so that has been uselessly scattered in the past 10 years might have been usefully diverted, for instance, to research in poliomyelitis.—We are, etc.,

Why Suffer from Rheumatism?

SIR.—Muscular pain is caused through increases of muscle tension. The physical secondary effects of such increased tension—i.e., mechanical defects and degenerative processes—are the conditions at which the Empire Rheumatism Council has directed its research (*Journal*, October 25, p. 1034). The primary cause of this increased tension in those conditions labelled rheumatism is psychological, and the site affected governed by the mental mechanism of symbolism.

There are complicated relationships between psychic activity and muscular innervations. As long ago as 1892 Freud postulated the conversion of psychic into motor excitement in hysteria. The psychic experiences were unpleasant to discuss, were not apparently remembered, and there was no idea of a causal connexion between exciting cause and the pathological phenomena. The individual suffering from obsessional neurosis is really substituting thought for action. In mild cyclothymics one sees conditions of inhibited and exaggerated phantasy run parallel with variations of liveliness of movement. There appears then to be some reciprocity of muscular innervation with thinking and attention, and an ability for conversion of psychic to motor or motor to psychic energies. To the unconscious mind symbols indicate not resemblance but identity. The child finds the whole world

Obituary

ARTHUR MILLER, F.R.C.S.Ed., D.L.O.

Mr. Arthur Miller, honorary surgeon in charge of the ear, nose, and throat department at both the French and Italian hospitals in London, died in London on October 11. He was 70 years of age.

Arthur Alfonse Miller was born on February 28, 1888, and qualified by taking the London Conjoint diploma in 1916. After qualification he held the appointments of house-surgeon and house-physician at Queen Mary's Hospital for the East End. He then served in France for the remainder of the first world war at various English and French military hospitals. In 1921 he was awarded the Cross of Chevalier of the Legion of Honour for his services to the French sick and wounded. After the war he settled in London as an ear, nose, and throat surgeon. He took the D.L.O. of the English Royal Colleges in 1928, and was elected F.R.C.S.Ed. five years later. He was appointed clinical assistant in his specialty at the Prince of Wales's General Hospital, Tottenham, in 1924, and soon afterwards took up a similar post at the French Hospital. Later he was appointed assistant surgeon to the French Hospital, and in 1934 became full surgeon. For a time in the mid-thirties he was chief clinical assistant at the Central London Ear, Nose, and Throat Hospital, and subsequently became laryngologist to the Italian Hospital. For some years he was also assistant aurist under the London County Council and the Ealing Borough Council, and he had been on the staffs of the British Dental Hospital and the Edgware General Hospital. A member of the Società Italiana di Laringologia, Otologia, e Rinologia, he was a corresponding member of the Société d'Oto-Rhino-Laryngologie of Paris. He leaves a widow.

G. E. P. writes: Arthur Miller worked at the Italian and French hospitals in London for more than 25 years, and in so doing became a household word to these quite considerable colonies of "strangers within our gates." He was known for those two qualities which matter most in medicine—professional skill and the confidence he inspired in his patients. To his colleagues on the staffs of these hospitals I think that he will always be remembered for the brusqueness with which he inadequately concealed the innate kindness of his mind. His loyalty was immutable. In the special work of dealing yearly with patients from no fewer than 20 countries he had those cosmopolitan qualities of mind which it will be hard indeed to replace. His private life was one of simple and total devotion to his wife, and those who were privileged to share happy moments with them in their home life will be with her in heart and sympathy at this time.

H. H. BROOME, C.I.E., M.B., Ch.B., F.R.C.S.

Lieutenant-Colonel H. H. Broome, a former principal of King Edward Medical College, Lahore, died at Salisbury on October 31. He was 83 years of age.

Harold Holkar Broome was born on March 6, 1875. From Owens College, Manchester, he went on to Edinburgh University as a medical student, and graduated M.B., Ch.B. in 1898. Distinguishing himself greatly as a student, he won several prizes and scholarships and a medal in practical anatomy. Returning to Owens College, he was junior demonstrator in anatomy, and after a term as house-surgeon at the North Lonsdale Hospital, Barrow-in-Furness, he returned to the college to become senior demonstrator in anatomy. He took the London Conjoint diploma in 1901, and was admitted F.R.C.S. in 1913. In 1903 he was awarded the Martin Memorial gold medal and entered the Indian Medical Service as a lieutenant. Five years later he was appointed professor of anatomy at the King Edward Medical College, Lahore. During the first world war he served on the North-West Frontier of India and in Meso-

Surely it is incumbent upon the medical profession not to delude itself or allow its prestige to be used in foisting on the public a promise of protection incapable of fulfilment. Civil Defence workers should understand that the very casualties they strive to help may well be dangerously radioactive and thus render these same defence workers themselves casualties. A dustbin lid seems scant shield against a hydrogen bomb. In this nuclear age the old adage "Prevention is better than cure" is our only hope of survival.—We are, etc.,

PAUL Z. HAMMET.
JOANN Z. HAMMET.

Darlaston, Staffs.

Driving Licences

SIR.—Judicious economy is to be welcomed, and the extension of the period of validity of a driving licence from one year to three years will no doubt save both time and labour. Incidentally it will also probably result in some quite unmerited profit to the Exchequer from those who cease to drive owing to death, departure, or disablement.

At times the possession of a long-term driving licence may be a mixed blessing. Thus, a young man who develops occasional attacks of epilepsy, having just acquired a licence permitting him to drive a motor vehicle for the next three years, is under undue temptation to make use of such a licence if he is free from attacks for some months. He may neglect medical advice, but he cannot be accused of having made a false statement for the purpose of obtaining a licence that is valid for three years to come.—I am, etc.,

London, W.1.

E. C. O. JEWESBURY.

After-dinner Speeches

SIR.—Sufferers from the incidence of this complaint (*Journal*, October 11, p. 904) may be interested, even if not particularly heartened, to learn that it does not occur amongst the Chinese. Speeches in that country, whether at official, mercantile, or private functions, are made before the meal, when all are seated at table. The knowledge that those present are far more anxious to eat than to listen, coupled with the shuffling of servants and the clink of dishes and bottles in the background, induces in the host or chairman a desirable brevity, apart from the fact that to keep guests from their food in an unreasonable manner is in itself an act of discourtesy. As a result of this sensible custom dinners tend to be enjoyed by all and not merely by some, while the speeches themselves provide material for leisurely table discussion.—I am, etc.,

London, N.W.3.

H. G. LOWDER,
Commissioner,
Chinese Customs Service (1908-1940).

POINTS FROM LETTERS

Pyrexia Agitans

Dr. H. DE GLANVILLE (Winneba, Ghana) writes: I have just belatedly noticed Dr. A. P. Millar's letter in the *Journal* of June 7 (p. 1355) on this subject, and I recall the instability of my own temperature when recovering in a tropical hospital five years ago from an embolic infective arthritis. My temperature chart refused to settle though I felt well, and showed an unexpected 6 o'clock rise each evening. To avoid this I tried not leaving my bed all afternoon, and not bathing before it was taken, but still the rise occurred. Next day I checked my temperature hourly with the same thermometer, but, although it was subnormal at 5 p.m., it was up again at 6 p.m. The following day I checked it every 10 minutes from 5.30 p.m., and to my considerable surprise it rose suddenly between 5.50 and 6 p.m., and was back to normal or subnormal by 6.20 p.m. I forget the exact figure to which it rose, but it was doubtless something between 99° and 100° F. (37.2-37.8° C.). I persuaded my medical attendant to ignore the chart, and shortly after left hospital and convalesced uneventfully. Since then, however, I have felt certain that in some patients the temperature remains unstable for a prolonged period into convalescence after a febrile illness, and I have been encouraged thereby metaphorically to throw the thermometer out of the window on more than one occasion when it has told a tale at variance with clinical sense.

potamia and German East Africa. Returning to India after the war, he was professor of surgery at King Edward Medical College from 1922 to 1930, and for most of that time was its principal. While holding these posts he was appointed C.I.E. in the New Year Honours List of 1929. A Fellow of Punjab University, he had been dean of its faculty of medicine. He retired from the I.M.S. in 1930. A member of the British Medical Association for over fifty years, he was president of the Punjab Branch in 1929-30. During the second world war he came out of retirement to act as medical superintendent and surgeon at the Alverstoke Emergency Hospital at Gosport, Hampshire. In 1902 he married Miss Clara Alice Finney, by whom he had two sons.

ALEXANDER MELLICK, M.D., F.R.F.P.S., D.O.M.S.

Dr. Alexander Mellick died suddenly at his home in Glasgow on October 19 at the age of 55. Though he had been under medical care for some time he had attended the meeting of the Orthoptic Society in London the previous day.

Alexander Mellick was born in Glasgow on July 23, 1903, and attended Alan Glen's School and Glasgow University, where he graduated in science in 1924, and medicine in 1926, proceeding to the M.D. five years later. He started his professional life as a general practitioner in the East End of Glasgow, with an attachment as physician to the outpatient department of the Glasgow Royal Infirmary. In 1933 he seized an opportunity to join the staff of the Glasgow Eye Infirmary as a clinical assistant. Becoming surgeon in charge of wards in 1949, he was admitted a Fellow of the Royal Faculty of Physicians and Surgeons of Glasgow in that same year. A man of quiet and retiring disposition, he was widely read in both medicine and ophthalmology. This medical bent was shown in his ophthalmological practice, and found scope in his appointment as consulting ophthalmic surgeon to the Southern General Hospital, Glasgow, and to the infectious diseases hospitals. He had done original work in orthoptics, and in the last few years he was surgeon in charge of the Orthoptic School at the Glasgow Eye Infirmary. He also became a member of the Orthoptic Board. Dr. Mellick was very musical, and a brilliant pianist. His death is a loss to ophthalmology, and in particular to orthoptics in Glasgow. He leaves a widow.

J. G. MacKENNA, M.B., Ch.B., D.P.H.

Dr. J. G. MacKenna, honorary consulting physician to the Royal Alexandra Infirmary, Paisley, died at his home at Paisley on October 16. He was 80 years of age.

John George MacKenna was born at Dumfries on March 20, 1878, the son of the Rev. Robert MacKenna. He was educated at Dumfries Academy and at the Royal High School, Edinburgh. He then entered Edinburgh University as a medical student, graduating M.B., Ch.B. in 1900. After graduation he held the appointment of assistant surgeon at the Southern Dispensary, Liverpool, for six months, returning to Edinburgh to take the D.P.H. of the Scottish Royal Colleges in 1901. In the same year he was appointed assistant medical officer of health and assistant bacteriologist at the Paisley Infectious Diseases Hospital. In 1907 he settled in private practice in the town, and, later, was appointed assistant surgeon to the Royal Victoria Eye Infirmary. For over thirty years he served the Royal Alexandra Infirmary, first as assistant visiting physician and then as full physician, and when he retired in 1944 he was appointed honorary consulting physician. Dr. MacKenna had many interests outside his profession. A staunch Liberal, he became president of the Paisley Liberal Association. On one occasion, when he took the chair at a political meeting at which both Mr. Herbert Asquith and Mr. David Lloyd George were among

the speakers to a packed audience, he conducted the proceedings so successfully that Mr. Asquith afterwards described him as the finest chairman he had ever sat under.

J. S. D. writes from Paisley: As a contemporary of the late Dr. John MacKenna I cannot help feeling that his death has cast a gloom over this town and the medical profession, of which he was a worthy and highly respected member for many years. Starting at the beginning of the century, he built up a large practice, and to his patients he was guide, philosopher, and friend in their illnesses and worries. Interested in literature, he read much and was an excellent public and after-dinner speaker. His chief sport was cricket, which he played in his early days, and in which he took a great interest till the end. Of a quiet, courteous nature, and endowed with a cultured mind and sound judgment, he attracted many friends, who enjoyed his company and conversation. Reared in the manse, he had strong religious convictions, which he consistently practised throughout his life. Retiring from practice several years ago owing to ill-health, which fortunately did not completely incapacitate him, he continued to take an alert interest in all around him till the end, which came, as he had wanted it, very quickly. To his widow, son, and daughter we extend our sincere sympathy.

KATHERINE J. S. CLARK, M.D., D.P.H.

Dr. Katherine J. S. Clark, for many years a school medical officer in Edinburgh, died at her home there on October 6. She was 92 years of age.

Katherine Jane Stark Clark, the fourth of the nine children of the Rev. John Clark, a minister of the United Presbyterian Church at Hardgate, Kirkcudbrightshire, was born on July 15, 1886. The whole family of nine went to Edinburgh for their education, and Katherine Clark attended the Merchant Company's School which is known as the Mary Erskine School. After leaving there she trained as a nurse at Dundee Royal Infirmary, and then spent some years doing private nursing. At this time she took an active part in the campaign for women's suffrage and in the efforts to gain advanced university education for women. When the University of Edinburgh decided to admit women to the professional examinations she made up her mind to enter the extra-mural school of medicine for women. She graduated M.B., Ch.B. in 1903, and then served as a house-physician at Leith Hospital and as resident medical officer at Craigleith (now the Western General Hospital). In 1906 she obtained the D.P.H. of the Scottish Royal Colleges. In the following year she proceeded to the M.D., taking rheumatism in children—in which she was very interested—as the subject for her thesis. For some time she was a school medical officer in Yorkshire, but in 1910 she returned to Edinburgh to take up a similar appointment under the School Board, and continued to work in the schools until her retirement in 1931. During the first world war she joined the R.A.M.C., and, when the Queen Mary's Army Auxiliary Corps was organized, was appointed medical controller in the Scottish Command, attaining the rank of colonel. At that time some doubt was expressed whether she was a member of the R.A.M.C. or of the Women's Army, but it was decided that she was in the R.A.M.C. After retirement she continued to lead a full and active life. A pioneer in her own work, she maintained her interest in the immense progress made in the care of children under local authorities. She was associated with many professional and social service organizations and gave outstanding service to the community. She found relaxation in the management of her home, in gardening, and in travel, and was happy with her books and her friends almost to the end. She died after a short illness, leaving many friends of a younger generation to remember her with pride and affection.—J. K. R.

C. W. JENNER, L.M.S.S.A.

Dr. C. W. Jenner, who had been living in retirement at Manningford Bohune, Wiltshire, died on October 22 at the General Infirmary, Salisbury. He was 74 and had formerly been in practice in Haslemere, Surrey.

Cyril William Jenner was born at Durrington, Wiltshire, on September 16, 1884. His forebears were well known in Wiltshire for over 200 years, and he was a great grand-nephew of the celebrated Edward Jenner, the pioneer of vaccination. After going to school in Cirencester and Salisbury he became a medical student at the London Hospital and qualified in 1913. Soon afterwards he went into practice in Haslemere, where he remained, an esteemed family doctor, for 44 years. On his retirement he had served the Haslemere Hospital for 43 years, being for many years chairman of the medical staff committee and a member of the house committee. He was keenly interested in all aspects of the hospital life, and, with the able assistance of his wife, was largely responsible for the acquisition and equipping of St. George's ward as a maternity unit. He also served on the medical advisory committee of the Guildford group of hospitals, and his quiet confidence and wise counsel were appreciated by all.

During the 1914-18 war he served as a captain in the R.A.M.C. in Gallipoli, Egypt, and Palestine, being attached to the 2nd South Midland Mounted Brigade Field Ambulance. A lover of Gilbert and Sullivan, he was a member of the cast in many productions at Haslemere during the period between the wars. For many years he rarely missed a meeting of the Guildford Division of the British Medical Association, being chairman of the Division in 1949 and one of the representatives at the Annual Meeting of the Association in Dublin in 1952. He did not consider that there was sufficient reason to alter course and give evidence before the Royal Commission, but once a firm decision had been reached he was prepared to co-operate. Only last year he resigned from the Surrey Local Medical Committee: he had been a member of it and of its predecessor, the Surrey Insurance Committee, for 35 years, a magnificent record of voluntary service.

The very large congregation at the memorial service on a recent Saturday afternoon in Haslemere Church was the fitting tribute of friends, patients, colleagues, and nurses to his long years of untiring and devoted service.—C. P. W.

IVOR CHANCE, M.B., B.S.

Dr. Ivor Chance, who had only recently established himself in general practice at Reading, died at Middlesex Hospital on October 27, four days before his 35th birthday.

Ivor Chance was born on October 31, 1923, the son of the late Major Maurice Chance, of Dorking. Receiving his medical training at the Middlesex Hospital, he graduated M.B., B.S. in 1948, and then held the appointments of house-surgeon in the ophthalmic department at Middlesex Hospital and house-physician in the cardiology department at Ashford Hospital, Middlesex. From 1955 until earlier this year he worked at a mission hospital in Uganda. He leaves a widow and two sons and two daughters.

W. R. B. writes: In 1955 Ivor Chance decided to give up his plans for obtaining a practice in England in order to work for three years in a mission hospital in Uganda. While at Mengo Hospital, Kampala, he threw himself with characteristic energy into all the varied activities of medical missionary work. Paediatrics was his great interest, and he spent much time devising plans for the new children's ward, in which the mothers are given their own dormitory and courtyard. To deal with the problem of kwashiorkor he enlisted the help of Church World Service of America, and

in co-operation with the Y.W.C.A. arranged for many tons of dried milk powder to be distributed to the under-5-year-olds in central Uganda. He did a great deal to help the Sanyu Home for motherless babies in Kampala, working hard to improve the facilities and the diets for these children. At the time of his death he was enlisting fresh support in England for the home, and had plans for an extension of cottage homes and foster-parents for the many orphan children in Uganda. In 1958 he returned to England for family reasons, and had just begun in practice in Reading when overtaken by his final illness. Although he was in Uganda for only three years, he made a lasting impression not only by his professional keenness but by his warm-hearted friendliness and generosity, his transparent sincerity, and his true Christian witness. He is remembered with gratitude and affection by many hundreds of his friends of all races, who think of him as a real friend and brother as well as a beloved doctor.

D. C. DRUITT, M.R.C.S., L.R.C.P.

Dr. D. C. Drutt, who was in general practice at Petworth, Sussex, for some 40 years, died there on October 12. He was 73 years of age.

Daniel Cuthbert Drutt was born at Christchurch, Hampshire, on August 12, 1885. His father was a solicitor, but his grandfather and great-grandfather were doctors. His grandfather, Dr. Robert Drutt, who died in 1883, was the author of the well-known *Surgeon's Vade Mecum*, which passed through eleven editions, and of a small work entitled *Cheap Wines, Their Use in Diet and Medicine*; he also had the distinction of being one of the last to receive the Lambeth M.D., which was granted to him in 1878. From Felsted School Daniel Drutt went on to Guy's Hospital for his medical training, and qualified M.R.C.S., L.R.C.P. in 1909 and then entered general practice at Saffron Walden, Essex. He served in the R.A.M.C. in the first world war from 1916 onwards, and was appointed to the Order of Leopold. In 1919, soon after his return to civilian life, he settled in general practice at Petworth, where he became also honorary surgeon to the cottage hospital.

A colleague writes: Dan Drutt came into general practice at Petworth in 1919, and in the subsequent forty years accepted the challenges of country practice and adapted himself to the tremendous changes which occurred during that time. He was a good doctor, a first-class diagnostician, and always maintained that he knew a little about everything and not too much about anything. In 1952 he retired from full-time practice because of illness, but continued to take an active interest in many of his patients. He was a family doctor, a lovable and kind man.

D. B. McGRIGOR, O.B.E., M.B., Ch.B., D.M.R.E.

D. C. B. writes: May I add a small personal note about Brigadier D. B. McGrigor, whose obituary you recently published (November 1, p. 1108)? I worked with him in Millbank in the 'twenties, and I had the privilege of his friendship ever since. He was a fine man, tall and handsome—he never lost his erect carriage even in the later years of his life—warm and generous. I never saw him during the last war, but afterwards it was a pleasure, and illuminating, to listen while he told of men and events during the war, for, whilst he was kindly in his judgments, he had a keen eye for frailties. "Elegant" was a favourite word of his, and he used it to describe a man who might, but need not, be eminent in his profession, but who was a man of whom men could approve. In this sense he was indeed an "elegant" man, and he will be missed by a very wide circle of friends all over the world.

Medical Notes in Parliament

HOUSE OF LORDS

Alcohol and Road Accidents

On November 4 Lord AMMON asked if the Government could now announce the publication date of the report from the Medical Research Council on the relation of drink and road accidents. Lord HAILSHAM, Lord President of the Council, replied that a paper giving the results of the experimental work conducted under the auspices of the Medical Research Council on the effect of alcohol upon the skill of drivers of motor vehicles had already been published in the *British Medical Journal* on October 25, 1958.* A more detailed presentation of the methods used, and the data upon which the conclusions were based, would be published by the M.R.C. in due course.

Report in "British Medical Journal"

Lord AMMON asked for the reason for the continual delay in publishing the report. "Is it usual to publish a report to this House in a journal before Parliament receives it?"

Lord HAILSHAM.—My Lords, with regard to the first part of the question, the reason for the delay in the publication of the full report is that those concerned have not yet completed the draft. The answer to the second part of the question is that it was thought desirable to give the findings to the public as soon as possible. When the full report came he understood that it would add nothing of importance, so far as the general public were concerned. It would, however, be of interest to other research workers in that it would give full experimental details. Lord AMMON asked if the Lord President did not know that an extract from the report was published in the *British Medical Journal* and an indication that they had the full report, and, in fact, had had it for some time? Lord HAILSHAM said the *British Medical Journal* did not have the full report because it was not ready. What was published on October 25 was a paper giving the results of the experimental work.

Lord MATHERS asked the Lord President whether he was aware that on several occasions publication of the report had been promised by the Government? What purpose was intended to be served by withholding the report from publication?

Lord HAILSHAM said the Government was not withholding publication of the report. They would publish it as soon as they had it. What was holding up its publication was the fact that the author or principal draftsman of it, as a university professor of psychology, was an independent worker who had undertaken this work with the aid of a grant from the Medical Research Council. He had been asked to produce the report as soon as possible, but there must be some limit to the amount of pressure put on a person in that position. There was no question of the Government's not making up its mind. It was a scientific report, and it was not ready yet.

QUESTIONS IN THE COMMONS

Atomic Radiation Effects

The PRIME MINISTER was questioned on November 4 about the United Nations Scientific Committee's Report on the dangers of radiation. He said he had given careful study to the report, and also to the statement on the report by the Medical Research Council presented to Parliament last August. In their consideration of all questions relating to the effects of radiation the Government would take the conclusions of the report into account. Mr. J. RANKIN (Glasgow, Govan, Lab.) asked him if he was now prepared

*See Drew, G. C., Colquhoun, W. P., and Long, H. A., *Brit. med. J.*, 1958, 2, 993.

to say that it was the Government's view that nuclear tests should be stopped for ever. Mr. MACMILLAN replied that the report made clear that the radiation dose to be expected from the fall-out of tests was minute compared with other causes, both natural and man-made. Some of these natural causes were due to the geological formation and radioactivity of rocks, and so forth, which were matters for further study. The man-made causes included luminous watches, clocks, television receivers, and shoe-fitting fluoroscopes. Regarding the latter, action had been taken by the Home Secretary. A committee under the chairmanship of Lord Adrian was inquiring into diagnostic radiology, and that was perhaps one of the most important aspects of it. There was also the question of occupational exposure among some industrial, medical, and atomic-energy research workers. There careful and minute medical procedure was carried out, but if it was necessary to tighten up that procedure they would examine that too.

Mr. PHILIP NOEL-BAKER (Derby, South, Lab.) called attention to the statement the previous week of the chairman of the U.S. Atomic Energy Commission that the U.S. made 32 test explosions last year, not 16 as had been previously declared. Did that mean that the studies made by the United Nations Committee and the M.R.C. were based on incomplete information about the amount of radiation released by tests? Mr. MACMILLAN said, "No." But apart from the radiation side there were other aspects. From natural and other man-made causes there were far greater dangers than from tests. "Of course, I hope we shall reach agreement on abolishing the tests, but I think the matter should be held in proportion."

Radio "Scatter" Stations

Mr. CHARLES ORR-EWING, Under-Secretary of State for Air, answered several questions on November 5 about the high-power tropospheric forward-scatter stations to be constructed in this country for N.A.T.O., and the possible effects of radiation from them on people living in the locality. He stated that the plans were still being examined. The stations were for radio communication, and not radar warning. Local authorities would be consulted whenever this was required. The stations would be so designed and located that no radiation hazards would arise to the general public, nor would any houses have to be evacuated. He was asked what was the scientific basis for this statement, and replied that the conclusion had been reached after mature consideration and consultation with the Medical Research Council, which was satisfied that radiation at the relevant wavelength had a thermal effect only, and that there was no biological effect.

Subliminal Advertising

Mr. NESS EDWARDS (Caerphilly, Lab.) asked the Postmaster-General to what extent he had been consulted under Section 4(5) of the Television Act, 1954, about the use of subliminal advertising by the Television for South Wales and the West of England contractors, and how far this form of advertising conformed to his approved rules. Mr. ERNEST MARPLES said that subliminal advertising would be contrary to the first paragraph to the Second Schedule of the Television Act. There had been no reason, therefore, for consultation or direction under Section 4(5) in this respect. The Authority had been assured by Television for South Wales and the West of England that the "keep watching" sign was transmitted at speeds at which it could be plainly seen, and that in any case the use of the message had ceased on October 21. The Authority also informed him that subliminal transmissions in any form were prohibited in its programmes, with the possible exception of some scientific programmes in which subliminal techniques would be openly examined.

On November 6 Mr. J. STONEHOUSE (Widnesbury, Lab.) asked the President of the Board of Trade whether he was aware of the dangers of the use of subliminal techniques

for advertising and other purposes; and if he would take steps to ban their use. Sir DAVID ECCLES said he understood that these techniques could be used in cinemas and on the television. Their use in cinemas would be subject to the local licensing authority.

Mr. STONEHOUSE: Is the right hon. gentleman aware of the very welcome lead given by the Institute of Practitioners in Advertising, which has declared these sinister techniques professionally unacceptable? Would he follow that lead and ban these techniques from all kinds of communication? Further to that, could he say what was being done about the importation of American horror films which use these techniques? Sir DAVID ECCLES said it was really not the Board of Trade's responsibility to ban these techniques from all forms of communication. He thought his responsibility rested probably on the part of the supplementary question which referred to the import of films. If they contained these practices and they were found to be bad, the Government would certainly see what could be done about it.

Law on Attempted Suicide

Mr. KENNETH ROBINSON (St. Pancras North, Lab.) asked the Home Secretary what progress he had made in his consideration of the law relating to attempted suicide. Mr. R. A. BUTLER told him that before a change in the law was proposed it was necessary to ensure that persons who attempted suicide, and needed care but could not be given it, or would not accept it, unless they were brought before the courts, could be looked after by other means. He was still studying this difficult problem, and could not at this stage give an undertaking about when legislation could be introduced.

Scottish Lunacy Law

Dr. J. DICKSON MABON (Greenock, Lab.) asked the Secretary of State for Scotland on November 4 if his consultations with the professional and other organizations concerning the Russell Report on Scottish Lunacy were concluded; and what action he intended to take. Mr. J. S. MACLAY replied that, at his request, the Scottish Health Services Council were considering the application to Scotland of the recommendations of the Royal Commission on Mental Health in England and Wales in the light of the Scottish White Paper issued in 1955. He had received their first report. He had also other memoranda from interested bodies under consideration. He expected to receive a second and final report from the council early next year.

Cyprus Doctors' Suggestion

Mr. D. WADE (Huddersfield, L.) asked the Secretary of State for the Colonies what answer had been given to the proposal by the Human Rights Committee of the Cyprus Medical Association that one of its members should be present at the post-mortem examination of persons who died while in the hands of the security forces in Cyprus. Mr. J. PROFUMO, Under-Secretary, stated that the Governor was considering the representations made to him on October 23. Mr. WADE, while recognizing the extreme provocation with which the troops were faced, asked if it would not be wise to take any opportunity to provide evidence to the people of Cyprus and the world that no unnecessary violence was used by the security forces, in spite of that provocation. Mr. PROFUMO said the Governor would have all these matters in mind when he considered the representations.

Polio Vaccine

Mr. FENNER BROCKWAY (Eton and Slough, Lab.) asked why supplies of the anti-poliomyelitis vaccine produced by the Glaxo Laboratories at Stoke Poges were not distributed after April; and for what period this hold-up continued. Mr. WALKER-SMITH said he understood that production difficul-

ties intervened. He could not yet say when the distribution of vaccine from this manufacturer would be resumed.

Royal Commission on Doctors' Pay

Mrs. LENA JEGGER (Holborn and St. Pancras, South, Lab.) asked the Minister of Health on November 10 when he expected to receive the report of the Royal Commission on doctors' pay. Mr. D. WALKER-SMITH.—The Commission are still taking evidence and collecting necessary information. They expect to be able to submit their report about next summer.

Composition of Flour

Mr. M. LIPTON (Brixton, Lab.) asked the Minister of Agriculture, Fisheries, and Food when the Food Standards Committee would complete their report on the composition of flour and bread, which had been under consideration since May, 1956. Mr. J. B. GODBER, Parliamentary Secretary, said that an interim report dealing with milk bread would be available early in the new year. The Minister understood, however, that investigation of the technical problems involved was taking longer than the committee had expected and that it would be some little time before the drafting of their main report could be put in hand.

Chronic Disease.—At the end of 1957 nearly 10,700 names were on waiting-lists for 57,600 chronic sick and geriatric beds in Health Service hospitals in England and Wales (Minister of Health, November 10).

Medico-Legal

THE CHEMISTS' FEDERATION JUDGMENT

[FROM OUR LEGAL CORRESPONDENT]

Judgment was given on November 3 by the Restrictive Practices Court in the Chemists' Federation case (*Journal*, October 18, p. 985, and October 25, p. 1049). The reserved judgment giving the Court's reasons for its general conclusions expressed on October 13 was delivered by Mr. Justice Devlin (*The Times*, November 4).

He started by explaining the principle adopted by the Federation that proprietary medicines should only be sold to the public by or through registered pharmacists. The restriction which the Court had to consider sought to control all medicines in the same way as the sale of medicines containing poisons or other dangerous substances was controlled by the Pharmacy and Poisons Act, 1933. The machinery through which control was exercised was the C.F. List, which originated in the desire of retail chemists to protect themselves from what they regarded as unfair competition. Manufacturing members of the Federation agreed that all their products falling within the definition "medical preparations" might be put on the List and distributed only to wholesalers who were members of the Federation. These undertook to supply them to retail chemists only. Sale was not restricted to retail chemists who were members of the Federation, nor were the retailers required to sell C.F. List goods only, although they were expected to promote the sale of C.F. goods as against non-C.F. goods.

Court's Task

By Section 20 (1) of the Restrictive Trade Practices Act, 1956, the Court was required to consider whether this restrictive machinery was contrary to the public interest. They were not to answer this question as a matter of policy, but by the test formulated by Parliament in Section 21 of the Act, which provided that a restriction was contrary to

public policy unless it fell within one of the seven categories set out in the section and was not unreasonable having regard to the balance between the relevant circumstances and any detriment to the public resulting from the restriction. The Court's task was that of any ordinary court of law, to construe the words of the Act and to see if upon the facts proved the case fell within them.

Protection of Only a Small Minority

The Federation's case was that their restriction fell within category (a) or (b) of Section 21. The case under category (a) was that the restriction was reasonably necessary to protect the public against injury in connexion with the consumption and use of medicines. The only significant difference between the sale of medicines by an unqualified person and by a chemist was that, if the chemist was told by the customer of the condition to be relieved, he had the training and ability to select the appropriate remedy. The C.F. restriction did not, however, require C.F. List products to be sold only by the chemist himself and not by his unqualified assistants. The restriction would protect only a small minority who, while in doubt about the right medicine to buy, had not the sense to ask for advice from a qualified person but yet gave some manifestation which would cause the chemist to make some inquiry about their condition. On the evidence the risk of injury through buying from unqualified persons could not be rated so high as to say that it balanced the detriment to the public from not being able to buy commodities it wanted from any retailer who was willing to sell them.

The Federation's case under category (b) was that the removal of the restriction would deny to the public specific benefits. These were: the opportunity which it afforded chemists to give advice; the work of the Federation's standards committee, which examined the formulae of medicines on the List for suitability and examined claims relating to their performance to see whether they were justified; and that it was only the protection from competition afforded by the restriction which kept country chemists in business and so available for the National Health Service.

The Court was not satisfied by the evidence on any of these heads that the restriction was justifiable under Section 21.

No Immediate Injunction

The Registrar had applied under Section 20 (3) for an injunction. The Court did not think that Parliament had intended any approach other than the normal rule that an injunction, breach of which carried committal as a penalty, would be granted only if there was reasonable apprehension that an offence was about to be committed or repeated. Until the judgment the Federation had not known whether its restriction would be declared illegal under the new Act or not. The Federation would be given a reasonable time to put its affairs in order, and should not have to do so under the shadow of an injunction. If the Registrar was dissatisfied with what was done he could apply to the Court specifying the particular activities he desired to be restrained.

The order of the Court would therefore consist simply of a declaration in the terms specified in the judgment.

DEAF-AND-DUMB DRIVER FINED

[FROM OUR LEGAL CORRESPONDENT]

On September 29 a deaf-and-dumb driver, Arthur James Callaway, aged 49, was fined £5 at Worthing for careless driving (*Daily Telegraph*, September 30).

When the chairman of the justices expressed surprise that Callaway, who communicated with the court through a deaf-and-dumb-club interpreter, should have been able to pass his driving test, particularly as he could not write and even had difficulty in interpreting deaf-and-dumb sign language, he was told that this was not an isolated case. Callaway, who according to his father was deaf and dumb

from birth, had ridden a bicycle for more than 30 years, and after six weeks' teaching by his father had passed his driving test at the first attempt in 1956. Since then he had driven 6,000-7,000 miles with no trouble. He had learnt deaf-and-dumb language at the age of 17 but had since forgotten it.

No statistics are kept on the number of deaf-and-dumb drivers, because this disability is not one of those specified in the driving licence application forms. On test the examiner's instructions are conveyed either in writing or through an interpreter.

Universities and Colleges

UNIVERSITY OF OXFORD

In Congregation on October 16 the degree of B.M. was conferred on F. S. Plumpton, G. O. M. Jones, and (in absence) on Gillian M. Shaw.

UNIVERSITY OF CAMBRIDGE

In Congregation on August 2 the following degrees were conferred:

M.D.—*Vishnu Sarma.
M.B., B.Chir.—*I. F. M. Buchanan, R. C. L. Feneley, *J. G. Lancaster.
M.B.—*I. D. Hunter-Craig, N. W. Oakley, J. C. Twomey, *W. G. Shakespeare, A. F. Fleming, J. Hedley-Whyte, A. C. Smith, *A. J. Earl, G. C. Sutton, N. E. S. Holden, *E. P. Brooks, I. Chippendale, R. H. Johnson, H. B. Valman, *A. Reynolds, D. A. Birkett, F. T. Brough, G. M. Davies, *P. J. Ball, D. M. Whiteford, *Shirley A. Bolt, *Heather M. Rumsey, *Nerys Davies, *Margaret R. Skelton, Mrs. Audrey E. Fairley.

*By proxy.

UNIVERSITY OF ABERDEEN

At a graduation ceremony held on November 5, the degree of M.D. was conferred on H. G. Richmond (with honours) and on R. S. Crow (with commendation).

UNIVERSITY OF DURHAM

In Congregation on September 27 the following degree and diplomas were conferred:

PH.D. IN MEDICINE.—Israel Kleinberg (*in absentia*).
DIPLOMA IN PSYCHOLOGICAL MEDICINE.—J. R. B. Ball, N. E. Crumpton, S. L. Davies, A. King, P. Roughhead.

UNIVERSITY OF LONDON

The following have been appointed or nominated for appointment or reappointment as representatives of the University on the governing bodies indicated in parentheses: Dr. R. A. Shooter (Mitchell City of London Educational Foundation) and Dr. Sybil Yeates (Waverley, Burrage, Church Manorway and King's Warren London County secondary schools).

The following have been recognized as teachers of the University in the subjects indicated in parentheses: *St. Mary's Hospital Medical School*, Dr. Michael Feiwel (Dermatology). *London Hospital Medical College*, Dr. G. P. Fox (Anaesthetics), Dr. R. S. Murray (Radiology) and Dr. Richard Creese (Physiology). *Institute of Ophthalmology*, Mr. C. A. G. Cook (Ophthalmology). *Institute of Child Health*, Dr. R. W. Cope (Anaesthetics). *Institute of Orthopaedics*, Dr. P. G. Walker (Biochemistry).

The Sir William Dunn Scholarship for 1958 has been awarded to David Edward Jewitt (King's College).

On August 6 the degree of M.D. was awarded to G. G. Meynell and A. Paton.

The following candidates at the London School of Hygiene and Tropical Medicine have been approved at the examination indicated:

ACADEMIC POSTGRADUATE DIPLOMA IN PUBLIC HEALTH.—L. Baldacci, J. L. Bosc, J. M. Davies, R. O. M. Jones.

UNIVERSITY OF BIRMINGHAM

The following appointments have been made: Drs. A. Glass and A. W. Rogers, Lecturers in Anatomy; Drs. H. A. Ellis and D. J. Parish, Lecturers in Pathology; Dr. J. D. Cumming, Lecturer in Physiology; Dr. S. H. Taylor, Lecturer in Medicine; Mr. G. T. Watts and Mr. F. Ashton, Lecturers in Surgery; Dr. E. M. Little, Lecturer in Obstetrics and Gynaecology; Dr. June K. Lloyd, Research Fellow in Paediatrics and Child Health.

UNIVERSITY OF LIVERPOOL

In Congregation on September 26 the degrees of M.B., Ch.B. were conferred on Malvina Harris.

UNIVERSITY OF LEEDS

The following have been approved at the examination of the degree of Ph.D. in the subjects indicated in parentheses: R. Fielden and R. D. Robson (Pharmacology), G. N. Graham (Medicine), and R. Wilson (Experimental Pathology and Cancer Research).

UNIVERSITY OF SHEFFIELD

Dr. Helen Beladi has been appointed full-time research assistant in virus diseases, and Dr. P. Chowdhuri full-time research assistant in the department of obstetrics and gynaecology.

The following resignations have been received: Dr. L. Robertson, honorary demonstrator in bacteriology; and Dr. K. D. Neame, lecturer in physiology.

ROYAL COLLEGE OF PHYSICIANS OF LONDON

At a quarterly comitia of the College, held on October 30, licences to practise were conferred upon the following 136 candidates who had passed the final examination in medicine, surgery, and midwifery of the Conjoint Board and who had complied with the by-laws of the College:

J. W. Abrams, O. O. Akinkugbe, J. G. Allardice, A. C. Ames, E. C. Ashby, Mary E. Ashworth, R. M. Ayadi, Judith M. Babb, J. R. Ball, N. S. Bamji, F. Bannerman-Lloyd, Anne P. Barrett, Patricia A. Blackwell, Ingrid J. Booth, Helen D. Bower, N. A. Boyd, P. P. Bricknell, M. F. H. Bush, J. S. Cameron, M. I. D. Cawley, M. Charlesworth, R. K. Clarke, L. J. Clein, R. J. Clement, Diana E. Clough, G. F. Cohen, L. Cook, S. Craske, A. N. Cruickshank, J. O. Dalrymple, D. J. C. Davies, E. T. L. Davies, J. B. Davis, W. R. Dean, Alison J. Dow, J. T. K. Duncan, A. Dunnill, N. J. L. D'Vaz, Margaret L. E. Eastcott, D. R. Edbrooke, Davnet A. V. Fenton, Frances E. Freeman, A. J. V. H. French, A. J. Gardner, Elzbieta E. Gielniwska, A. V. Gillespie, G. T. Gooding, Judith M. Hall, J. W. Harcup, G. Hass, R. T. Hawley, B. Hayes, V. N. Highman, O. Holmes, J. M. Howell, Doreen M. Hudson, Margaret J. Hunter Rowe, T. A. Russell, P. B. Jacobs, R. W. James, Rosemary A. Johnson, O. P. Jones, Mary O. Joseph, P. M. Katrak, C. W. Keen, A. Kenyon, Angela R. Kosky, M. J. S. Langman, M. I. Leckie, J. P. Lee-Potter, L. A. Lees, Valerie Little, L. S. S. Lung, K. H. McCraith, G. W. McKenna, B. W. Maitland, R. Marks, Sylvie Marston, Margaret Masterton, Ann R. Matthews, T. S. Matthews, N. S. S. Meimary, Yvonne M. Metcalf, D. J. O. Mills, P. V. Mills, D. F. Munro, Jane A. Napper, J. L. Nimmo, R. F. Norris, J. B. Nuttall, J. O. Onyeachonam, A. A. Osindero, Mary W. Parry, P. G. Parry, P. O. D. Pharoah, J. W. Porter, L. A. C. Pugh, H. B. Raeburn, T. Ramsamy, Marjory M. R. Reid, N. A. Retz, A. B. Richards, G. A. Richardson, R. M. Riddell-Smith, Gwyneth M. Riley, R. R. Roberts, Hildegard M. I. Seeman, Olive P. Sharp, Muriel A. Shiel, R. M. Simons, Cynthia G. Smith, I. S. Smith, S. Sprague, Shirley H. Stanness, J. F. Steele-Perkins, Hazel G. Stephens, M. P. Sternberg, D. J. Steward, J. D. M. Stewart, D. W. B. Summers, J. L. K. Tamakloe, Veronica Thatcher, M. J. A. Thompson, R. A. Thompson, M. K. Tidman, J. M. Todd, E. W. B. Varley, S. O. Wamuo, K. H. Warden, J. B. Warren, T. P. Welch, M. P. Wilderspin, M. C. T. Wilkes, G. E. Winbolt, Yvonne Young.

Diplomas in Ophthalmology were granted, jointly with the Royal College of Surgeons of England, to R. J. M. Boucherat and to the other successful candidates whose names are printed below in the report of the meeting of the Royal College of Surgeons of England held on October 9.

Diplomas in Child Health were granted, jointly with the Royal College of Surgeons of England, to Margaret S. Brothwood and R. B. Razvi and to the other successful candidates whose names are printed below in the report of the meeting of the Royal College of Surgeons of England held on October 9.

Diplomas in Industrial Health were granted, jointly with the Royal College of Surgeons of England, to M. C. Gupta and P. V. Krishnamurti.

Diplomas in Tropical Medicine and Hygiene and in Physical Medicine were granted, jointly with the Royal College of Surgeons of England, to the successful candidates whose names are printed below in the report of the meeting of the Royal College of Surgeons of England held on October 9.

Other diplomas were granted, jointly with the Royal College of Surgeons of England, as follows:

DIPLOMA IN PUBLIC HEALTH.—D. S. Jani.

DIPLOMA IN PSYCHOLOGICAL MEDICINE.—G. Woolfson.

DIPLOMA IN ANAESTHETICS.—D. M. Davies.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At a meeting of the Council of the College held on October 9, with Sir James Paterson Ross, President, in the chair, the Mitchiner Medal was presented to Lieutenant-Colonel R. H. Robinson by the Director-General of the Army Medical Services (Lieutenant-General Sir Alexander Drummond).

The Handcock Prize was presented to Mrs. E. M. Cooke, of the Royal Free School of Medicine.

Mr. F. R. Jackaman (Queen Elizabeth's School, Barnet, and Cambridge University) was admitted as Macloghlin Scholar.

The John Hunter Medal and Triennial Prize were awarded to Dr. L. W. Proger, Pathology Curator, for his devoted services to the Hunterian Museum.

The award of a Mackenzie Mackinnon Research Fellowship to Mr. K. E. D. Shuttleworth was announced.

Arrangements were approved for the celebration next year of the centenary of the institution of the licence in dental surgery.

A diploma of Fellowship was granted to B. P. Scrivener, and a diploma of Membership to A. B. Richards.

Diplomas of Fellowship in the Faculty of Anaesthetists were granted to the following successful candidates:

Jean M. Horton, S. W. Kemp, B. R. J. Simpson, J. D. K. Burton, T. M. McAneny, A. McL. Keil, Patricia Painter, R. L. Hargrove, T. M. Ness, S. Thirumalai, J. L. Hadley, Ellen R. S. Armitage, A. J. Booth, Sheila R. Clarke, B. J. Muir, J. R. Munro, B. Solomon, F. R. Bhupalan, P. S. Keddie, R. M. Nicholl, T. J. Stanton, G. Tay, H. R. P. Coutanceau, G. W. Duckworth, G. L. F. Lau, F. M. Mehta, I. A. Sloan, J. V. Farman.

The following diplomas were granted, jointly with the Royal College of Physicians of London:

DIPLOMA IN OPHTHALMOLOGY.—A. K. Banerjee, J. C. Chang, K. K. Chau, S. R. Chowdhuri, B. P. Cooper, R. J. Croke, Elizabeth L. R. Douglas, L. K. Dutta, J. M. Elby, Asuncion N. Fernandez, R. S. Garkal, J. H. L. George, P. K. Ghosh, Elizabeth F. Hamilton, A. C. A. Hempel, D. E. Hone, M. I. Khan, S. Khoshnevis, A. Krishna Murthy, P. Lancer, M. G. Lyall, A. J. Lyne, A. Lytton, K. J. Modi, V. S. Pande, M. V. Parikh, J. A. Pearce, H. J. Penkala, Pe Than Maung, D. N. Randeria, J. M. Rodd, P. G. Rowsell, I. S. Roy, M. I. Sharma, S. A. Sheikh, G. E. M. Smith, G. C. Sood, D. J. Thornton, N. H. Welsh, G. S. Willett, M. S. Wilson.

DIPLOMA IN CHILD HEALTH.—V. K. Agarwal, V. C. Agarwal, Hilary Allin, Elizabeth M. F. Andrews, K. D. Austin, J. F. Baden-Daintree, S. Barua, N. Bhaktlingam, Josephine Bradford, Helen R. L. Brown, K. W. Browne, Anne J. Buge, Mary S. Campbell, J. C. Chakrabarti, C. P. Chin, D. R. Chopra, R. K. Chopra, J. Connolly, M. J. Conway, Izette R. Coulton, P. N. Cretney, Edith Danos, B. S. David, G. N. Dubey, V. Dubowitz, F. M. Elderkin, J. H. Fairley, Hazel M. Fearn, W. R. Forbes, R. A. Gould, Margaret S. Hall, Jean G. Harrison, I. A. Hashimi, Anne Heath, C. P. Hindley, Barbara L. Hooker, M. J. Howell, D. Hull, Rosemary P. W. Johnston, J. Keane, Katie Keane, P. N. Krishnamurthy, Julie S. S. Lim, H. M. Lipman, Gwendolen Mallal, A. V. Mar, Valerie J. Marrian, Miller, A. Mithal, D. M. Morgan, Khurshed Moulvi, Janice H. Mount, O'Neill, M. S. Pardiwalla, K. M. Patel, P. N. Krishnamurthy, Julie S. S. Lim, Ann Priestman, Gillian Prosser-Ashby, K. A. Rahimulla, Shirley G. Ratcliffe, L. Sash, R. Schofield, S. Shabbir, Jean Shackleton, A. J. H. Shepherd, K. Soni, Anne L. Stewart, Susan Stonestreet, M. K. Strelling, Margaret J. D. Surges, Hui Lim Helen Tay, A. F. Taylor, Dileas M. Tingle, H. L. Utian, N. A. Vellani, Geraldine M. Walshke, K. Warburton, R. W. Watton, Mary Wilkie, R. Winstone, Lina Yut Lin Yung.

DIPLOMA IN TROPICAL MEDICINE AND HYGIENE.—S. Abedin, A. A. Ahmed, K. Bery, F. S. Boi-Doku, M. C. Brain, K. R. Bremner, D. G. Carlson, Hin-Wing Chan, D. P. Daly, M. E. Fearnley, R. D. Foord, D. A. Gandhi, D. J. Hansman, T. Htin, H. A. Jesuthasan, B. Jha, H. A. J. Kassam, H. J. Khambatta, M. A. Khan, M. D. Khan, K. K. Koraiah, M. C. Latham, P. B. Lees, M. H. Mahmoud, K. K. Mallik, M. A. Mannan, F. X. Martin, M. C. Mathews, R. A. Miller, D. Misra, M. T. Moore, H. Nadiy, Rosemary A. Page, G. M. J. Pais, Valerie J. Prior, S. H. Qureshi, W. H. Rees, S. P. Shah, J. Sharan, R. P. Singh, R. Singh, D. R. Stein, B. V. Suryanarayana, N. A. Syed, I. Taha, Tha Khin, T. Thavornstiri, E. Trinick, K. E. Usher, N. A. Vellani, C. Vesuna, A. E. Wanigesooria, Anie Wiersinga, M. H. Zafar.

DIPLOMA IN PHYSICAL MEDICINE.—E. N. Coomes, R. Danbury, Helene V. Goodman, G. Holden, K. H. Nixon, S. K. Sarkar, V. L. Steinberg, W. G. Wenley, V. B. Whittaker.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND

At the annual meeting of Fellows, held on October 18, the following officers were appointed for 1958-9: *President*, Dr. P. T. O'Farrell; *Vice-President*, Dr. M. Crowe; *Representative of College on General Medical Council*, Dr. Edward T. Freeman; *Registrar*, Dr. Charles Dickson; *Treasurer*, Dr. Geoffrey Bewley.

ROYAL AUSTRALASIAN COLLEGE OF PHYSICIANS

At a meeting of the Council of the College held in Melbourne on October 9 the following candidates, who were successful at an examination by the Australian Board of Censors, were admitted to Membership of the College: Dr. W. Berns, Dr. F. J. T. Croll, Dr. J. C. Farrell, Dr. H. G. Gallagher, Dr. B. R. Huxtable, Dr. K. P. W. Moore, and Dr. T. Selby, of New South Wales; Dr. N. McK. Bennett, Dr. R. A. Chenoweth, Dr. A. E. Doyle, Dr. A. D. Grounds, Dr. F. L. Johnson, Dr. D. S. Nurse, Dr. R. G. Shaw, Dr. L. E. G. Sloan, Dr. B. M. Spence, Dr. J. B. Webb, and Dr. C. W. E. Wilson, of Victoria; Dr. B. J. Knapp and Dr. J. P. Masel, of Queensland; Dr. I. J. Forbes and Dr. J. G. Wilson, of South Australia; Dr. J. A. Bonnin, of South Australia, and Dr. K. V. Smith, of New South Wales, were admitted under the special provisions of Article 37.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending October 25 (No. 43) and corresponding week 1957.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the whole of England and Wales (London included). London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES	1958					1957

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenzal pneumonia.
‡ Includes puerperal pyrexia.

Vital Statistics

Typhoid: Oysters Suspected

Seven cases of typhoid fever suspected of being caused by infected oysters have been reported recently. They are in the London area, except for one at Sidcup, Kent, and one at Sudbury, Suffolk. The last patient ate the oysters in Colchester, Essex, the others in London. In three cases the oysters are known to have come from the West Mersea beds, and in four cases the West Mersea strain of the bacillus has been identified.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the years 1949-57 are shown thus -----, the figures for 1958 thus ———. Except for the curves showing notifications in 1958, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Week Ending November 1

The largest fluctuations in the notifications of infectious diseases in England and Wales during the week ending November 1 were increases of 782 for measles, from 4,232 to 5,014, 86 for scarlet fever, from 803 to 889, 53 for acute pneumonia, from 263 to 316, 43 for whooping-cough, from 594 to 637, and 26 for dysentery, from 525 to 551.

The largest rises in the incidence of measles were 155 in Yorkshire West Riding, from 461 to 616 (Halifax C.B. 167), 106 in Yorkshire East Riding, from 195 to 301 (Kingston-upon-Hull C.B. 263), 88 in Lincolnshire, from 165 to 253 (Scunthorpe M.B. 83), 87 in Surrey, from 60 to 147, 82 in Middlesex, from 200 to 282, and 79 in Sussex, from 82 to 161; the largest falls were 68 in Caernarvonshire, from 134 to 66, 56 in Devonshire, from 169 to 113, and 49 in Hampshire, from 101 to 52. Only small changes in trend were reported in the local areas for scarlet fever and whooping-cough. 6 cases of diphtheria were notified, being 2 more than in the preceding week; 3 of these cases were notified in London.

The notifications of acute poliomyelitis numbered 79 and were 8 fewer for paralytic and 12 more for non-paralytic cases than in the preceding week. The largest returns were Lancashire 19 (Manchester C.B. 9), Yorkshire West Riding 12 (Nidderdale R.D. 6), Durham 5 (Sunderland C.B. 2), Hampshire 5 (Southampton C.B. 2), London 5.

The chief centres of infection for dysentery were Yorkshire West Riding 100 (Leeds C.B. 44), Lancashire 53 (Liverpool C.B. 20), Glamorganshire 52 (Cardiff R.D. 22, Barry M.B. 12), London 46 (Islington 10, Wandsworth 10), Northumberland 32 (Newbiggin-by-the-Sea U.D. 19), Warwickshire 25 (Coventry C.B. 16); Essex 24 (Walthamstow M.B. 14), Hampshire 23 (Southampton C.B. 18), and Durham 22.

The New Zealand Department of Health (P.O. Box 5013, Wellington) has published a *Directory of Homes and Clubs for Old People*. This is based on a survey carried out in February last, and it is hoped to publish supplements from time to time.

Medical News

Epsom College Scholarships.—The council of Epsom College will, about the end of May, 1959, elect to one or more Henry Robinson scholarships, tenable from September, of a maximum value of £250 a year. These scholarships are open only to sons of registered medical men or women, aged between 12 and 14 on January 1, 1959. They are awarded on the results of a competitive examination, and there is no means test. About 5 or 6 open scholarships will be given on the results of the same examination, maximum value £150 a year; for these, boys of medical parentage compete on level terms with sons of the laity. Full details can be obtained from the Headmaster, Epsom College, Epsom.

Royal College of Obstetricians and Gynaecologists.—A large gathering of obstetricians and gynaecologists, their guests, and their ladies attended the College's annual dinner at the Dorchester Hotel on November 7. The president, Professor ANDREW CLAYE, was in the chair, and after the dinner and speeches there was dancing. Sir MALCOLM TRISTRAM EVE, Q.C., First Crown Estate Commissioner, welcomed the College as new tenant of the Crown in Regent's Park. It was the desire of the Crown Commissioners to save all the Nash terraces if possible, he said; each building facing the park would revert to residential use, and each terrace would be largely rebuilt, but retaining, or returning to, Nash's original elevation. The College was privileged in being allowed to build its new house in what is a "residential area," and Sir Malcolm expressed the hope that some other colleges might join them there. Professor CLAYE, responding, said the building was progressing steadily and should be finished by the end of 1959. While they could now see enough money forthcoming to build and equip it, funds for its maintenance were still urgently needed. It would become the focal point of almost all their work. The College, he continued, was engaged, with the help of its councils in the Dominions, in revising the M.R.C.O.G. Extramurally, it was taking part with other bodies in the review of the N.H.S. and in other matters of professional concern. Dr. T. F. Fox, for the guests, replied to Mr. JOHN PEEL's gracious toast: the evening, he said, had been positively Caesarean.

Doctors' Hobbies.—The second Doctors' Hobbies Exhibition, organized by Benger Laboratories Ltd., was opened on November 10 by Sir CLAVERING FISON, chairman of the Fison Group, in the Great Hall of B.M.A. House. More than 500 doctors showed samples of the things they do in their leisure time, to make an impressive collection of over 700 exhibits. First prize was won by Dr. A. W. FAWCETT, of Sheffield, whose 4 ft. model of the torpedo-boat destroyer *Tigress*, in which he served, had taken him 14 years to complete. The second prize went to Dr. A. H. WORTMAN, of London, for a collection of stamps issued by Imperial Russia in 1858. Dr. S. COMPTON, of Guildford, took the third prize for tapestries of exceptional quality. The exhibits were grouped in 23 classes, of which easily the most popular were those for photography (transparencies, portraiture, and general) and painting (oil and watercolour). Next in popularity were "authorship," embroidery, woodwork, and sculpture and wood-carving. But such a list gives little idea of the great variety of the profession's leisure interests: they include, for instance, tame chinchillas, popular songs, stage properties, Esperanto, the collection of abbreviations from newspapers and journals, poetry, an electronic organ, sock-darning, a telephone-tapping device, ships in bottles, models of all kinds, ceramics, violins, and match-box labels. The standard was far higher than last year, and once again the photographs were outstanding. The paintings were more numerous and included some fine work, notably the prize-winning industrial landscapes by Dr. A. B. FOLLOWS and Dr. PH. TUTTNAUER's imaginative "Boats at Rest." The exhibition was open for five days.

Transatlantic Clinical Conference.—The British panel for the transatlantic clinical conference on December 5 between the B.M.A. Annual Clinical Meeting in Southampton and the A.M.A. Meeting in Minneapolis, U.S.A., will be Dr. W. D. BRINTON (chairman), Professor JOHN MCMICHAEL, F.R.S., and Mr. HOLMES SELLORS. The Clinical Meeting, which lasts from December 4 to 7, will also include four panel discussions and three general sessions on practical clinical subjects. Advance registration forms for the meeting are obtainable from the Executive Officer, B.M.A. House, Tavistock Square, London, W.C.1. These should be completed and returned without delay.

London Medical Exhibition.—Sir ROY CAMERON, F.R.S., gave the address at the opening of the 42nd London Medical Exhibition, held at the Royal Horticultural Hall, Westminster, from November 10 to 14. The exhibition is staged each year by the British and Colonial Druggist Ltd. Pride of place at the exhibition, said Sir Roy, went to treatment. Doctors would find new measures for the more effective use of healing drugs, not only by prolonging their local and general action and removing unpleasant side-effects but by promoting their absorption, simplifying their administration, and, above all, by doing away with even the remote possibility of danger. No less important was reduction in cost, something that must appeal to everyone in these days of financial stringency. It was fitting, too, that new discoveries in the recognition of disease should be placed as early as possible before the profession, and the London Medical Exhibition had certainly accepted its responsibilities in that direction. Simpler apparatus for blood-pressure determination, reliable stains for microscopical diagnosis, and less complicated methods for examination of the urine, blood, and body excretions would appeal to those who spent their lives in the quiet alleys of medical endeavour. As one whose life had been given up to teaching and investigation, he commended this display of the development and application of medical research.

Royal College of Physicians of Edinburgh.—At a quarterly meeting of the College held on November 4, 1958, with the president, Dr. A. RAE GILCHRIST, in the chair, the following were elected Fellows of the College:

F. P. Reid, Maung E. K. N. Gour, R. Schneider, T. Schneider, I. Singh, N. Ali, I. Schrire, H. A. Reid, J. M. Staveley, G. B. Tait, M. Watt, S. G. Nelson, G. M. Carstairs, J. N. Swanson, D. H. Clark, M. A. Keith, A. C. Bhabha, N. C. Begg, R. Grenville-Mathers, A. M. Kassim, S. R. K. Padmavati, J. D. Matthews, P. C. Mitchell, J. F. McHarg, S. E. Large, W. S. Watson, J. Harper, W. Macleod, M. Macleod, H. B. Craigie, S. P. V. Sherlock.

The following were elected Members of the College:

D. F. Cappell, D. M. Fraser, W. M. Millar, K. M. Robertson, K. S. Grover, F. R. D. Minett, P. K. Roy, M. O'Mahony, R. D. Spooner, S. N. Mukherjee, E. T. Hughes, D. J. Hodges, J. C. Ghosh, J. G. Sowerbutts, S. Janaki, W. A. Penman, A. M. Womack, N. S. Dhillon, E. C. Knox, P. V. Vora, S. G. F. Mads, M. D. Kay, L. L. Sinha, S. S. Syalee, E. S. Emslie, D. Montgomery, T. D. Grant, G. P. McGovern, C. E. Rotem, T. K. Chaudhuri, T. C. Dennison, P. S. Terespolsky, P. C. Sharma, D. J. Robinson, S. V. Bakshi, A. J. Watson, S. S. Jhaveri, G. W. Ashcroft, J. S. Beck, W. K. C. Morgan, E. J. Raffle, J. R. Tighe, P. Ganeriwala, J. A. Fuller, H. R. Klein, O. P. Gupta, I. W. Delamore, A. Mitra, J. Dominian, E. Chesler.

Royal Faculty of Physicians and Surgeons, Glasgow.—Besides the election of Mr. A. H. Jacobs as president (*Journal*, November 8, p. 1171), the following were elected office-bearers at the annual general meeting of the Royal Faculty of Physicians and Surgeons of Glasgow on November 3: Visitor, Dr. J. H. Wright; hon. secretary, Dr. Gavin B. Shaw; hon. treasurer, Mr. R. B. Wright; hon. librarian, Dr. A. L. Goodall; representative on the G.M.C., Dr. Andrew Allison; councillors, Dr. G. J. Aitken, Dr. W. Ferguson Anderson, Dr. W. Malcolm Gibson, Dr. D. McKay Hart, Dr. A. Cameron Macdonald, Dr. T. J. Thomson, and Professor G. M. Wyburn. Dr. C. G. A. Thomas was presented with a cheque for his winning essay

in a competition sponsored by the council of the Faculty for the trustees of the Glasgow Lock Hospital Fund.

Poisons List.—The Home Office announces that Statutory Instruments are being prepared to give effect to recommendations from the Poisons Board. It is proposed to make the following changes in the Poisons List and Rules:

1.—Anileridine, dextromoramide, etoxeridine, levomoramide, methylhydromorphone, morpheridine, myrophine, oxymorphone, racemoramide, trimeperidine, and the esters of 1-methyl-4-phenyl-piperidine-4-carboxylic acid, and the salts of these substances, will be added to Part I of the Poisons List and the First Schedule to the Poisons Rules. The existing entries relating to pethidine and the isopropyl ester of 1-methyl-4-phenylpiperidine-4-carboxylic acid and their salts will be deleted.

2.—Derivatives of 3-(10-phenothiazinyl) propane substituted in the 1-position, and the salts of these substances, will be added to Part I of the Poisons List and to the First and Fourth Schedules to the Poisons Rules. The existing entries relating to chlorpromazine and promazine and their salts will be deleted.

3.—Endrin will be added to Part II of the Poisons List and to the First, Fifth (in respect of "preparations for use in agriculture or horticulture"), Seventh, Eighth, and Ninth Schedules to the Poisons Rules.

4.—2-Methoxycarbonyl-1-methylvinyl dimethyl phosphate ("phosdrin") will be added to the list of phosphorus compounds in Part II of the Poisons List, in Rule 14(2)(b)(vi) of the Poisons Rules and in the First, Third, Fifth, Seventh, Eighth, and Ninth Schedules. It will also be added to the Sixteenth Schedule.

5.—Organic compounds of mercury in aerosols will be included in the First Schedule to the Poisons Rules regardless of their percentage content of mercury, and also in paragraph 6 of the Seventh Schedule.

6.—The entry in the second column of the Fifth Schedule to the Poisons Rules relating to calcium arsenates will be amended to read "preparations for use in agriculture or horticulture."

7.—The requirement in Rule 12(2)(e) and (f) of the Poisons Rules that a prescription for a poison included in the Fourth Schedule shall show the total amount to be supplied or the total amount intended to be administered or injected will be amended to exclude preparations included in the *British National Formulary*.

Central Midwives Board Headquarters.—The MINISTER OF HEALTH, accompanied by Mrs. WALKER-SMITH, officially opened the new offices of the Central Midwives Board during a reception held in the new building, at 39, Harrington Gardens, London, S.W.7, on November 6. The Board has taken a 64-year lease of the house, which provides enough accommodation for its increasing work. Last year there were 4,039 successful candidates for the first part of the midwives certificate examination, and the names of 2,800 women were enrolled on the register as having been successful in the second part. The chairman of the Board, Dr. ARNOLD WALKER, and Mrs. WALKER received the guests at the reception.

Birmingham University.—The title of reader in comparative neurology has been conferred on Dr. J. T. EAYRS, senior lecturer in neuro-anatomy and at present Henry Head research fellow of the Royal Society in the department of anatomy. Dr. H. A. SALMON has been appointed a temporary lecturer in physiology, and Dr. B. J. KEY a research fellow in the department of experimental psychiatry.

N.E. Metropolitan Board.—Sir JAMES PATERSON ROSS, P.R.C.S., was the principal guest at the eighth annual dinner of the North-east Metropolitan Regional Hospital Board on October 22. Over 300 attended, under the chairmanship of the Board's chairman, Sir GRAHAM ROWLANDSON.

St. John Ambulance Brigade.—Mr. G. W. WOODHILL, Cadet Officer for London District since 1955, has been appointed secretary of the Brigade in succession to the late Mr. GEORGE QUILTER.

Professor W. C. W. Nixon has been elected a foreign member of the Turkish Society of Obstetrics and Gynaecology.

COMING EVENTS

University College, London.—Dr. D. A. DENTON, director of the Ion Exchange Research Unit, Melbourne, will lecture on "The Control of Secretion of the Transplanted Adrenal Gland" on November 19 at 5.30 p.m. in the physiology theatre.

Institute of Neurology.—Professor J. N. CUMINGS will deliver his inaugural lecture as professor of chemical pathology at the Institute of Neurology, Queen Square, on November 24 at 5.30 p.m. His subject will be "Neurochemistry and Neurochemists."

Kettle Memorial Lecture.—Dame JANET VAUGHAN will lecture on November 27 at 5 p.m. at St. Bartholomew's Hospital Medical College on "The Relation of Radiation Dosage to Radiation, with Reference to Bone-seeking Isotopes."

Richard Bright Centenary.—On December 1 Guy's Hospital Medical School is celebrating the centenary of Bright's death with a combined round on Bright's disease (2.15 p.m.) and a memorial lecture (5 p.m.) by Professor M. L. ROSENHEIM on "The Syndromes of Bright's Disease." Further details are obtainable from the Medical School.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, November 17

GUY'S HOSPITAL.—At Anatomy Lecture Theatre, 5.15 p.m., lecture demonstration in endocrinology by Dr. P. M. F. Bishop: Acromegaly. **HUNTERIAN SOCIETY.**—At Apothecaries' Hall, 8.30 p.m., discussion: This Society Accepts the Need for Human Artificial Insemination. Speakers, Rt. Rev. the Lord Bishop of Croydon, Mr. W. A. Fearnley-Whittingstall, Q.C., and Mr. V. B. Green-Armytage.

Tuesday, November 18

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. W. Hayes: Bacterial Genetics and Gene Structure. **HEATHERWOOD ORTHOPAEDIC HOSPITAL.**—8.30 p.m. Mr. J. Charnley: Lubrication of Joints, with Special Reference to Arthroplasty. **INSTITUTE OF DERMATOLOGY.**—5.30 p.m., Dr. G. C. Wells: Mechanisms of Epidermal Sensitization. **KEIGHLEY AND DISTRICT MEDICAL SOCIETY.**—At Skipton General Hospital, 8.30 p.m., Dr. P. C. Reynell: Some Recent Advances in the Treatment of Liver Disease.

MANCHESTER MEDICAL SOCIETY.—At Large Anatomy Theatre, Manchester University, 4 for 4.30 p.m., University Lecture on the History of Medicine by Dr. W. S. C. Copeman: Doctors and Disease in Tudor Times. **MANCHESTER UNIVERSITY: DEPARTMENT OF OCCUPATIONAL HEALTH AND NORTH-WEST ENGLAND FACULTY, COLLEGE OF GENERAL PRACTITIONERS.**—At Theatre 1, Clinical Sciences Building, York Place, 8.30 p.m., Professor R. E. Lane: Effect of Work on Some Selected Medical Conditions. **RESEARCH OFFENCE SOCIETY.**—At Lecture Theatre, Zoological Society of London, Regent's Park, N.W.1, 5.30 p.m., 27th Stephen Paget Memorial Lecture by Mr. Richard Fort, M.P.: The Irrational in Public Life. **ROYAL COLLEGE OF PHYSICIANS OF LONDON.**—5 p.m., Charles West Lecture by Dr. E. M. Creak: Child Health and Child Psychiatry—Neighbours or Colleagues?

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Institute Theatre, 5 p.m., Mr. J. S. Tompkinson: History and Present-day Practice of Contraception. **UNIVERSITY COLLEGE LONDON.**—At Anatomy Theatre, Gower Street, W.C.1, 1.15 p.m., Mr. D. A. Sholl: Randomness of the Brain. **UNIVERSITY COLLEGE LONDON: DEPARTMENT OF PHARMACOLOGY.**—At Physiology Theatre, Gower Street, W.C.1, 5.30 p.m., Professor J. F. Danielli, P.R.S.: Generalized Cell Theory and Its Relevance to Certain Problems of Drug Action. **WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.**—5.30 p.m., Mr. K. I. Nissen: Carpa Tunnel Syndrome.

Wednesday, November 19

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. J. A. Dudgeon: Virus Diseases. **INSTITUTE OF DISEASES OF THE CHEST.**—5 p.m., Mr. V. C. Thompson: Carcinoma of the Lung: Early Diagnosis. **INSTITUTE OF UROLOGY.**—4.30 for 5 p.m., Mr. Harland Rees: Differential Diagnosis of Frequency of Micturition. **MIDLAND MEDICAL SOCIETY.**—At Dudley Road Hospital, 8.15 p.m., clinical meeting. **NATIONAL COLLEGE OF RUBBER TECHNOLOGY,** Northern Polytechnic, Holloway Road, N.1, 4.30 p.m., Mr. O. F. Mackinnon: Plastics in Dentistry. **NORTH-WESTERN THORACIC SOCIETY.**—At Aintree Hospital, Liverpool, 5 p.m., Dr. D. L. Caldwell, Selection of Patients for Admission to a Chronic Bronchitic Unit; Dr. G. Yates, Chronic Bronchitis in General Practice; Dr. M. Davies, Bronchitis and Atmospheric Pollution. **POSTGRADUATE MEDICAL SCHOOL OF LONDON.**—2 p.m., Guest Lecture by Dr. S. M. Cohen: Turnover of Plasma Proteins. **ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.**—3.30 p.m., Mr. J. Sharp Grant, Some Comments on the Development of Occupational Medicine. (Illustrated.) **SCIENTIFIC FILM ASSOCIATION.**—At 4th Floor Temporary Lecture Theatre, Royal College of Surgeons of England, 6.30 p.m., subject: Presenting Medicine to the Public on Television. Principal speaker, Mrs. Mary Adams. Discussion to be opened by Mr. A. Dickson Wright.

UNIVERSITY COLLEGE LONDON.—At Department of Pharmacology, 5.30 p.m., Dr. D. A. Denton (Melbourne University): The Control of Secretion of the Transplanted Adrenal Gland. **WEST LONDON MEDICO-CHIRURGICAL SOCIETY.**—At Nurses' Hall, West London Hospital, W.1, 8.30 p.m., Mr. J. Johnston Abraham: The West London 50 Years Ago.

Thursday, November 20

BRISTOL UNIVERSITY.—At Reception Room of University, 8.15 p.m., Carey Coombs Memorial Lecture by Dr. Bernard Schlesinger: Course and Treatment of Rheumatoid Diseases in Childhood. **BRITISH INSTITUTE OF RADIOLOGY.**—8 p.m., subject: Use of the Rad as a Dose Unit in Radiotherapy. To be opened by Dr. F. Ellis, Dr. C. W. Wilson, and Mr. D. E. A. Jones. **BRITISH POSTGRADUATE MEDICAL FEDERATION.**—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. J. H. Humphrey: What are Gamma-globulins? **HONEYMAN GILLESPIE LECTURES.**—At Anatomy Theatre, University New Buildings, Teviot Place, Edinburgh, 5 p.m., Professor J. Walker: Foetal Dissociation Curve for Oxygen. **HYPONOTHERAPY GROUP.**—At Royal Society of Medicine, 8 p.m., Dr. Peter Scott: Crime and Adolescence. **INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.**—At Chelsea Hospital for Women, 4.30 p.m., Guest Lecture by Mr. D. M. Stern: Abnormal Uterine Haemorrhage. **LIVERPOOL MEDICAL INSTITUTION.**—8 p.m., Hugh Owen Thomas Memorial Lecture by Mr. H. Jackson Burrows: Prosthetic Replacement of Bone. **MANCHESTER MEDICAL SOCIETY: SECTION OF ANAESTHETICS.**—At Staff House, Manchester University, 7.45 for 8 p.m., Presidential Address by Dr. A. J. Gray: On Veins and Needles. **NEW HEALTH SOCIETY.**—At Board Room, Y.W.C.A. Central Club, Great Russell Street, London, W.C.1, 3 p.m., Mr. T. T. Stamm: Foot Troubles. **ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.**—At Liverpool School of Tropical Medicine, 7.30 p.m., laboratory meeting. **ST. ANDREWS UNIVERSITY.**—At Physiology Department Lecture Theatre, 5 p.m., Dr. Agnes R. Macgregor: Changing Problems of Paediatric Pathology. **ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.**—5 p.m., Dr. Maurice Partridge: postgraduate demonstration in psychiatry. **UNIVERSITY COLLEGE LONDON: DEPARTMENT OF BIOCHEMISTRY.**—At Physiology Theatre, Gower Street, W.C.1, 5 p.m., Dr. E. M. Shooter: Configuration of Proteins in Solution.

Friday, November 21

FACULTY OF RADIOLOGISTS.—At Royal College of Surgeons of England, 5 p.m., 4th Crookshank Lecture by Lord Cohen of Birkenhead: Contribution of X-rays to the Basic Medical Sciences. **INSTITUTE OF DERMATOLOGY.**—5.30 p.m., Dr. D. I. Williams: clinical demonstration. **INSTITUTE OF DISEASES OF THE CHEST.**—5 p.m., Mr. J. R. Belcher and Dr. E. H. Hudson: clinical demonstration. **INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.**—(1) 3.30 p.m., clinical discussion for general practitioners by Mr. Maxwell Ellis: Malignant Diseases of the Pharynx. (2) 5.30 p.m., demonstration of films by Dr. T. V. L. Crichtlow. **INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.**—At Queen Charlotte's Hospital 2 p.m., Guest Lecture by Mr. D. McKay Hart: Virus Diseases *Complicating Pregnancy. **LEICESTER CHRISTIAN MEDICAL ASSOCIATION.**—At Leicester Royal Infirmary, 8.45 p.m., Dr. Robina A. Taylor (Ghana): Racial Problems in Medical Practice. **MIDLAND CENTRE FOR NEUROSURGERY, HOLLY LANE, SMETHWICK.**—8 p.m., Sir Russell Brain: Endocrine Exophthalmos. **POSTGRADUATE MEDICAL SCHOOL OF LONDON.**—10 a.m., Guest Lecture by Mr. T. Holmes Sellers: Diagnosis and Treatment of Atrial Septal Defects.

Saturday, November 22

SCOTTISH OTOLARYNGOLOGICAL SOCIETY.—At Royal Infirmary, Dundee, 2 p.m., 77th meeting.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Naylor.—On October 28, 1958, at Ann Arbor, Michigan, U.S.A., to Paz Buenaventura (formerly Dominado) and Bernard Naylor, a son—Patrick John. **Winter.**—On October 18, 1958, to Dr. Margery Joan, wife of Dr. David Winter, 292, Hagley Road, Birmingham, a daughter—Sarah Elizabeth.

DEATHS

Cohen.—On October 23, 1958, at 35, Bath Hill Court, Bournemouth, Jack Cohen, L.R.C.P.&S.I., of Southport. **Coulson.**—On October 21, 1958, at a nursing-home, James Edmund Coulson, M.R.C.S., L.R.C.P., aged 92. **Galloway.**—On October 20, 1958, at Castle Street, Banff, John Charles Galloway, M.D., D.P.H., aged 82. **Hay.**—On October 19, 1958, at Stoneham, The Mall, Brading, Isle of Wight, Arthur Edgar Hay, M.R.C.S., L.R.C.P., aged 80. **Hughes.**—On October 19, 1958, at 20, Broomfield Lane, Hale, Cheshire, Thomas Martin Hughes, M.R.C.S., L.R.C.P., L.D.S.R.C.S., aged 80. **James.**—On October 15, 1958, at Gateacre Grange, Liverpool, Dorothy Mary James, M.D., D.P.H., aged 54. **Jenner.**—On October 22, 1958, Cyril William Jenner, L.M.S.S.A., of Mortimers, Manningsford Bohune, Wilts, late of Cherrimans, Shottermill, Haslemere, Surrey. **Knight.**—On October 19, 1958, at 162, Willesden Lane, London, N.W.1, Stephen John Knight, M.R.C.S., L.R.C.P. **Macdonald.**—On October 21, 1958, at Harpenden Memorial Hospital, Herts, William George Macdonald, M.B., Ch.B. (1908). **Thomas.**—On October 20, 1958, Arthur Henry Thomas, M.B.E., M.B., Ch.B., aged 84. **Todd.**—On October 20, 1958, Arthur Theodore Todd, O.B.E., M.B., Ch.B., of Upton Cheyne, Bilton, near Bristol. **Wilson.**—On October 21, 1958, John Stephen Herbert Wilson, M.R.C.S., L.R.C.P., of Old Forge House, Hatfield Broad Oak, Bishop's Stortford, Herts.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Haemorrhage from Anticoagulants

Q.—What is the treatment for haemorrhage in patients who are on phenindione or similar anticoagulants?

A.—Patients on prolonged anticoagulant treatment at home should carry two capsules of vitamin K₁ and take these with a drink of fruit juice immediately any bleeding is noticed. They should also carry an ampoule of vitamin K₁ for a doctor to inject if necessary. In addition, the patient must be instructed to stop taking the anticoagulant completely until he has a medical check-up and a blood test. The treatment is the accepted one and is preferable to blood transfusion, which may give rise to the production of undesirable circulating antibodies. Blood transfusion should be used only to replace blood loss when haemorrhage has been very severe. The sudden withdrawal of anticoagulant treatment and the rapid return of prothrombin levels to normal may, in certain cases, precipitate coronary thrombosis, but the dangers of this are negligible when measured against those of haemorrhage. Haemorrhage occurs only when the prothrombin levels are below 12% of normal, while anticoagulant action is still partly efficacious at 40% level. There is, therefore, usually time to assess the patient's condition before the danger level for thrombosis has been reached, and anticoagulant therapy may rapidly be restarted if bleeding has stopped.

Treatment of Anthrax, Botulism, and Snake-bite

Q.—Where may emergency supplies of therapeutic and prophylactic agents for anthrax, botulism, and snake-bite be obtained in England and Wales?

A.—A memorandum (H.M.(58)66) issued by the Ministry of Health in August lists the following centres as holding supplies of these agents. A 24-hour service is maintained at each centre.

Region 1: Newcastle.—The Pathological Laboratory, Cumberland Infirmary, Carlisle (anthrax antiserum and snake-bite antivenom only) (Carlisle 22332); The Dispensary, Newcastle General Hospital (Newcastle 38811).

Region 2: Leeds.—Castle Hill Hospital, Cottingham, Hull (Cottingham 47371); Seacroft Hospital, York Road, Leeds (Leeds 648164).

Region 3: Sheffield.—Nottingham City Hospital, Hucknall Road, Nottingham (Nottingham 63361).

Region 4: East Anglia.—Regional Transfusion Centre, Brooklands Avenue, Cambridge, Monday-Friday, 8.30 a.m.-5.30 p.m. and Saturday, 8.30 a.m.-12.30 p.m. (Cambridge 56912); all other times Cambridge 56913.

Region 5: North-west Metropolitan.—Edgware General Hospital (Edgware 2381).

Region 6: North-east Metropolitan.—North Middlesex Hospital, N.18: Day—Chief Pathologist, Night—Resident Pathologist (Edmonton 3071).

Region 7: South-east Metropolitan.—South London Transfusion Centre, South-east Sub-depot, David Salomon House, Southborough, near Tonbridge: day service (Southborough 1480); night service (Maidstone 4463 and 4660).

Region 8: South-west Metropolitan.—South London Transfusion Centre, Stanley Road, Sutton, Surrey (Vigilant 8221); Royal Portsmouth Hospital, Commercial Road, Portsmouth (snake-bite antivenom only) (Portsmouth 22281); *The Dispensary, Royal South Hants and Southampton Hospital (botulinus antitoxin and snake-bite antivenom only) (Southampton 26211); Royal Victoria Hospital, Shelley Road, Bournemouth (snake-bite antivenom only) (Boscombe 35201).

* This hospital carries snake-bite antivenom not only against native snakes but against tropical snakes which may be imported with cargoes arriving at the docks.

Region 9: Oxford.—Northampton General Hospital (Northampton 4680); Royal Berkshire Hospital, Reading (Reading 81721).

Region 10: South-western.—Ham Green Hospital, Bristol (Pill 2165); Pathological Department, Royal Devon and Exeter Hospital, Exeter (Exeter 73519; Exeter 72261 when laboratory closed); Scott Isolation Hospital, Plymouth (Plymouth 64311 and 61437); Pathological Department, Royal Cornwall Infirmary, Truro (Truro 3029).

Region 11: Wales.—Cardiff Isolation Hospital, Cardiff (Cardiff 21466); West Wales General Hospital, Glangwili, Carmarthen (botulinus antitoxin and snake-bite antivenom only) (Carmarthen 6733); Aberystwyth General Hospital (botulinus antitoxin and snake-bite antivenom only) (Aberystwyth 374); Caernarvon and Anglesey General Hospital, Bangor (botulinus antitoxin and snake-bite antivenom only) (Bangor 3321-5); Maelor General Hospital, Wrexham (Wrexham 3512).

Region 12: Birmingham.—The Dispensary, Selly Oak Hospital, Birmingham (Selly Oak 1361).

Region 13: Manchester.—The Dispensary, Manchester Royal Infirmary (Ardwick 3300).

Region 14: Liverpool.—Fazakerley Hospital, Longmoor Lane, Liverpool, 9 (Aintree 2342).

Anthrax antiserum for use prophylactically

Antiserum required for persons exposed to infection may also be obtained in 10-ml. containers during the day-time from the following centres:

Region 1: Newcastle.—Public Health Laboratory, Institute of Pathology, General Hospital, Westgate Road, Newcastle, 4 (Newcastle 38811).

Region 2: Public Health Laboratory, 16/18, Edmund Street, Bradford, 5 (Bradford 24314); Public Health Laboratory, 184, High Street, Kingston-upon-Hull (Hull Central 35371).

Region 5: North-west Metropolitan.—Central Public Health Laboratory, Colindale Avenue, London, N.W.9 (Colindale 7041).

Region 9: Oxford.—Public Health Laboratory, General Hospital, Northampton (Northampton 347).

Region 10: South-western.—Public Health Laboratory, Musgrove Park Hospital, Taunton (Taunton 5753).

Region 11: Wales.—Public Health Laboratory, Institute of Preventive Medicine, The Parade, Cardiff (Cardiff 29110 and 23967).

Region 12: Birmingham.—Public Health Laboratory, Royal Infirmary, Worcester (Worcester 5238/9).

Region 14: Liverpool, Public Health.—Laboratory, 126, Mount Pleasant, Liverpool (Royal 3636).

Pregnancy and Hodgkin's Disease

Q.—What is the effect of pregnancy on Hodgkin's disease and on leukaemia?

A.—There is no evidence that pregnancy has any adverse or beneficial effect upon the course of either Hodgkin's disease or leukaemia. 306 pregnancies occurring in 229 patients with Hodgkin's disease have been reported in the literature. Myles¹ analysed all the reported cases and showed that the relapse rate was no greater than that expected over a nine-month period in non-pregnant patients. Southam *et al.*² concluded from their own series that pregnancy probably does not alter the course of Hodgkin's disease. However, disease first manifest during a pregnancy tends to be more acute.

Sheehy³ reviewed the course of chronic granulocytic leukaemia in 94 patients in whom an associated pregnancy had been reported. He found no significant difference in survival from a similar group without pregnancies. Yahia, Hyman, and Phillips⁴ analysed 73 cases of acute leukaemia associated with pregnancy. Abortion or premature labour were common, but the course of the disease was not apparently affected. Very few cases of pregnancy occurring during the course of chronic lymphocytic leukaemia have been reported, probably because the age of onset of this type of leukaemia is most commonly post-menopausal and because the disease is in any case less common in women.

NOTES AND COMMENTS

Mortality from Whooping-cough.—Dr. PAUL DE BELLEFEUILLE (Ottawa, Ontario, Canada) writes: Many paediatricians will differ with the answer on mortality from whooping-cough ("Any Questions?" August 30, p. 574) on the matter of treatment. In the convulsant child "lumbar puncture is certainly useless." Perhaps, but I have seen protracted convulsing cease immediately upon relieving pressure thus. In the answer antibiotics are advised only in the treatment of secondary infection; in fact, whooping-cough itself, especially when seen fairly early, responds well to streptomycin, the tetracyclines, and chloramphenicol (the latter is perhaps preferred), and such therapy should not be withheld from the infant whooper. But even more important is serum therapy, using either human hyperimmune serum or rabbit hyperimmune serum, whereby death in infancy and troublesome bronchial disability in the future may be avoided. The last statement in the answer, on the uselessness of vaccine therapy once an attack has developed, should be modified by adding that an injection of vaccine to a child who has previously been vaccinated will have an early "booster" effect and help the child in fighting the infection.

OUR EXPERT replies: In a carefully controlled trial, conducted by the Medical Research Council,¹ chloramphenicol and chlortetracycline were both shown to have a slight beneficial effect in whooping-cough provided they were given in the first eight days of the disease—i.e., often before the whoop had developed. After this stage they were shown to have no effect and they should therefore not be given as a routine to children suffering from whooping-cough. They are perhaps best used in contacts of obvious cases when the disease can be suspected in the pre-whooping stage. The pathology underlying the severe type of convulsions is complex and the cerebrospinal fluid pressure is not always raised. Convulsions which clear up following a lumbar puncture can scarcely be due to the severe brain damage, which often causes coma lasting for weeks, if not death: probably every patient has a lumbar puncture carried out by a house officer, but the writer bases his opinion of its uselessness on over 20 years' experience of such cases. It would be difficult to prove that hyperimmune serum prevents death or future pulmonary disability without a control trial on a vast scale, for, after all, death is a comparative rarity in whooping-cough and future pulmonary disability very difficult to assess. Results from small published trials seemed to indicate that it might have some effect given early in young infants, but its effect was probably less conclusive than the effect of antibiotics already mentioned. With regard to the use of a booster dose of vaccine to children already immunized, surely the natural infection with live *H. pertussis* provided by an attack of the disease would be at least as potent a booster as an injection of dead vaccine. A large number of doubtful remedies for whooping-cough have been tried over the years with varying degrees of enthusiasm. I tried in my answer to give realistic suggestions for the prevention and treatment of the causes of mortality from the disease.

Extra Skin Crease.—Dr. R. D. LAURENSEN (Kingston, Ontario, Canada) writes: Congenital dislocation of the hip is once more being discussed (*Journal*, June 14, p. 1432; July 5, p. 58; September 20, pp. 743 and 753). Interest is centred on the early diagnosis of this condition because delay in diagnosis so frequently leaves a tragic aftermath. It so happens that I have just completed a review of the literature on this subject in order to establish a background for further investigations into its aetiology. As a result of my findings, I consider the reply by your expert to the comment of Mr. H. H. Nixon ("Notes and Comments," September 20, p. 753) to be worth more than just a corner of a page. Your expert states: "Abnormal skin creases and limited abduction are in themselves not infallible but are certainly most suspicious." Exactly so. They are the very signs which may encourage a doctor to seek the guidance of an experienced orthopaedic surgeon. From my recent studies I am certain that to cast away any sign which may lead to an early diagnosis of congenital dislocation of the hip would be sheer folly.

Mr. H. H. NIXON (London, W.1) writes: I would like to take up a few points arising from your expert's reply to my letter ("Notes and Comments," September 20, p. 753). I agree wholeheartedly that everything possible should be done to diagnose congenital dislocation of the hip as early as possible. I still maintain that asymmetry of skin creases is an unsuitable test and that limitation of abduction is more suitable. The two cases your expert mentions from Caffey's paper¹ did indeed have normal

abduction at first and yet subluxated later. He did not mention that they also had asymmetric skin creases so that neither test would have discovered them. I am not surprised at this, because his radiographs show that the subluxation was not present either. When it developed so did its physical signs. Early tests can be expected only to diagnose congenital dislocations. Post-natal dislocation will still need to be sought later. The relative frequency of these types is not yet known. Nor is there any reliable criterion of "dysplasia" or the inherited potential dislocation. Regarding the 44.2% of babies with limitation of abduction in Caffey's figures, it should be noted that most of them were slight limitations and that only 8.2% had limitation to 60% and only 3.8% had unequal limitation. In my experience the limitation in cases of congenital dislocation has been marked. It has been my practice to have x-rays of all such cases. In milder degrees of limitation the mother has been shown abduction exercises and the child seen again in three months. If the condition is simply what Denis Browne calls an asymmetric pelvis then abduction will have become freer. If it were a dislocation then persistence of the limitation would lead to an x-ray which would reveal it without undue loss of time. In fact, none of these milder asymmetries has yet proved to have a dislocation. Dr. E. Loewenstein-Kuester's letter (*Journal*, September 20, p. 743) reminds us how important this condition is. My anxiety is that enthusiasm may lead to a spate of unnecessary (and not necessarily harmless) pelvic radiography, and even unnecessary treatment of alleged "preluxations."

REFERENCE

¹ Caffey, J., Ames, R., Silverman, W. A., Ryder, C. T., and Hough, G. *Pediatrics*, 1956, 17, 632.

OUR EXPERT replies: The further comments of Mr. Nixon and of Dr. Laurenson are of interest. It is appreciated that there are difficulties, but, like Dr. Laurenson, I feel that the occasional abnormal skin crease is an indication for examination, and if necessary radiology, to avoid the tragedy of late diagnosis of congenital dislocation of the hip.

Corrections.—Dr. M. J. TARSH writes: My attention has been drawn to certain historical inaccuracies in my summary of the background of the Hebrew University Medical School (*Journal*, September 6, p. 605). The British Mandate in fact ended on May 14, 1948, and not in 1947. Mr. Ben Gurion declared the existence of the State of Israel on the next day. The "year of intermittent fighting" that I mentioned took place immediately from this date and is usually referred to as "The War of Liberation." The combined Arab attack to which I referred started also on May 15, 1948. Mount Scopus was and still is an area of great strategic importance.

There was a mistake in Figure 1 in the article entitled "The Physiological Activity of D-Thyroxine" by Dr. Raymond Greene and Miss Helen E. A. Farran (November 1, p. 1057): under "Dosage," in the bottom right-hand corner of the figure, the squares denoting L-thyroxine and D-thyroxine should be transposed.

In the article "Rationale of Antihistaminic Therapy in Thermal Injury," by Drs. D. L. Wilhelm and Miss Brenda Mason (*Journal*, November 8, p. 1141), line 31 of the first column on page 1142 should read "... was graded $\pm$, $\pm$, $\pm$, $\pm$, $\pm$, $\pm$," and the last line of the first column on page 1142 should read "... as little as 10 μ g./kg. to $\pm$ (Fig. 1)."

Collected Articles from the "British Medical Journal"

PNEUMONIA COMPLICATING ASIAN INFLUENZA

BY

NEVILLE C. OSWALD, T.D., M.D., F.R.C.P.,
PhysicianR. A. SHOOTER, M.D.,
BacteriologistM. P. CURWEN, M.A.,
Statistician

St. Bartholomew's Hospital, London

The epidemic of influenza which later became known as "Asian flu" apparently originated in China in February, 1957, and its causative organism, a new variant of influenza virus A, was first identified in cases which occurred in Hong Kong in April, 1957 (Meyer, Hilleman, Miesse, Crawford and Bankhead, 1957). The epidemic spread rapidly across Asia and Europe, and appeared sporadically in Britain during the summer months. The first wave of infection occurred in Yorkshire; it spread almost immediately to the North and more slowly to the South, the North having the more severe experience (Martin, 1958). Local outbreaks developed in many places in the latter half of August, but October was the peak month, and the infection had virtually disappeared by the end of November.

Asian influenza attacked an estimated twelve million people in Britain, and was directly or indirectly responsible for about 16,000 deaths, two-thirds of the fatalities being in persons over the age of 55 (W.H.O. Weekly Epidemiological Record, 1958). The mortality rate was not exceptional, possibly owing in part to the outbreak having passed its peak before the usual minor respiratory infections and winter ailments had become widespread. The incidence of pulmonary complications, principally pneumonia, was also low, figures for general practices being 3.5% of 750 (Fry and Hume, 1957) and 5% of 542 (Edmundson and Hodgkin, 1957), and amongst R.A.F. recruits 5% of 391 (Gilroy, 1957); it increased steadily as the epidemic progressed (Cantor, 1957; Gilroy, 1957). No accurate figures are available to indicate the frequency of pneumonia amongst emergency hospital admissions for Asian flu, but it is unlikely to have been much in excess of one-half, at least so far as London hospitals were concerned: this was also the experience of Walker, Douglas, Leckie, Pines, and Grant (1958) in Edinburgh.

Early in the epidemic it became evident that no single hospital was likely to have sufficient clinical material for a comprehensive study of the various pulmonary complications. Also, with much interest attaching to the significance of superinfection by *Staphylococcus aureus*, a special investigation of staphylococcal pneumonia would necessitate the inclusion of a large number of hospitals.

Material

Two surveys were devised—one to examine the general pattern of all influenzal pneumonias admitted to a group

of hospitals, and the other to assess the clinical significance of secondary invasion by *Staph. aureus* by collecting instances of staphylococcal pneumonia from a wide range of hospitals. The following comprised the material.

1. The clinical, radiological, and pathological records of all cases of pneumonia occurring in the ten London undergraduate teaching hospitals during the autumn of 1957. Firm clinical evidence of influenza was required in each case, together with radiological or pathological proof of pneumonia, except in a very few in which the clinical evidence appeared to be unquestionable. Many doubtful cases were discarded, including some with probable pneumonia which were not x-rayed at the height of the disease. A total of 165 cases satisfied these criteria, of which 20 (12%) were regarded as instances of staphylococcal pneumonia. The design of the survey was such that viral identification could not be insisted upon.

2. The clinical, radiological, and pathological records of cases of staphylococcal pneumonia admitted to hospitals in the London area, mainly in the North-east Metropolitan Region (93), the Royal Navy (8) the Army (13), and the Royal Air Force (21), making 135 cases altogether, during the autumn of 1957. The criteria of influenza were the same as for the teaching hospitals.

Comparison between Staphylococcal and non-Staphylococcal Pneumonia

In order to compare staphylococcal and non-staphylococcal pneumonia, the 20 staphylococcal cases have been extracted from the teaching hospital series and added to those from non-teaching hospitals, so that the comparison is between 145 non-staphylococcal pneumonias from teaching hospitals and 155 staphylococcal pneumonias from all sources.

The serious consequences of secondary infection by *Staph. aureus*, particularly in children and young adults, are amply confirmed by this investigation. Table 1 shows the mortality rates by age and sex in the two groups. The high proportion aged 15-34 in the staphylococcal group is partly accounted for by the inclusion of Service patients. The most striking feature is that for staphylococcal pneumonia age had no effect upon mortality, whilst for non-staphylococcal pneumonia almost all the deaths were in the oldest age group.

TABLE I.—Mortality in Relation to Age and Sex

	Total	Age (Years)				Sex	
		0-14	15-34	35-54	55-	Male	Female
Staphylococcal pneumonia	No. . . 155 Deaths 44 % . . 28	10 3 30	74 19 26	28 8 29	43 14 33	98 25 26	57 19 33
Non-staphylococcal pneumonia	No. . . 145 Deaths 18 % . . 12	10 — —	38 1 3	35 1 3	62 16 26	86 11 13	59 7 12

An attempt was made to grade the severity of the infection in each case into mild, moderate, or severe. Although complete accuracy was not possible, mainly because of difficulties in definition, consideration of the various clinical aspects and their responses to treatment resulted in the allocation of individual cases to one or other of the three categories with reasonable confidence. Table II shows the distribution. In the staphylococcal

TABLE II.—Severity of Infection in Staphylococcal and Non-staphylococcal Pneumonia Complicating Asian Influenza

	Mild	Moderate	Severe
Staphylococcal pneumonia	19	65	71
Non-staphylococcal pneumonia	42	69	34

group, 71 (46%) of the patients were severely ill, compared with 34 (23%) of those with non-staphylococcal pneumonia, many of whom were elderly and had associated chronic bronchitis or cardiac disease.

In a review of the various clinical features the staphylococcal series consistently showed the severer reaction. The median duration of symptoms before admission was five days for the patient with staphylococcal pneumonia and four days for the others; 18% of each group had symptoms for less than two days, and their mortality was higher than those with longer histories. The median duration of stay in hospital of the survivors in the staphylococcal group was 26 days, compared with 16 days for the others. Only 12 of the staphylococcal patients were in hospital for less than a fortnight, compared with 50 of the others. Part of this difference is accounted for by the long stay of the Service patients; of the 42 with staphylococcal pneumonia, 25 were in hospital for four weeks or more, but, even excluding these, the median for the remainder was 24 days.

Examination of temperature charts showed that deaths occurred in patients with maximum recorded temperatures ranging from 99° F. (37.2° C.) to over 105° F. (40.6° C.), and that a high temperature by itself did not carry a poor prognosis. However, the median duration of fever in the survivors was twice as long in the staphylococcal group (eight compared with four days), as was the duration of a temperature above 100° F. (37.8° C.) (four compared with two days); 32% of the staphylococcal and 4% of the non-staphylococcal patients had a temperature of 100° F. (37.8° C.) or over for more than a week. In assessing the total length of fever, some account must be taken of the four to five days' duration of symptoms before admission, which, so far as could be determined from the notes, was usually a febrile period. Hence the total duration of fever in the survivors was probably of the order of two weeks for the staphylococcal cases and eight days for the others.

There was a sharp difference in the radiological features in the two groups (Table III). In the staphylococcal pneumonias 37% of all patients had three or

more zones involved, compared with 19% for the others. In each group mortality increased sharply with the number of zones affected. Although no radiographs were taken of almost half the patients who died, necropsy proof of extensive pulmonary involvement was almost invariable when this examination was performed. The excess of lung abscesses in the staphylococcal series is to be expected.

TABLE III.—Radiology at Height of Disease

	Total	No. of Zones Involved				Abscess	No Radiograph Taken
		1	2	3	4 or More		
Staphylococcal pneumonia	No. . . 155 Deaths 44 %.. 28	27 2 7	44 4 9	27 4 15	30 11 37	21 — —	27 23 85
Non-staphylococcal pneumonia	No. . . 145 Deaths 18 %.. 12	65 — —	38 4 11	16 3 19	12 6 50	2 — —	14 5 36

These findings amply confirm the virulent nature of staphylococcal pneumonia complicating Asian influenza. Compared with non-staphylococcal pneumonia, it caused a severer and longer illness, with a higher and more prolonged fever, radiological evidence of more extensive pulmonary involvement, and, most important of all, a high mortality in children and young adults.

Pathological Aspects

Bacteriology

Table IV shows the principal pathogenic bacteria which were isolated from sputum. In the staphylococcal series, *Str. pneumoniae* and *H. influenzae* were found on a few

TABLE IV.—Principal Pathogenic Bacteria in Sputum

	Cases	Organisms*						Not Tested
		<i>Staph. aureus</i>	<i>Str. pneumoniae</i>	<i>Strep. pyogenes</i>	<i>H. influenzae</i>	<i>Kleb. friedländeri</i>	Non-pathogens	
Staphylococcal pneumonia	155	151	7	—	6	—	—	4
Non-staphylococcal pneumonia	145	—	24	2	23	2	74	30

* More than one organism was cultured from several cases in both series. Of the four cases in the first series in which the sputum was not tested the diagnosis was made in one from a blood culture and in three at necropsy.

occasions. Whether *H. influenzae* should be regarded as a pathogen in this context is not clear; certainly it is capable of producing pneumonia, but the evidence that it does so very often is uncertain. In the non-staphylococcal group, almost exactly one-half yielded no pathogens, and a further 21% either had no sputum or did not have it examined; of the remainder *Str. pneumoniae* and *H. influenzae* occurred with equal frequency (16 and 17% respectively), and *Str. pyogenes* and *Kleb. friedländeri* were found on two occasions each.

Antibacterial Therapy

Table V shows the frequency with which the various antibacterial drugs were used. In the non-staphylococcal series, penicillin was administered to no less than 74% of the patients and one or other of the tetracycline group to 32%. Most of the patients had an illness of only mild or moderate severity, and a single drug sufficed to effect a cure in most of these. Indeed, 60% of patients had only one antibacterial drug. The other remedies, such as streptomycin and chloramphenicol, were usually reserved for severe infections and were given either in conjunction with the first choice or after it had failed.

In the staphylococcal series, the pattern of chemotherapy was rather different. Although penicillin (76%) and the

TABLE V.—Number of Patients Treated with Various Drugs

	No. of Patients Treated	
	Non-staphylococcal	Staphylococcal
Sulphonamides	16	12
Penicillin	108	118
Tetracycline	47	76
Chloramphenicol	13	25
Streptomycin	20	37
Erythromycin	2	39
Novobiocin	—	3

tetracycline group (49%) were the most popular, erythromycin, streptomycin, and chloramphenicol were used much more frequently than in the non-staphylococcal series. Only 28% were given a single drug. The great majority had at least two of the remedies listed in Table V, and two had as many as five. These were usually given either in an effort to overcome fulminating influenza or in order to conform with the results of tests for drug sensitivity. The sensitivities of the various staphylococci are given in Table VI, according to whether they were isolated (a) within four

TABLE VI.—Sensitivities of Staphylococci Isolated from Patients with Staphylococcal Pneumonia Following Influenza

	(a) Isolated Within 4 Days of Admission			(b) Isolated More Than 4 Days After Admission			(c) Influenza Contracted in Hospital			% Resistant (b+c)
	No.	Resistant	%	No.	Resistant	%	No.	Resistant	%

Erythromycin	60	4	7	17	1	6	8	0	4	4

days of admission and were presumably acquired outside hospital, (b) more than four days after admission and could well have been acquired within hospital, and (c) from patients already in hospital when they contracted influenza. As might be expected, the latter groups show a considerably higher resistance rate to the more commonly used antibiotics, penicillin, streptomycin, and tetracycline, the figures being 93%, 62%, and 74% respectively, compared with 49%, 12%, and 22% of strains isolated within four days of admission. The low rate of resistance to chloramphenicol and erythromycin probably reflects the relatively restricted use of these drugs in the past. An attempt was made to correlate the *in vitro* sensitivities with therapeutic responses, but, chiefly because of the many occasions on which two or more drugs were prescribed either together or in succession, no valid conclusions could be drawn.

White Blood Cell Count

In almost all hospitals a white blood cell count was done as a routine, usually with a differential count in addition. In 26 patients the count was repeated after an interval, but the great majority had only a single observation. Table VII shows that the test was carried out in all but 40 of the

TABLE VII.—White Blood Cell Counts Within Five Days of Admission to Hospital Related to Deaths and Survivors from Severe Infections

	W.B.C.	Cases	Deaths (a)	Survivors from Severe Infections (b)	% of Deaths and Survivors from Severe Infections (a+b)
Staphylococcal pneumonia	<6,000 . . . 6,000— . . . 14,000— . . . Not known . . .	18 63 34 40	3 17 6 18	5 10 9 5	44 43 44 57
Non-staphylococcal pneumonia	<6,000 . . . 6,000— . . . 14,000— . . . Not known . . .	34 71 23 17	5 5 1 7	3 9 5 2	24 20 26 53

155 staphylococcal patients and all but 17 of the 145 non-staphylococcal patients. In both groups counts were omitted in several patients who died shortly after admission. The findings strongly suggest that no relationship exists between a white cell count taken within five days of admission and either the severity of the illness or the mortality. Despite the theoretical argument that it might help to differentiate a predominantly viral infection from one with secondary invasion by a pyogenic organism, this examination, at least so far as pneumonia complicating influenza is concerned, seems to provide little information of value, and the rarity of serial counts confirms this view.

Clinical Aspects

Although the majority of patients overcame their infections without causing undue alarm, many had features which are associated with a grave prognosis, such as mental changes, prostration, pallor, cyanosis, and excessive dyspnoea. In a number of instances the influenza was superimposed upon other diseases—for example, chronic bronchitis and cardiovascular disorders. In order to enlarge the experience of these more formidable aspects, a further 79 cases of non-staphylococcal pneumonia have been added to the staphylococcal and non-staphylococcal groups compared above, making 379 cases altogether. The further 79 cases were from non-teaching hospitals; some were thought originally to be instances of staphylococcal pneumonia, the others were from hospitals which supplied non-staphylococcal in addition to staphylococcal material. They were to some extent a selected group with severe infections, and so could not be included in the foregoing comparison between staphylococcal and non-staphylococcal pneumonias.

Previous History

Chronic Bronchitis and Emphysema.—A previous history of chronic bronchitis was noted in 84 patients, and of these 25 (30%) died. The great majority were over the age of 55, and this mortality is similar to the overall rate within this age range. Almost certainly more would have died if the epidemic had reached its height in the winter months, but some credit must be given to their medical attendants, principally general practitioners, for instituting early and effective treatment in this vulnerable group. The pattern of infection did not differ appreciably from that in non-bronchitics, but any tendency to asthma or bronchospasm exaggerated the degree of dyspnoea.

Ischaemic heart disease was present in 11 patients, of whom six died, and hypertensive heart disease in six, with two deaths. Cardiac failure contributed to a fatal outcome in several of these.

Several authors have been impressed by the seriousness of Asian influenza in patients with *chronic rheumatic carditis*, particularly mitral stenosis. Reid (1957) saw nine such patients with two deaths, and Govan and Macdonald (1957) had experience of nine patients who were also pregnant, of whom four died. Hers, Goslings, Masurel, and Mulder (1957) found 10 rheumatic hearts in 252 necropsies, and Giles and Shuttleworth (1957) seven in 46 necropsies; Roberts (1957), examining 12 cases of fatal fulminating influenza, noted mitral stenosis in three. In our series, eight patients had chronic rheumatic carditis (six mitral stenosis, two aortic incompetence), of whom four died. These figures are well in excess of the expected mortality, and associated rheumatic heart disease must be regarded as a serious disadvantage.

Pregnancy.—In its later stages, pregnancy certainly constitutes a hazard when influenzal pneumonia is superimposed. Of seven pregnant women in this series, two died, one having mitral stenosis in addition. The others were all very ill, and four delivered their babies at the height of the infection.

Diabetes.—Of nine diabetics, six died, four of whom were admitted in a state of coma with grossly disordered carbohydrate metabolism.

Nervous Features

Mental changes are among the most alarming features of influenzal pneumonia. They vary from confusion to delirium and coma, and were present in some degree in 15% of this series. They can be accounted for by three entirely different mechanisms—namely, by anoxia and carbon dioxide retention resulting from pre-existing chronic pulmonary disease or extensive involvement of the lungs and air passages; by "general toxæmia," in which case the adrenals may play a part; or by direct invasion of the brain by viruses or bacteria. The invasive nature of influenzal pneumonia is such that gaseous exchange in the lungs may easily become inadequate, particularly in patients with pre-existing chronic pulmonary diseases, and the resulting acute anoxia will readily contribute to mental impairment. "General Toxæmia" is discussed later in relation to fulminating influenza. Evidence of direct microbial invasion of the brain is fragmentary.

Although the existence of true influenzal encephalitis remains somewhat nebulous, the clinical features in several of the cases reported in the present outbreak have been typical of a viral encephalitis; but the organism has not been found in the brain, and the changes in the cerebrospinal fluid have been scanty or absent (Dubowitz, 1958; Smith, 1958; Dunbar, Jamieson, Langlands, and Smith, 1958). McGill and Goodbody (1958) report an instance with extensive haemorrhages in the white matter, conforming to the acute haemorrhagic leuco-encephalitis described by Crawford (1954), but Giles and Shuttleworth (1957) were unable to find any microscopical evidence of encephalitis in two patients admitted to hospital in coma and whose brains showed intense congestion and oedema. Perhaps further evidence of the possible neurotropic properties of the Asian strain will be forthcoming. The following are instances of neurological involvement in this series.

L. S., male aged 44. On admission, two days' history of cough, sputum, pleurisy, stiffness of neck, and mental confusion. Temperature 104° F. (40° C.); purulent sputum containing *H. influenzae*; radiological consolidation in three zones. Diagnosed as "meningism," the cerebrospinal fluid containing 27 cells per c.mm., 90% lymphocytes, 10% polymorphs. Treatment with penicillin and "sulphatriad" resulted in a complete clinical recovery in six days; discharged from hospital after 16 days.

A. M., male aged 17. Admitted to hospital on day of onset, with general aches, cough, and mental confusion. Temperature 103° F. (39.4° C.), scanty mucopurulent sputum containing no pathogens, radiological consolidation right base. Treated with penicillin, but fever persisted with increasing delirium leading to coma and generalized convulsions. Died on the tenth day. Post-mortem examination showed deeply congested superficial cerebral veins with slightly blood-stained fluid in both ventricles; no microscopical evidence of haemorrhage or encephalitis.

T. B., male aged 22. On admission, six days' history of increasing illness with moderate fever and delirium. Radiological consolidation of right middle and lower zones; *Staph. aureus* isolated from thin right purulent effusion on day of admission. Treated with penicillin, streptomycin, and erythromycin in full doses. Became rapidly comatose, the cerebrospinal fluid being purulent and containing 2,160 cells per c.mm., mainly polymorphs. Died on tenth day of illness. Necropsy showed extensive pneumonia of both lungs with multiple small staphylococcal abscesses. The brain contained several septic infarcts in addition to meningitis.

D. C., male aged 22. On admission, three days' history of increasing headache, dyspnoea, and mental confusion. Temperature 104° F. (40° C.); purulent sputum contained *Staph. aureus* sensitive to all drugs; patchy radiological consolidation in all zones of both lungs. Stiffness of the neck led to a diagnosis of meningism, and the cerebrospinal fluid contained 12 cells per c.mm., of which 11 were lymphocytes. Treated with penicillin, tetracycline, and chloramphenicol, he made a complete recovery in a month.

The third of these patients evidently died from septic emboli which derived from the lungs. The others had fairly firm clinical evidence of encephalitis, but pathological proof was lacking.

Amongst the minor neurological disorders, one young adult, who had a sharp attack of influenza, developed weakness and tingling of one leg which was attributed to a toxic neuritis; it resolved completely in three weeks. Another had a transient weakness of one arm.

Post-influenzal depression was noted on a number of occasions.

Fulminating Influenza

A diagnosis of fulminating influenza is often made in patients whose clinical features are alarming and in whom the degree of toxæmia is extreme. Despite the lack of a clear definition, the term is a useful one. In the 1918-19 epidemic the graver forms were referred to as "pneumonic influenza," the course of the illness being regarded as "fulminating" (French, 1920). Clearly, emphasis upon the pulmonary component to the exclusion of the state of the air passages and the degree of toxæmia is undesirable, and the somewhat non-committal term fulminating influenza is now generally used to describe the severest forms of this infection (Scadding, 1937; Stuart-Harris, 1953).

In this series 132 patients were judged to have been gravely ill, of whom 76 (58%) died. How many of these should be regarded as instances of fulminating influenza is a matter of opinion, but, so far as could be judged from the records, they all fell within the category. They had the features ordinarily associated with this diagnosis in the following proportions: prostration (55%), cyanosis (80%), pallor (12%), mental disturbance (48%), excessive dyspnoea (62%), and blood-stained sputum (36%). The figures are comparable to those from previous epidemics, and the reason for the large total is that the cases were derived from a considerable number of sources and contained a high proportion (71, or 54%) of instances of staphylococcal pneumonia.

Perhaps the outstanding qualities of fulminating influenza are the short duration of the acute illness and the severe degree of toxæmia, so that effective treatment to combat collapse must necessarily be given quickly. In addition to oxygen therapy, antibacterial drugs, and the maintenance of a clear airway, which are considered elsewhere, the possibility of steroid therapy arises, the value of which in the present epidemic has produced conflicting opinions. Plaza de los Reyes and Cruz-Coke (1957) and Rotem (1957) claim to have obtained good results; Walker *et al.* (1958) are not particularly impressed; and Gunn (1957), after observing four fatal cases treated in this way, thinks that they should not be given and suggests that they may interfere with immunity mechanisms. Librach (1957), summarizing the evidence for and against steroid therapy in acute infections, advocates caution. Before passing final judgment, three aspects need to be considered.

(a) *Evidence of Adrenal Damage.*—Macroscopic evidence of damage was rarely encountered in the present epidemic. Amongst the necropsies in this series, the state of the adrenals was recorded on 24 occasions. None showed gross changes, but the following were observed: acute congestion (2), loss of cortical lipoid (2), enlargement and tenseness (1), and a few focal haemorrhages (1). Warrack (1957) cites an instance of fulminating influenza in which the adrenals showed only a minimal amount of functional tissue, with heavy intercellular haemorrhage. Adrenal haemorrhage was noted on only eight occasions in a survey of 219 necropsies undertaken by the Public Health Laboratory Service (1958). Hence evidence of structural damage is not impressive.

(b) *Effect of Toxæmia upon the Adrenals.*—Adrenal impairment, which need not necessarily be accompanied by evidence of macroscopic or microscopic damage, may prevent the output of large quantities of hydrocortisone and thus lead to a relative failure. The acute toxæmia of fulminating influenza rarely lasts for more than a few days, so that the administration of hydrocortisone would be no more than a form of substitution therapy. Its frequent use in similar crises, such as post-operative states, suggests that it does not interfere with the processes

of inflammation and healing provided that it is used for a short time only.

(c) *Nature of Fulminating Influenza.*—The essential components are inflammation and obstruction of the airway to the lungs, pulmonary oedema, haemorrhage and pneumonia, and toxæmia. Steroid drugs can hardly be expected to relieve tracheobronchial obstruction, and their ability to restrict the spread of infection in the lungs is doubtful. Where they are most likely to succeed is in the suppression of circulatory collapse resulting from toxæmia, and this is the purpose for which they are given.

Biochemical proof of inadequate adrenal response to fulminating influenza is not so far forthcoming, and when we are faced with a desperately ill patient the results of such tests as are available cannot be awaited. Surely the best policy is to give hydrocortisone for a few days in the reasonable hope that it will be effective and the almost certain knowledge that it will do no harm.

In this series some 27 patients had steroid therapy in adequate dosage, usually 100 mg. of hydrocortisone intravenously, followed by 50 mg. 6- or 12-hourly; of these, 17 died. The relative importance of obstructed airway, loss of effective alveolar surface, and toxæmia in each case cannot be accurately assessed from the notes. Also, eight of the deaths occurred within 24 hours of admission to hospital. However, the impression is that the survivors were those with a reasonably free airway and comparatively little radiological evidence of consolidation who responded promptly to a combination of hydrocortisone and antibiotics.

The following case illustrates the difficulties of clinical assessment.

L. S., female aged 16. Influenza started with a cough, sore throat, and left pleuritic pain. She remained at home, feeling reasonably well with a mild fever, until the fifth day, when she was admitted to hospital with a few hours' history of increasing illness and delirium. On examination she was prostrate, pale, and semicomatose. She had a tachycardia and a temperature of 104° F. (40° C.). Her breathing was unembarrassed, she had no sputum, and there were signs of bronchitis in her lungs; a radiograph of her chest showed patchy consolidation at the left base. Within an hour of admission she had 50 mg. of hydrocortisone and 250 mg. of erythromycin intravenously, and 20 ml. of anti-staphylococcal gamma-globulin. After four hours she was much improved, and at the end of 24 hours she seemed to have fully recovered. Erythromycin was continued, by mouth, for a further two days, and she was discharged from hospital perfectly well after 16 days.

Obstructed Air-passages

In the early stages of influenza the brunt of the infection often falls upon the epithelium of the trachea and bronchi. The inflammatory reaction may be severe enough to cause obstruction to airflow, with consequent stridor and indrawing of the soft tissues of the neck during inspiration; if unrelieved, it can by itself lead to a fatal outcome. On reaching the lungs the infection characteristically passes through the phase of oedema and haemorrhage before frank consolidation develops. Hence, from the therapeutic standpoint, the need to relieve respiratory obstruction occasionally overshadows all other measures, and this particularly applies in fulminating influenza.

Tracheobronchial intubation serves the dual purpose of enlargement of the airway by the removal of debris, usually at the expense of damage to the acutely inflamed respiratory epithelium, and the aspiration of inflammatory products and oedema which derive from the lungs; these latter may not amount to more than an ounce or two at a single aspiration, but their removal often gives considerable symptomatic relief. Therefore, adequate clinical and, if possible, radiological assessment must be made before intubation in order to determine so far as is possible the extent both of the obstruction to airflow and of the pulmonary oedema.

Bronchoscopy, perhaps because it is the commoner procedure, can often be performed more quickly and easily than tracheotomy. It has the advantage that the larger bronchi can be aspirated under direct vision, but it is dis-

tressing and exhausting, and the inevitable epithelial damage is such that the instrument should not be passed more than once. Indeed, bronchoscopy should probably be reserved for acute emergencies only.

Tracheotomy, the treatment of choice in tracheobronchial intubation, is a minor procedure in the hands of experts, and enables the nursing staff to carry out repeated suction by catheterization.

Despite the theoretical objections of some authors (Sheldon, 1957), intubation was regarded as a life-saving procedure in the present epidemic by the majority (Anderson and Niblock, 1957; Rawlins, 1957; Walker *et al.*, 1958). Almost certainly it should have been performed earlier and more frequently. In this series bronchoscopy was carried out three times (no deaths) and tracheotomy six times (three deaths). Several other patients had clinical evidence of a stridor, which usually resolved with antibiotic therapy; but a very large number had extensive pulmonary oedema, and upon them aspiration was not attempted.

L. P., female aged 9. Admitted with two days' history of increasing dyspnoea, sore throat, and vomiting. On examination temperature 104° F. (40° C.), extreme dyspnoea, cyanosis, stridor, and sucking in of soft tissues of the neck during inspiration. Lung fields radiologically clear; purulent sputum contained scanty *Staph. aureus*. Dramatic recovery in four days with antibiotics, tracheotomy, and repeated tracheobronchial aspiration.

D. P., female aged 8. Admitted with two days' history of general aches, rigor, and increasing dyspnoea. On examination temperature 104° F. (40° C.), she was collapsed, cyanosed, and breathless with stridor. Extensive confluent radiological opacities in all zones of the right lung. Purulent sputum contained *Staph. aureus*. Failed to respond to tetracycline and erythromycin, becoming increasingly breathless, and died on the sixth day of her illness. No bronchoscopy or tracheotomy. Necropsy showed that the whole of the trachea and main bronchi were filled with thick tenacious yellowish-brown mucopus. The lungs showed extensive haemorrhagic oedema and bronchopneumonia with multiple small abscesses.

Lung Abscess

Radiology cannot reflect the true incidence of abscess formation in the acute stages, because the ring shadows are often obliterated by surrounding pneumonia and oedema. This was frequently seen when comparing radiographs with necropsy specimens, and applied particularly to the smaller abscesses which occur so commonly in acute staphylococcal pneumonia. However, radiological cavitation was observed on 25 occasions—staphylococcal 21 (14%), others 4 (2%). There were no deaths in this group, principally because they could not be diagnosed in the acute stage.

In the staphylococcal series, several of the large lung abscesses were diagnosed two weeks or more after the onset of influenza in patients who felt that they had more or less recovered from their infections but who were troubled by excessive purulent sputum. Most of the abscesses responded rapidly to antibiotic therapy. During the short period of observation available, 13 resolved completely, 5 became hairline cysts of which 2 persisted, 2 continued as thin-walled cavity systems, and 1 remained a rather thick-walled cavity after two months. The four lung abscesses in patients from whom *Staph. aureus* was not isolated resolved with treatment; staphylococci might well have been found in these if they had been looked for earlier and more thoroughly.

Pleural Effusion

Pleural effusions occurred in 24 patients: staphylococcal 18 (12%), and others 6 (3%). For the most part they were small and serous, and resolved without treatment or following simple aspiration. There were four empyemata, three of which were successfully treated by aspiration and the instillation of penicillin. The fourth was a classical example of an acute staphylococcal lung abscess which ruptured into the pleural cavity and produced a pyopneumothorax. Aspiration was followed by pleural decortication and a full recovery.

Cardiovascular Complications

Acute myocarditis may have been the precipitating cause of death in a few cases of fulminating influenza, probably resulting more from the general toxæmia than from any specific effect of the virus upon the myocardium. Giles and Shuttleworth (1957), in a series of 46 post-mortem examinations, frequently encountered cardiac enlargement for which there seemed to be no adequate explanation, and myocardial oedema was in their opinion the most constant microscopical finding. The following are instances of myocardial involvement.

P. M., female aged 19. Admitted to hospital with one day's history of general aches, lassitude, cough, and pleuritic pain. During the next six days her condition gave rise to no anxiety, her temperature did not exceed 100° F. (37.8° C.), and a radiograph of her chest after four days showed no abnormality. Her scanty sputum was not examined. On the seventh day of her illness she rapidly became worse, with delirium leading to coma, and died on the eighth day, despite large doses of penicillin, chloramphenicol, intravenous steroids, and staphylococcal antitoxin. Post-mortem examination revealed extensive pneumonia and haemorrhagic oedema of both lungs, a culture growing *Staph. albus* only. The pericardial sac contained a few ounces of clear yellow fluid, and there were a few subpericardial petechiae. The heart was dilated, weighed 251 g., and the myocardium was pale, soft, and claylike in consistency. Subendocardial haemorrhages were seen throughout the left ventricle.

P. McL., female aged 23. Admitted to hospital with seven days' history of lassitude, general aches, and pleurisy. On examination she was semicomatose, cyanosed, breathless, and had a temperature of 102° F. (38.9° C.). She was treated with intramuscular chloramphenicol and intravenous hydrocortisone, but died 30 hours later. Necropsy showed extensive bronchopneumonia and haemorrhagic oedema of the lungs with one acute abscess, measuring an inch (2.5 cm.) across. The pericardium contained 400 ml. of green purulent fluid with rough fibrin deposits. The heart was dilated, weighed 300 g., and the myocardium was creamy white, very soft, and of claylike consistency; there were a few small abscesses in the wall of the left ventricle. Coagulase-positive staphylococci and haemolytic streptococci group A were cultured from the trachea, the lungs, and the lung abscess; the streptococci were also grown from the blood and the pericardial fluid.

Embolic Phenomena.—Instances of embolic spread to sites outside the thorax were seen only in the staphylococcal series, and then only on four occasions (3%). An example of multiple cerebral infarcts has already been cited. Another patient developed several emboli of his fingers and toes, and acute arthritis of the knee. *Staph. aureus* was cultured from his blood, and he recovered completely in three weeks with appropriate antibiotics. A third patient developed a septic infarct of his foot which required incision and from which *Staph. aureus* was isolated.

J. C., male aged 23. Admitted to hospital with a history of influenza two weeks previously, from which he never fully recovered. Three days before admission he developed acute arthritis of the ankle. A radiograph of his chest showed confluent consolidation of the greater part of the left lower lobe, and his purulent sputum contained *Staph. aureus*. He responded well to antibiotics, and was discharged from hospital after three weeks with his foot in plaster.

Discussion

Every few years epidemic influenza presents its challenge to medical resources. Reports of outbreaks of Asian influenza during its passage from the Far East suggested that the pulmonary complications were few and the mortality rates low (Guthrie, Forsyth, and Montgomery, 1957; Lim, Smith, Hale, and Glass, 1957; Rowland, 1958). In Britain several problems associated with the pneumonic forms were anticipated, such as the possible number of deaths in the various age groups, particularly in the elderly with pre-existing cardiac and pulmonary diseases, the frequency of the fulminating variety, the nature of the complications, the pattern of secondary bacterial invasion, and the efficiency of the newer remedies such as tetracyclines, chloramphenicol, erythromycin, and the corticosteroids.

The mortality among the 165 patients in London undergraduate teaching hospitals was 10%, the majority of deaths

occurring at or after the age of 55; this compares with 11% of 262 pneumonic patients analysed by the Combined Study Group, Dundee (1958), and 17% of 69 similar patients seen by Walker *et al.* (1958) in Edinburgh. Death rates from pneumonic influenza before antibiotics were discovered were 27.5–40% in the pandemic of 1918–19 (Brem, Bolling and Casper, 1918; Opie, Freeman, Blake, Small, and Rivers, 1919; Chickering and Park, 1919; French, 1920), with no improvement in later epidemics (Collins, 1931; Scadding, 1937). Direct comparisons between Asian influenza and pre-antibiotic epidemics are naturally hazardous, owing to differences in virulence of the viruses concerned and of associated bacteria, and the variable times of onset and duration; but if they are limited to cases with pneumonia, these difficulties are to some extent overcome. Certainly, the consistently lower death rates in recent years cannot easily be explained other than by attributing them to improved methods of treatment.

Instances of fulminating influenza occur in all major epidemics and constitute a considerable clinical problem. Owing to the lack of a satisfactory definition, their frequency in this or other epidemics cannot be determined. In the present context they seemed to occur unevenly in and near London, some large hospitals admitting none and others as many as five or six. Of the 132 patients whose influenza was regarded as fulminating, 58% died; 30% of the deaths occurred within 24 hours and 80% within a week of admission. At the height of the outbreak many hospitals were crowded with patients. The medical and nursing staffs, often depleted by the infection, had to care for many influenza patients, one or two of whom might be suffering from this acute medical emergency, against which some of the newer remedies had not been adequately tested. As the epidemic progressed, the pattern of infection became clear and the treatment more definitive. Several hospitals formulated emergency plans for the very ill which were carried out on admission, and consisted in the main of oxygen therapy, intravenous erythromycin and hydrocortisone, and, if available, staphylococcal antitoxin. These measures almost certainly saved lives in the present series, but a study of the records suggested that insufficient use was probably made of early intratracheal intubation.

Secondary invasion by *Staph. aureus*, as had been anticipated, undoubtedly added materially to the severity of the outbreak. It was encountered in 12% of the 165 patients in London undergraduate teaching hospitals, and was very common in pathological series from other sources. Roberts (1957) found *Staph. aureus*, usually in pure culture, in 8 out of 9 cases of fulminating influenzal pneumonia. Hers *et al.* (1957) in 61% of 103 fatal cases of influenza, Giles and Shuttleworth (1957) in 33% of 46 influenza deaths, and the Public Health Laboratory Service (1958) in 62% of 477 fatalities.

Experience in this epidemic has left the question of the choice of antibiotics for routine use to some extent unsolved. The majority of patients overcame their pneumonia uneventfully, and penicillin and tetracycline appeared to be equally effective. The problem lay with the 10–15% who developed staphylococcal pneumonia. Patients treated at home in the first instance, as were one-third in this series, may reasonably be given penicillin or tetracycline in the knowledge that it is suitable for non-staphylococcal infections, and will rapidly resolve about one-half of the staphylococcal infections. Once patients have been admitted to hospital, close co-operation with the laboratory is necessary, so that staphylococci may be identified in direct smears of sputum within two hours and their sensitivities reported from primary cultures in 24 hours. This system was in use in many hospitals taking part in this investigation, and accounts partly for the frequent changes in antibiotic therapy within 48 hours of admission in the staphylococcal series.

The complications were remarkably few. Pleural effusions, with one exception, responded to simple measures, and antibiotics were almost uniformly successful in resolving

From time to time in the history of mankind influenza has taken its toll in terms of human life and suffering. The present pandemic, which appears to have started in North China in the early spring of 1957, spread to Hong Kong, and was first reported from Singapore in May. Cases started to appear in Madras in the same month, after the arrival in the port of s.s. *Rajula* from Singapore. Very soon after, other Indian ports also reported the occurrence of cases. The epidemic thence spread fanwise throughout the country, and by the end of the month most of the towns of South India were affected. The vast majority of these cases conformed to the usual clinical picture associated with influenza and described in previous epidemics (Abrahams *et al.*, 1919; Stuart-Harris, 1945). Early in this epidemic we realized that some of the cases showed unusual clinical features referable to the central nervous system and the liver. These cases were therefore studied in detail, and the observations form the subject of this paper.

Present Investigation

Out of 9,459 cases of influenza admitted to the various military hospitals in South India, a total of 30 showed the features mentioned. All the cases occurred during the peak period of the epidemic in the stations. Sixteen occurred in one station in 17 days. The usual incidence of encephalitis in this station is one or two cases a year. Five cases occurred in another station in 27 days, whereas the usual incidence of encephalitis there is about one a year.

Clinical Features.—These are shown in Table I. They do not pertain to the initial signs and symptoms of influenza but to those of the subsequent illness, during which neurological and hepatic manifestations developed. In a typical case after an attack of influenza the patient was afebrile and progressing well, when suddenly there was an onset of severe persistent vomiting followed very soon by delirium, boisterousness, and coma. Some of these cases had convulsions. In a few, localizing neurological signs were noted. A third of these cases had raised serum bilirubin. Complete recovery occurred in 13, and 17 proved fatal.

Age-and-Sex Incidence.—Age varied from about 14 to 26 years, except one case of a child aged 2 years and 9 months and another of an adult aged 36. All the patients were males. No inference can, however, be drawn from this age-and-sex incidence, since the number of cases affected was small, and the community at risk was of a similar age-and-sex group.

Onset.—As already indicated, after a typical attack of influenza there was an afebrile period varying from one to

Summary

The clinical and pathological records and radiographs of 165 patients with pneumonia complicating influenza admitted to the 10 London undergraduate teaching hospitals in the autumn of 1957 are reviewed. Of these, 20 (12%) were instances of staphylococcal pneumonia.

The non-staphylococcal cases are compared with the staphylococcal cases, together with a further 135 instances of staphylococcal pneumonia complicating influenza during the same period which were derived from hospitals in and near London, mainly in the North-east Metropolitan Region and from the three armed Services.

The severer course and higher mortality in the staphylococcal series are discussed.

The clinical assessment and emergency treatment of fulminating influenza are described, with special reference to bacteriology, choice of antibiotics, steroid therapy, and tracheobronchial intubation.

In order to enlarge experience of the severer forms of influenzal pneumonia and the less common forms of treatment, the records of 79 cases were added to the above series, making a total of 379 cases.

We record our sincere thanks to the many physicians and pathologists who made the collection of so large a series possible, particularly the medical committees of the 10 London undergraduate teaching hospitals, the Senior Administrative Medical Officer, and the medical committees of the hospitals in the North-east Metropolitan Region, and the Medical Directors General and medical officers of the Royal Navy, Army, and Royal Air Force. We are also indebted to individual physicians and pathologists at the following hospitals—Bedford General, Brompton, Buchanan, Lister, Mount Pleasant, North Herts, Royal East Sussex, Royal Northern, Schrodel's, St. Andrew's, Bow, St. Helier, and St. Olave's.

seven days in 20 cases. In seven there was no such interval, while in the remaining three the history of respiratory infection was atypical. Vomiting, which was invariably the first symptom, was present in 29 cases and absent in only one. It started suddenly in 27 and insidiously in two (Cases 6 and 24).

Fever.—This was not a constant feature in all the cases. It was high in eight, and the rest had either a low pyrexia or were afebrile. Headache, which was present in 12, was not a prominent symptom except in one. Some degree of toxæmia was recorded in 13 cases.

Central Nervous System.—Of all the 30 cases showing neurological involvement, 19 went into coma with or without convulsion after passing through a phase of confusion, delirium, and boisterousness. Four of the patients who developed coma ultimately recovered. Seven were only drowsy, and four others were conscious throughout. The degree of cerebral aberration did not affect the ultimate outcome. Fifteen cases showed localizing neurological signs in the form of involvement of the pyramidal tract or conjugate deviation. One patient (Case 24) developed extensive paralysis of muscles of the trunk and limbs but not of the head and neck. He was conscious throughout and died of respiratory failure.

Other Systems.—Icterus was apparent in only one patient, although serum bilirubin was raised in 10—eight died and two recovered.

Laboratory Findings

The laboratory findings are given in Table II. Total and differential leucocyte counts were carried out in all cases and were within normal limits. Urine examination showed the

presence of bile in only one case. Albumin was found in 13 and sugar in four. The presence of sugar in urine, however, was not regarded as very significant, as all these cases were on intravenous concentrated glucose therapy. The serum bilirubin level was raised above 1 mg./100 ml. in 10 cases, the highest level being 4 mg. C.S.F. examination was carried out in 25, but did not show any significant abnormality. Blood-sugar estimation was carried out in 20 cases; the results were within normal limits. Blood urea was estimated in 25. It was raised above 40 mg./100 ml. in four fatal and three non-fatal cases.

Serological findings are given in Table III. In addition to Case 1, as shown in this table, influenza virus A was also isolated from lungs removed at post-mortem examination in Cases 3, 5, 17, and 28. Influenza virus A has also been isolated from the brain of Case 24. The exact relationship of this virus to virus A/Asia/57 is being studied in the Pathology Department of the Armed Forces Medical College, Poona. The serological study for influenza was inconclusive.

The H.I. and complement-fixation tests against arthropod-borne encephalitis viruses were carried out in four cases. The tests were put up against Chikungunya and AR 339 strain of Sindbis of group A viruses and Japanese B. Murray Valley, Egypt 101 strain of West Nile, and Trinidad 1751 strain of Dengue of the group B arthropod-borne viruses. This study did not incriminate any of these viruses as the causal agent.

Treatment

In the absence of any specific therapy various lines of treatment were tried, either singly or in combination.

0=Nil. +=Slight. ++=Moderate. +++=Severe.

+++=Gross. D.=Died. R.=Recovered.

Eighteen cases were treated with heavy doses of intravenous vitamins and concentrated glucose. Tetracycline or chlor-tetracycline in full doses, either parenterally or orally, was administered to 22 cases. Hydrocortisone parenterally, 100 mg. eight-hourly, was used in four cases. Penicillin alone was administered to five cases. It may be reiterated that some of the patients received a combination of vitamins, tetracycline, and hydrocortisone, whereas others received one or two of these products only. No conclusion could be drawn about the effectiveness of any of the treatment given in the present series of cases.

Post-mortem Appearances and Histopathology

All the 17 patients who died were subjected to post-mortem examination, which was performed 2½ to 25 hours after death. Special attention was paid to the lungs, brain, and liver, since all these cases had a history of influenza, and had cerebral symptoms with neurological signs and clinical or biochemical evidence of jaundice.

Lungs.—Naked-eye appearances varied from an intense congestion to patchy haemorrhagic pneumonia. Histologically the general picture was a complete denudation of the ciliated epithelium of the mucous membrane of the bronchial tree. Haemorrhagic consolidation was also present in many of these cases. Case 24, from whose brain influenza virus A was isolated, showed the characteristic bronchial mucosal change without any pulmonary involvement.

Brain.—Naked-eye appearances varied from moderate to severe congestion with petechial haemorrhages in the white matter in all cases, and histology confirmed the presence of diapedesis of cells into the Virchow-Robin space in some. In a few cases neuroglial proliferation was also present. Case 24 showed evidence of neurone degeneration, including satellitosis and neuronophagia.

Liver.—On naked-eye examination no specific change was noticed. Appearances varied from a normal to a mild congestion or a patchy yellowish discoloration. Histologically there was evidence of fatty change not confined to any zone. In 12 out of 17 fatal cases there was evidence of portal or periportal round-cell infiltration. In the majority of cases there was no necrosis of liver cells.

Discussion

In association with various epidemics and pandemics of influenza, respiratory and abdominal complications have been described. Of these the former have been responsible for most of the fatalities. To our knowledge the neurological and hepatic features manifested by our patients have so far not been recorded in the literature, including reports of the recent pandemic (Lim *et al.*, 1957; Holland, 1957; Smith *et al.*, 1957). Non-specific non-localizing cerebral symptoms have been described by many (Cole, 1918; Benjafield, 1919; Abrahams *et al.*, 1919). Edmundson and Hodgkin (1957) have also mentioned facial neuralgia and peripheral neuritis as complications or as possible concomitant diseases with influenza.

All the cases which showed the unusual neurological or hepatic manifestations occurred during the height of the influenza epidemic in the various localities. Every one of them had a preceding influenza-like illness. In the fatal cases incontrovertible evidence of respiratory infection with influenza virus was present. These facts would indicate that the unusual features are in some way related to the influenza infection. Hyperbilirubinaemia was not invariably present, and where serum bilirubin levels were abnormal they were not very high. Cholaemia could not therefore account for the neurological manifestations. Besides, the type of neurological signs seen have not, in our experience, been associated with liver-cell failure. Apart from coma, convulsions, etc., localizing features like pyramidal signs were present in both comatose and non-comatose patients. These facts would indicate that we are here dealing with an encephalitic syndrome.

The clinical manifestations of these patients do not resemble those of the sporadic or epidemic cases of encephalitis reported from Jamshedpore (Chari and Swamy, 1955) or from Lucknow (Kaul, 1955), nor do they conform to the features of arthropod-borne encephalitis (Webb and Pereira, 1956). Serology also excludes the latter group. Such aetiological factors as measles, mumps, and vaccination were not responsible for the abnormal neurological signs.

Although the post-mortem examination (and virus culture) and histopathology have confirmed the presence of respiratory infection with influenza virus, the morbid appearances both of the liver and of the nervous system are variable and indefinite. They have been recorded here for the sake of completion, but it must be mentioned that no definite inference can be drawn from them. Influenza virus A has been isolated from the brain in one patient (Case 24), who also had marked histopathological changes in the C.N.S. Influenza virus has not, to our knowledge, been

isolated from the brain so far, and its significance cannot therefore be assessed without further study. This is being carried out in the Pathology Department of the Armed Forces Medical College, India. It is difficult to state whether the neurological and hepatic syndromes were caused by a new mutant of influenza virus, by the activation during the influenza epidemic of an associated neuro-viscerotropic virus, or by a hybridization of viruses of the type produced by Burnet (1957) in his experimental genetic studies on viruses.

Summary

A short account of the origin and spread of the pandemic of influenza of 1957 is given. In India cases started appearing in Madras in May, 1957, and very soon after it spread to the rest of South India.

Out of a total of 9,459 cases of influenza admitted to military hospitals in South India, 30 developed manifestations of neurological and hepatic involvement. Sixteen of these were reported from one station in 17 days and five from another in 27 days.

These manifestations usually developed after an afebrile period following a typical attack of influenza.

They were ushered in by incessant vomiting followed by delirium, boisterousness, and coma. Half the patients showed localizing neurological signs: raised serum bilirubin was present in one-third.

All the 17 fatal cases were subjected to post-mortem examination. Respiratory system showed appearances typical of influenza. Influenza virus was isolated from the lungs in five of them. The liver showed a variable and indefinite picture. The brain showed congestion and diapedesis of cells. In one case neurone degeneration was present and influenza virus A was isolated from the brain substance.

Serological tests did not indicate an infection with arthropod-borne encephalitis viruses.

From the evidence presented it appears probable that the clinical manifestations of neurological and hepatic involvement are closely related to infection with influenza virus and are of a type not so far described in any other form of encephalitis reported from India. The significance of the morbid anatomy and histology and the exact causal relationship of the influenza virus to the syndrome are, however, not clear.

Our thanks are due to the medical officers who helped in the management and follow-up of the cases and to the officers and staff of the Pathology Department of the Armed Forces Medical College, Poona, for their help in the investigation of cases and examination of post-mortem material. We acknowledge the help and co-operation of the Virus Research Centre, Poona, in undertaking serological studies. Our thanks are also due to Dr. I. G. K. Menon, Deputy Director, Pasteur Institute, Coonoor, for his co-operation. We are grateful to various officers commanding military hospitals in Southern Command, D.M.S. Army, and the D.G. A.F.M.S., for permission to publish the report.

ASIAN INFLUENZA (1957) IN ALLERGIC PATIENTS

BY

B. BENDKOWSKI, M.B., Ch.B.

General Practitioner; Clinical Assistant, Allergy Clinic,
North Lonsdale Hospital, Barrow-in-Furness

The clinical, epidemiological, and pathological aspects of Asian influenza have already been described (*Brit. med. J.*, 1957; Smith *et al.*, 1957; Sweet and Dourado, *Lancet*, 1957; Roberts, 1957; Zhdanov *et al.*, 1957; Fry, 1958; Martin, 1958).

Altogether I treated 344 cases of influenza in general practice during the epidemic in 1957, the first case being seen on August 25, 1957, and the last on November 3, 1957. The practice is an industrial one with 5,560 patients, and I am one of three partners. It was estimated that there were 216 allergic patients in this practice (Hamilton and Bendkowski, 1954). The number of allergic patients has risen with the increase in the size of the practice, and there are now about 250. I treat most of these, and have had an opportunity of studying the clinical course of Asian influenza among them.

Classification

The 344 influenza patients were divided into three groups: (1) allergic (124 cases); (2) non-allergic, but who came from allergic families (59 cases); and (3) non-allergic (161 cases). The distribution of allergic diseases in patients suffering from influenza is shown in Table I.

TABLE I.—Severity of Symptoms Among the 344 Patients

Allergic Disease	No. of Cases			Total
	Very Severe	Severe	Mild	
<i>Allergic Patients</i>				
Bronchial asthma ..	49	4	2	55
Allergic rhinitis ..	20	8	2	30
Respiratory allergy ..	9	2	2	13
Urticaria and angio- neurotic oedema ..	7	7	6	20
Atopic eczema ..	2	1	—	3
Contact dermatitis ..	1	1	1	3
Total ..	88	23	13	124
<i>Other Patients</i>				
With family history of allergy ..	12	25	22	59
Non-allergic ..	27	45	89	161

Findings

Each patient was examined and assessed according to severity of symptoms. This was judged by temperature, headaches, aches and pains, dizziness, vomiting, cough, dyspnoea, sweating, and prostration. Table I shows the severity of symptoms among the allergic patients and among the others.

TABLE II.—Main Finding on Physical Examination

Clinical Finding	No. of Cases		
	Allergic	With Family History of Allergy	Non-allergic
Laryngitis	15	29	105
Bronchitis	48	28	48
Bronchopneumonia	11	1	5
Lobar pneumonia	3	—	3
Bronchitis with asthma	47	1	—
Total	124	59	161

Every patient was examined with special attention to the respiratory system. Table II shows the main clinical finding. There were three cases of epistaxis among the allergic and one case of fits among the non-allergic patients.

Some patients managed to come to the surgery, but the majority of those suffering from influenza asked to be visited at their homes. Table III shows the distribution of home visits among the three groups.

All the patients suffering from influenza were ordered to bed. The duration of bed rest varied in the three groups of patients (Table IV).

TABLE III.—Home Visits

No. of Visits	No. of Cases		
	Allergic	With Family History of Allergy	Non-allergic
1	15	19	50
2	46	28	59
3	31	3	10
4	15	—	5
More than 4	9	—	8
Surgery attendance only	7	9	28
Admission to hospital	1	—	1 (died)
Total	124	59	161

TABLE IV.—Bed Rest

Duration	No. of Cases		
	Allergic	With Family History of Allergy	Non-allergic
< 1 week	24	20	65
1 week	59	24	50
1 week to 10 days	24	1	8
2 weeks	7	—	3
Over 2 weeks	4	—	2
No bed rest at all	6	14	33
Total	124	59	161

In an epidemic of influenza there is no time to wait for complications that might arise. The general practitioner has to deal with the cases promptly. His knowledge of the patients, their previous ailments, their house conditions, and the nursing facilities, as well as the clinical findings—all have to be considered before prescribing treatment. Table V shows the therapy given.

TABLE V.—Therapy

Drugs	No. of Cases		
	Allergic	With Family History of Allergy	Non-allergic
Antibiotics	101	27	65
Sulphonamides	16	14	30
Antispasmodics	54	—	—
Steroid hormones	11	—	—
Analgesics and cough mixtures	7	18	66

TABLE VI.—Time Away From Work or School (221 Cases)

Duration	No. of Cases		
	Allergic	With Family History of Allergy	Non-allergic
1 week	2	13	50
2 weeks	36	25	36
3 weeks	32	1	15
1 month	4	—	4
Over 1 month	2	—	—
Carrying on working	—	—	1
Total	76	39	106

All the working patients and the schoolchildren were advised to rest at home for at least a week to avoid any after-effects (Table IV).

Some of the patients complained of weakness, tiredness, dizziness, and other ill-defined symptoms. Such after-effects were diagnosed as post-influenza debility. Table VII shows the nature of after-effects in patients suffering from influenza.

TABLE VII.—After-effects

Nature of After-effects	No. of Cases			Total
	Allergic	With Family History of Allergy	Non-allergic	
Chronic cough	39	3	11	53
Bronchial asthma	40	1	—	41
Debility	2	—	13	15
Otitis media	3	—	—	3
Total	84	4	24	112

Discussion

Asian influenza affected both the allergic and the non-allergic patients. The virus had a predilection for the respiratory tract, causing laryngitis, bronchitis, and in some cases pneumonia. Patients suffering from bronchial asthma, nasal allergy, or both together (respiratory allergy) were severely afflicted by influenza. Their symptoms were worse than those of the non-allergic patients. The majority of the non-allergic patients (105 out of 161) had only laryngitis. In the allergic group the majority of patients developed bronchitis or bronchitis with exacerbation of asthma, and there were 14 cases of pneumonia. Eight cases of pneumonia occurred among the non-allergic patients. Patients with a family history of allergy showed a tendency to develop bronchitis more readily than the non-allergic patients; there was one case of pneumonia among them.

The duration of bed rest and of the time away from work or school was longer in the allergic patients than in the non-allergic.

The therapy in allergic patients consisted of great amounts of antibiotics, antispasmodics, and steroid hormones; only seven cases were treated with analgesics alone. One non-allergic patient aged 83 died of bronchopneumonia.

The allergic patients caused a great deal of anxiety to their families and to the practitioner during the influenza epidemic. The after-effects, mainly exacerbation of asthma, persisted for a long time. The explanation for the severe clinical picture of influenza in allergic patients is beyond the scope of this article and beyond our present knowledge. Infectious and allergic diseases however, have one thing in common: the antigen-antibody reaction.

Summary

Observation was kept on 344 cases of Asian influenza occurring in general practice. There were 124 patients with personal history of allergic diseases. Allergic patients were severely afflicted by influenza, developing bronchitis, asthma, and pneumonia more readily than the non-allergic patients. The incidence of after-effects among the allergic patients was higher than in the non-allergic.

AGE AND ASIAN INFLUENZA, 1957

BY

JOHN WOODALL, M.B., D.Obst.R.C.O.G.
St. Paul's Cray, Kent

K. E. K. ROWSON, M.A., M.D., Dip.Bact.

AND

J. C. McDONALD, M.D., S.M., D.P.H.
Central Public Health Laboratory, Colindale, London

The object of this investigation was to study the influence of age and related factors on susceptibility to influenza during the 1957 autumn epidemic. Certain other clinical and epidemiological observations that were made are also included in this report. The inquiry was conducted in a general practice in a post-war housing estate on the south-eastern outskirts of London; the doctor (J. W.) had just over 2,000 patients on his list, but those entering or leaving during the study, and a large group of about 200 gypsies, were excluded, leaving a total of 1,732 on whom the results are based.

Methods

From the middle of August, 1957, to the end of the year an attempt was made to record all acute respiratory illnesses in the 1,732 patients who were present during the whole of this period. The illnesses were divided clinically into those that probably were influenza and those that probably were not. Illnesses recorded were those for which the doctor was consulted and others of which he learned by inquiry. Ascertainment in families of four or more persons was probably fairly complete because these were included in a special study of secondary attack rates. Nearly all such families known to have a case of influenza were followed for at least two weeks and a record was made of acute respiratory illnesses before and after the first case seen; families without a known case were visited in December and inquiry was made. Information on smaller families was less complete; illnesses seen were noted and inquiries made about other members of the family then and at any subsequent opportunity. Although there must inevitably have been illnesses which were not recorded and some mistakes in clinical diagnosis, we believe that, for the epidemic period at least, a reasonable estimate of the incidence of influenza was obtained.

For the study of secondary attack rates, 104 families of four or more, in which a probable case of influenza occurred, were investigated in greater detail. So far as possible these were consecutive and unselected families, but some, where good co-operation was not anticipated, were excluded. The clinical features of all acute respiratory illnesses in these families were recorded in a standard manner. Acute and convalescent paired sera were obtained from 99 patients in 89 of the 104 families. Fifteen families were included but not tested, usually because the first subject seen was too young to bleed and there was no further illness in the family. It is possible that a slight bias towards high secondary attack rates in families tested serologically was thereby introduced.

The blood specimens were taken in vacuum tubes (Bayer) and posted to the laboratory, where serum was separated and completed pairs were examined for evidence of influenza-A infection by the complement-fixation test. Of the 99 pairs a fourfold or greater rise in titre was found in 61 and a twofold rise in a further 12; the 61 serologically confirmed cases were in 59 families.

Findings

Age and Sex Incidence

The epidemic lasted about eight weeks and reached its peak in all age groups in the week ending October 13. Most cases in the few weeks preceding the epidemic were in young adults. Attack rates by age and sex up to the end of November are given in Table I. Almost a third (31%) of

TABLE I.—Clinical Attack Rates by Age and Sex (Up to November 30)

Age in Years	Males		Females		Total	
	At Risk	Percentage Attacked	At Risk	Percentage Attacked	At Risk	Percentage Attacked
0-4	115	36	92	25	207	31
5-14	194	51	172	48	366	49
15-39	323	25	352	28	675	27
40-59	192	21	169	29	361	25
60 and over	55	15	68	10	123	12
All ages	879	31	853	30	1,732	31

the patients in the practice had influenza during this period, and, apart from a rather higher rate among males aged 0-4 years, there was little difference between the sexes. About half the schoolchildren were ill, a third of the pre-school children, a quarter of adults under 60, and about an eighth of the older persons. Between December 1, 1957, and January 5, 1958, there were a further 60 illnesses, including five who had been ill before; no specimens were taken from any of the five, so the cause of their illness is uncertain.

Effect of Schoolchildren

As the highest attack rates were among children aged 5 to 14 years, it seemed possible that families with children

FIG. 1.—Weekly incidence of influenza in a Kent practice.

of this age might have suffered more from influenza than those without. That this was so is shown in Fig. 1, which shows that the epidemic was almost confined to schoolchildren and their families. Of the 529 persons who were recorded as having had influenza, 399 (75%) were children aged 5 to 14 or members of families with a child of this age.

TABLE II.—Influenza Attack Rates in Families With and Without Schoolchildren (Up to November 30)

Age Group	With Schoolchildren		Without Schoolchildren	
	No.	Attacked	No.	Attacked
0-4 years	104	34%	103	29%
5-14	357	34%	318	18%
40-59	181	32%	180	17%
60 and over	13	31%	110	10%
Total	655	33%	711	18%

In families that included a school child the attack rate was about 33% in all other age groups (Table II). In families without a school child, only children under 5 had an attack rate approaching this level; the rates among the adults were much lower.

Secondary Attack Rates

There were 59 families in which at least one case of influenza was confirmed by serological tests and a further 45 families similarly studied in which no confirmation was obtained. Secondary attack rates—that is, attack rates among the remainder of the family after exclusion of the first case—were calculated in an attempt to find out whether there was any relation between age and susceptibility under the conditions of home exposure. A family outbreak (or episode) in this calculation was defined as a group of influenzal illnesses, no two consecutive cases being separated by more than seven days. In 86% of episodes all cases occurred within seven days of onset of the first case. Persons with influenza more than seven days prior to the beginning of an episode were excluded from those at risk.

It may be seen in Table III that the secondary attack rates for all age groups under 40 years were similar, but over this age they fell away. Rates based on 59 episodes in families with a serologically confirmed case did not differ greatly from those based on all 104 families (105 episodes).

TABLE III.—Secondary Attack Rates in 104 Families with 4 or More Persons

Age (Years)	All Episodes		Serologically Positive Episodes	
	No. Exposed	Percentage Attacked	No. Exposed	Percentage Attacked
0-4	60	37	57	37
5-14	59	57	38	63
15-39	63	54	26	61
40-59	41	54	20	55
60 and over	28	44	26	58
All ages	39	48	33	64
	82	37	33	36
	56	19	16	13
	21			
All ages	389	49	229	53

TABLE IV.—Order of Onset of Illness in Relation to Age (105 Family Outbreaks)

Age Group	No. Illnesses	1st	2nd	3rd or More
0-4 years	40	13%	52%	35%
5-14	121	52%	29%	19%
15-39	102	30%	34%	35%
40+	40	37%	15%	48%

The lower rates in persons of 40 and over could be explained either by lower susceptibility or by less exposure to infection. The primary cases in family episodes were most frequently in schoolchildren aged 5-14 years and least frequently in children under 5 (Table IV). The subsequent order of becoming ill also varied with age, those of 40 or

more seldom being infected next but most often being third or later. This suggests that older persons may have been less exposed to infection from the younger ones, who introduced it to the family, than were infants and young adults.

In an attempt to overcome the difficulty of unequal exposure the records of all families in the practice without a child aged 5-14 were searched for episodes in which the first case was in a husband or wife. There were 83 such families, and in 14 (17%) the spouse also developed influenza within seven days. Of 59 spouses aged 20-49 years, 9 (15%) were attacked, compared with 5 (21%) out of 24 aged 50 or more.

Serial Intervals

As influenza is probably most infectious during the first few hours of illness serial intervals between dates of onset in family outbreaks may provide a measure of the incubation period. The distribution of serial intervals in the 104 families specially studied is illustrated in Fig. 2; there is a periodicity of about two days, which agrees well with previous estimates.

Clinical Features

There have been many descriptions of the symptomatology of influenza in this and in previous epidemics, but most of them have been based on the study of adults, and little attention has been given to variations associated with age. In the 59 family episodes in which at least one case was confirmed serologically there were 187 illnesses. An analysis of the clinical features in these illnesses is presented in Table V. The general clinical picture was similar to that

TABLE V.—Clinical Features of Illnesses in Serologically Confirmed Family Outbreaks

Age group: No. of Cases:	0-4 24	5-14 71	15-39 70	40+ 22	Total 187

Days in bed (median)	2	3	3	3	3

usually found in influenza, the most prominent complaints being cough, headache, sneezing, nasal symptoms, sore throat, sweating, shivering, and aches and pains. The onset was described as sudden in about half the cases only—less than is usually stated.

Some of the age differences in symptomatology can probably be attributed to the young being less able to describe their troubles; thus it is not surprising that sore throat, headache, and aches and pains were infrequent in those under 5 years of age, whereas malaise was relatively prominent. Other differences, however, may be more real—for

example, the greater frequency of drowsiness, vomiting, diarrhoea, and nose bleeds in the young, or delirium in children of school age, and of aches and pains and faintness or giddiness in adult life. Six cases of pneumonia (3%) and three of otitis media (2%) were the only important complications, and there were no deaths. Two children developed fever and polyarthritides 4 and 12 days after the onset of illness; but haemolytic streptococci were isolated from one, and the sister of the other had otitis media, so it is uncertain whether these should be regarded as complications of influenza.

FIG. 2.—Distribution of serial intervals between first and subsequent cases in family episodes.

Discussion

Much of the value of the age-incidence figures shown in Table I depends on the extent to which they are representative of the country as a whole. From August 21 to the end of the year the number of new claims for National Insurance sickness benefit in Britain was about 2½m. more than the average for the same periods in the previous five years—that is, an increase equivalent to about 12½% of the insured population. We are indebted to the Ministry of Pensions and National Insurance for the information that the excess, compared with the previous year, of claims received by their nearest office (Sidcup) also amounted to about 12½% of the estimated population at risk. As no figure exists for the population normally served by a given insurance office this can be only a rough estimate, but it encourages the belief that the incidence figures are fairly representative of the national experience.

About a quarter of the adults of working age in this practice had an influenza-like illness, which is much greater than the National Insurance figure of 12½%. Sickness benefit can be paid only for incapacity lasting more than three days, whereas many illnesses, either because they were mild or at a week-end, caused lesser or no absence from work, which probably accounts for the difference. Sickness statistics for the past three years, kindly supplied by Morphy-Richards, Ltd., who have a large factory in the same area, showed that the proportion of their employees who were absent rose to 23% during the influenza epidemic compared with a level of about 6% in previous years. The absence rate from influenza was therefore probably more than 17%, and so compatible with the practice figures. If the age-specific attack rates in this practice are applied to the population of England and Wales we may estimate that there were about 12m. cases of influenza—a similar figure to that put forward by Fry (1958). Unfortunately, both these estimates are based on practices in the same part of the country.

From the figures for secondary attack rates (Table III) we infer that the high incidence of influenza among school-

children in the general population was not due to any greater susceptibility to infection in this age group, but to other factors. Outbreaks among schoolchildren appeared to play a big part in the spread of Asian influenza in the country generally last autumn, and it is clear that, in this practice at least, the epidemic was almost confined to schoolchildren and their family contacts. The low attack rate among older people may well have been due to the fact that comparatively few have close contact with schoolchildren.

Though the proportion of schoolchildren who escaped infection with Asian virus was probably small, perhaps three-quarters of the adult population were still susceptible to Asian virus after the autumn epidemic. It is possible that infection smouldering on during the winter contributed to the relatively high mortality in the country during December and January (McDonald, 1958). But even when the winter was over most older persons must still have been susceptible to the Asian virus. It remains to be seen, however, whether any further epidemic is possible until the school population become susceptible once more, either as a result of waning immunity or of antigenic variation in the virus.

Summary

During the autumn epidemic 31% of the patients in a practice on the south-eastern outskirts of London had clinical influenza. About half the schoolchildren were ill, a third of pre-school children, a quarter of adults under 50, and an eighth of adults over 60. It seems probable from National Insurance statistics that the prevalence of influenza in this part of Kent was similar to that for the country as a whole; there may therefore have been about 12m. cases of influenza in England and Wales during the autumn epidemic.

Three-quarters of patients in the epidemic were children aged 5 to 14 years or members of families with a child of this age. In such families the proportion attacked was about 33% at all ages. The falling attack rate with age in the practice as a whole was entirely due to the experience of families without children of school age.

Secondary attack rates were calculated for a group of 104 families in which a case of influenza occurred. Serological confirmation of influenza virus A infection was obtained in at least one patient in 59 of the families. Secondary attack rates for all age groups up to the age of 40 years showed little variation, but above that age the rates fell away. The sequence of becoming ill in these family outbreaks suggested that the lower rates in older people were possibly due to less exposure to infection. Attack rates in husbands and wives supported this view.

The clinical features of illnesses in family outbreaks where at least one case was confirmed serologically varied with age: drowsiness, vomiting, diarrhoea, and nose bleeds were more prominent in the young; delirium in children of school age; and headache, aches and pains, and faintness and giddiness in adult life.

The annual report (1958-59) of the National Marriage Guidance Council (78, Duke Street, London, W.1) states that the past year has been one of steady expansion and new work. "It is unfortunate," continues the report, "that this has not been matched by a corresponding increase in Government grant." 197 candidates attended the sixteen selection conferences for marriage guidance counsellors, of whom 128 (65%) were accepted for this work.

THE PROBLEM OF SUSPECTED RECURRENCES IN CANCER OF THE ALIMENTARY TRACT

BY

K. CRONIN, F.R.C.S.

AND

H. ELLIS, M.Ch., F.R.C.S.

Surgical Registrars, the Radcliffe Infirmary, Oxford

In recent years important advances have been made in the treatment of recurrent and disseminated cancer, resulting both in prolongation of life and in palliation of symptoms.

Radiotherapy remains a well-tried and useful method of treatment for recurrences from a wide range of tumours, and to this has now been added the use of sex hormones and endocrine gland ablations for prostate gland and breast secondaries, radioactive iodine for thyroid metastases, and cytotoxins (Bodley Scott, 1958) for some cases of disseminated bronchial and testicular growths.

Unfortunately the adenocarcinoma of the alimentary tract are relatively insensitive to conventional radiotherapy, are not hormone-dependent, and show no response to any of the available cytotoxic agents. For this reason it is not unnatural to find a pessimistic attitude often taken by the patient's doctor when recrudescence of such a growth is suspected following removal of the primary tumour. Should a recurrence have in fact developed, any further attempt at cure depends on the possibility of excision of the secondary deposit.

The more aggressive surgical attitude which is developing to this problem of secondaries in the alimentary tract is engendered by modern advances in technique. Of particular importance are the use of relaxant drugs, chemotherapy, blood transfusion, and the possibilities of excising major vessels with graft restoration of continuity and of successful right or left hepatic lobectomy; all contribute to the possibility of adequate excision of intra-abdominal, body-wall, pulmonary, or even intracerebral secondary deposits.

In this paper we present a number of encouraging examples of later surgery carried out because of suspected recurrence of growth following resection of a primary tumour of the alimentary tract. Recurrences may be completely removable with hope of ultimate cure of the patient; a second operable primary growth may be encountered; or, most happy of all, the symptoms may be found to be due to a non-malignant condition such as adhesions, stricture, or intra-abdominal abscess. In many cases exploration unfortunately reveals a hopelessly incurable situation, but, even here, relief of symptoms may be achieved by short circuit, colostomy, or palliative resection.

Case 1. Repeated Excision of Abdominal Secondary Deposits Following Hemicolectomy for Carcinoma of Caecum

A civil servant aged 54 had a right hemicolectomy performed in December, 1953, for a carcinoma of the caecum 2 cm. in diameter. Histologically this proved to be a Broders grade II growth, and none of the eight lymph nodes examined contained secondary deposits.

He was readmitted in October, 1955, complaining of attacks of severe abdominal colic. Clinical examination was negative, but occult blood was present in the stools, and a barium follow-through examination showed dilated loops of upper jejunum.

Second Operation.—Laparotomy on October 12 revealed a stenosing tumour obstructing the mid small bowel. There were hard enlarged glands in the adjacent mesentery and nodules of growth on the serosa of both bowel and mesentery. A nodule 5 cm. in diameter was also found in the posterior rectus sheath near the umbilicus. This nodule, the small-bowel tumour, and the affected mesentery were removed together with 19 cm. of small intestine.

Microscopical examination showed this small-bowel tumour to be a secondary deposit from the original growth lying deep to but ulcerating through the mucosa. The lymph nodes, serosal nodules, and mass in the abdominal wall all proved to be secondary deposits.

In October, 1956, routine examination revealed a mass at the umbilicus; there was no clinical evidence of dissemination elsewhere.

Third Operation.—On November 8 the palpable mass was found to be a tumour 4 cm. in diameter adherent to the umbilicus, and this was excised widely. A further deposit 2 cm. in diameter was removed from the omentum. Numerous small nodules of growth were found in the mesentery of the terminal ileum, and a wide resection of mesentery together with about 50 cm. of ileum was performed. Again histological examination confirmed the malignant nature of all the involved tissues. The patient recovered smoothly and remained in excellent health, but in August, 1957, a small lump in the operation scar was detected at follow-up.

Fourth Operation.—On September 6 a wide excision of abdominal wall was carried out removing a 3-cm. deposit within the rectus abdominis. Laparotomy revealed no evidence of intra-abdominal malignant disease.

In April, 1958, his abdominal wall was soundly healed and he was very well, clinically free from disease more than four years from the date of the first operation.

Case 2. Resection of Solitary Secondary Deposit in Lung Two Years After Abdomino-perineal Excision for Carcinoma of Rectum

A solderer aged 49 had an abdomino-perineal excision performed for a carcinoma of the rectum in November, 1955. Histologically this proved to be a Dukes stage C. Broders grade III growth. He attended the follow-up clinic in August, 1956, complaining of a cough with blood-stained sputum; an x-ray film of his chest showed: "Some shadowing of the right lung." He was seen again in February, 1957, when the report on his chest x-ray examination was: "The shadow at the right base is getting bigger. This has the appearance of a neoplasm." In July, 1957, his chest x-ray film showed "further increase in the size of the right basal shadow." During the whole of the year, the patient's general condition remained excellent and there was no sign of any abdominal recurrence.

As the growth in the lung appeared to be very slowly growing he was referred to the thoracic surgical unit. A bronchogram confirmed the presence of a tumour in the right lower lobe of the lung, and in October, 1957, this lobe was resected. The histology showed that the growth was a secondary deposit from the original carcinoma of the rectum. At the time of writing the patient was alive and well.

Case 3. Anterior Resection for Carcinoma of Rectum. Abdomino-perineal Resection for Second Primary Growth in Rectum

A gas-fitter aged 65 had an anterior resection performed for a carcinoma of the rectum in November, 1953. Histologically this proved to be a Dukes stage A, Broders

grade III growth. The patient was seen regularly in the follow-up clinic, and in April, 1955, on rectal examination, a polypoid mass was felt at 3 in. (7.5 cm.). At this time the patient had no symptoms.

The growth was removed with diathermy, and the histology showed it to be adenocarcinoma of the rectum (Broders grade I). It was hoped that, as the tumour was of a low grade of malignancy, local excision would be sufficient. A recurrence, however, was soon evident, and an abdomino-perineal excision of the rectum was performed in August, 1955. Histologically, this new primary proved to be a Dukes stage A, Broders grade I growth. At the time of writing the patient is alive and well with no sign of recurrence.

The completely different histology of the two tumours strongly suggests that the second growth had arisen *de novo*.

Case 4. Resection of Pelvic Colon for Annular Carcinoma. Laparotomy for Suspected Recurrence. Small-bowel Obstruction Found to be Due to Adhesions: No Recurrence of Growth

A housewife aged 46 had a resection of the pelvic colon for an annular carcinoma in October, 1954. Histologically this proved to be a Broders grade II growth, and none of the lymph nodes examined showed secondary deposits. In July, 1956, she was seen in the follow-up clinic, where "some fullness" was noted beneath the scar in the left iliac fossa. At this time she was quite well, but admitted to having occasional attacks of abdominal colic and vomiting.

In January, 1958, she was admitted with a subacute intestinal obstruction. A straight x-ray film of the abdomen showed dilated loops of small bowel with some fluid levels, and a barium enema demonstrated some distortion at the site of the old anastomosis, possibly due to a growth.

At laparotomy a loop of ileum was found to be snared by a band running to the site of the colonic anastomosis. There was no sign of any recurrence of the original growth. The band was divided and the patient made an uninterrupted recovery. She remains alive and well.

Case 5. Chronic Abscess of Abdominal Wall Simulating Secondary Deposit

A man of 71 had an emergency ileo-transverse colostomy followed by a right hemicolectomy performed for an obstructing carcinoma of the ascending colon in June, 1953. He remained well until late in 1957, when he noted a lump in the abdominal scar. When seen at the follow-up clinic in February, 1958, there was a mass 7 cm. in diameter deep in the abdominal wall, which was hard and rather tender. He was afebrile. A confident diagnosis of a secondary deposit was made. At operation, however, this proved to be a chronic thick-walled abscess of the abdominal wall containing a length of nylon suture. Culture of the pus grew *Streptococcus pneumoniae*, and histological examination of the abscess wall showed a non-specific chronic inflammatory change only. He made a smooth recovery from this operation, over four and a half years after his original resection.

Comment

In the five years, 1953-7, 31 patients had laparotomies for suspected recurrent cancer; the operative findings are detailed in Table I. In 11 cases it was possible to remove the recurrence, and the case histories of these patients are summarized in Table II. Palliative procedures were done in four patients (one colostomy and three short circuits). One patient (Case 3) was found to have a new primary growth. In only four instances was it found impossible to do anything at operation.

It is a striking fact that in 11 patients, although a recurrence was suspected on clinical grounds, a benign condition was found at operation. One interesting feature of this last group is that in three patients the late appearance of a chronic abscess simulated a recurrence. Two patients had

TABLE I.—Patients Explored for Suspected Recurrences (1953-7)

Sex and Age	Original Operation	Site of Excised Recurrence	Interval Between Original Operation and Excision of Recurrence	Length of Survival After Last Excision
Excision of recurrences				
Palliative operations (1 colostomy, 3 short circuits)				
Inoperable				
Excision new primary growth				
Non-malignant conditions discovered (3 deep abscesses, 1 anastomotic ulcer, 7 intestinal obstructions due to adhesions)				
F 67	Bilroth I gastrectomy for carcinoma of stomach	1. Scar 2. Scar 3. Both axillae	7 months 17 " 21 "	Alive and well, 4 months after last excision
F 53	Hartman's operation for carcinoma of sigmoid colon	Scar	25 "	Alive and well at present, 17 months after last excision
F 54	Abdomino-perineal resection for carcinoma of rectum	Scar	5 "	Dead, Survived 6 months
F 66	Right hemicolectomy for carcinoma of caecum	1. Umbilicus 2. Scar of above excision	26 " 29 " Also given deep x-ray therapy	Dead, Survived 4 months
F 65	Abdomino-perineal resection for carcinoma of rectum	Perineum	2 months. Also given deep x-ray therapy	Dead, Survived 26 months
M 54 (Case 1)	Right hemicolectomy for carcinoma of caecum	1. Small intestine, mesentery, and abdominal wall 2. Small Intestine, omentum, and abdominal wall	22 months 35 "	Well, 10 months after last excision
F 67	Hartman's operation for carcinoma of recto-sigmoid junction	3. Scar Mass in left iliac fossa involving small bowel	45 " 39 "	Died in post-operative period
F 66	Anterior resection for carcinoma of rectum	Small bowel	22 "	" "
F 60	Resection for carcinoma of pelvic colon	Anastomotic line; abdomino-perineal excision performed	34 "	Dead, Survived 25 months
F 47	Resection for carcinoma of descending colon	Right Sylvian fissure	16 "	Dead, Survived 4 months
M 49 (Case 2)	Abdomino-perineal excision of carcinoma of rectum	Lung	24 "	Well, 6 months after last excision

deep abdominal-wall abscesses 18 months and four years (Case 5 above) after colectomy; both had had pre-operative and post-operative chemotherapy, and both had nylon suture material within the abscess cavity. The third patient developed an intra-abdominal abscess adjacent to the anastomosis of a right hemicolectomy, performed seven years previously, which was followed by a course of penicillin and streptomycin.

Such abscesses probably represent either flare-ups in foci of latent infection or sterilized collections of necrotic material which become secondarily infected. With extensive use of chemotherapy these delayed abscesses, presenting many months or even years after abdominal operations, will probably become more common (we have seen two following gastrectomy) and constitute an important differential diagnosis from secondary deposits in a laparotomy scar.

Discussion

A radical approach to the problem of recurrent abdominal cancer is the "second look operation" introduced by Wangenstein *et al.* (1954). He undertakes re-exploration of the abdomen six to eight months after the initial operation in cases where examination of the resected specimen shows that adjacent lymph-node involvement has occurred. At the second laparotomy any suspicious tissue is excised.

and, if this in turn proves to be involved, further explorations are undertaken at similar time intervals until no recurrences are found. He quotes one patient who had a total of five re-explorations following resection of a carcinoma of the caecum. At the last operation no malignancy was found, and the patient was well more than five years after the original hemicolectomy.

Although this scheme has been adopted by some other surgeons (Wilson, 1956), it is still admittedly in its trial stage. There are two disadvantages; first, it is necessary to explain to the patient the exact nature of his disease and its prognosis, a procedure which is inadvisable in a proportion (we would say a very high proportion) of cases; and second, in this country, the "second look" operation would impose a heavy strain on the available general surgical hospital beds. However, this procedure may well offer the possibility of improving the prognosis in relatively young and intelligent patients with intra-abdominal cancer.

Although the "second look" idea remains to be evaluated, there is no question that much can be gained from periodic careful clinical follow-up examination by the surgeon or general practitioner of all patients who have had resections of tumours of the alimentary tract. In some, evidence of recurrence will be found on clinical examination before symptoms have appeared.

Now that a standard technique has been devised for right hepatic lobectomy (Raven, 1947; Lloyd-Davies and Angell, 1957), as well as the comparatively simple resection of the left lobe for solitary or localized deposits, re-exploration can be undertaken with more confidence and with a greater chance of success than in the days when liver secondaries appeared to be a hopeless problem.

Pulmonary metastases were for long regarded as evidence of inoperable dissemination of malignant disease. Further research has shown that they may occur as a solitary deposit, and, where careful investigation reveals an isolated pulmonary secondary with no effusion and no evidence of spread elsewhere, surgery should be advised. The number of reports of successful removals of secondary pulmonary deposits is steadily increasing. Alexander and Haight (1947), for example, collected 24 cases, 12 of the patients being still alive (eight for more than a year after operation); one patient was well 12 years later. By 1956 Kelly and Langston reviewed 109 patients who had undergone surgery for lung secondaries: 19 (23.2%) had survived for two years or more without recurrence. Nelson *et al.* (1957) reported the resection of two successive pulmonary deposits from a patient who had had a resection of a carcinoma of the left colon, and collected 11 other cases where two lung secondaries had been removed.

Even cerebral secondaries are by no means always irremovable; Störtebecker (1954) reported a study of 158 resections of metastatic brain tumours, although only 13 of these came from primary carcinomata of the alimentary tract. The present series includes a deposit in the Sylvian fissure from a carcinoma of the descending colon.

Although our thesis is that recurrent growths are not necessarily irremovable, their prevention is better than cure. It will be seen that five patients in the present series had secondaries in the abdominal wall removed—one on two occasions and one on three. These deposits probably represent direct implants of malignant cells at the time of the original operation. Naunton Morgan (1958, personal communication) believes that conventional skin towels are inadequate to prevent inoculation of cancer cells at operation, and advocates the use of macintosh-reinforced towels over the raw wound surfaces and wrapped around the growth itself before this is handled extensively.

Recent cytological investigations have demonstrated cancer cells in the venous blood draining tumours of the large bowel in between 30 and 50% of cases examined (Fisher and Turnbull, 1955; Burns and Pfaff, 1956). Moore *et al.* (1957) have even detected tumour cells in the peripheral blood in 25 out of 57 patients with tumours of the alimentary tract.

It seems logical, therefore, that ligation of the vascular pedicle should be carried out before proceeding with manipulation of the tumour whenever possible, in an attempt to limit dissemination of malignant emboli into the blood stream (Cole, 1955).

Goligher *et al.* (1951) analysed the causes of recurrence following anterior resection of the rectum. Some are almost certainly second primaries (see Case 3), others result from inadequate resection, and others still from tumour-cell implantation at the anastomosis; an example of the latter occurred in the present series. Not only should excision be adequate (a 2-in.—5-cm.—clearance as the minimum distally) but the distal bowel should be washed out with 1:500 perchloride of mercury to kill off free cancer cells and prevent their implantation.

Unfortunately many patients will present with evidence of recurrences so hopeless that laparotomy is contraindicated; these will include the cases with ascites, a fixed mass in the pelvis, jaundice, and extensive liver secondaries. Pain in these sufferers can be controlled by analgesics and opiates, supplemented by chlorpromazine. Some selected cases may benefit from cordotomy, splanchnic blocks, and permanent local spinal blocks (Maher, 1955). Ascites and malignant pleural effusions may both be controlled in some measure by instillation of radioactive gold (MacKay, 1957), with relief from distension and dyspnoea. Above all, the "hopeless case" must not feel that he is being abandoned; attention to small details of nursing care will give considerable relief in the terminal stages of malignant disease.

Summary

Recurrence of symptoms after resection of a primary tumour of the alimentary tract may be due to secondary deposits, but these may be operable even if in lung or brain. In other cases the symptoms may be caused by the development of a fresh primary tumour or even by some non-malignant condition.

A more optimistic surgical attitude towards suspected recurrences is advocated and some encouraging examples are presented.

We thank the surgical consultant staff of the Radcliffe Infirmary, Oxford, for permission to study the patients recorded in this series. We are grateful to Mr. D. A. Abernethy and Mr. A. Elliot Smith for their advice and criticism.

"To-day, we understand the means by which tuberculosis can be prevented, and we have the drugs through which, provided treatment is begun early and continued properly, the illness can be cured. . . . In 1957 there were 4,784 deaths, as against 23,076 ten years ago, though over 30,000 new patients are still discovered every year. Tuberculosis has been removed from among the great killers of men, and demoted to the position of a lesser—though still formidable—enemy. There are still 350,000 patients attending our chest clinics in Britain; and if we add their families (who are at risk) this means at least a million lives directly affected by a preventable disease."—From the *NAPT Annual Report, 1957-1958*.

HEPATIC COMA IN LIVER FAILURE AND GASTRO-INTESTINAL HAEMORRHAGE TREATED WITH NEOMYCIN

BY

W. H. J. SUMMERSKILL, D.M., M.R.C.P.

Senior Registrar, Department of Gastro-enterology,
Central Middlesex Hospital, London

The introduction of protein withdrawal, oral broad-spectrum antibiotics, and enemata as a basis for treating hepatic impending coma and coma (Sherlock *et al.*, 1954) has been supported by encouraging results in larger groups of patients (Sherlock *et al.*, 1956; Summerskill *et al.*, 1957a). However, the relative contribution of each measure to the therapeutic response is uncertain, and protein deprivation, which may have to be long-continued, is particularly undesirable when liver disease is associated with undernutrition. No comparative studies are available to indicate the most effective antibiotic in hepatic coma, but the recent use of neomycin in three patients by Fisher and Faloon (1957) is important, as temporary clinical improvement was compatible with continued protein administration. Dawson *et al.* (1957) treated acute hepatic coma in 12 patients with neomycin, protein deprivation, and other measures. No conclusions were drawn in regard to its specific therapeutic action in either series, as coma was often due to multiple factors and additional methods of treatment were employed simultaneously. In this paper the effect of neomycin is compared with that of other antibiotics under controlled conditions, and the degree to which protein withdrawal and other procedures may be modified as a result of neomycin therapy is also studied.

Material

Six patients (three male and three female) with impending hepatic coma or coma complicating cirrhosis were studied (Table I). Cirrhosis was thought to be the

TABLE I.—Biochemical Findings

Case No.	Sex and Age	Serum Bilirubin (mg./100 ml.)	Serum Albumin (g./100 ml.)	Thymol Turbidity (Units)	Serum Sodium (mEq/l.)
1	F 60	6.0	2.2	16	137
2	F 75	4.0	2.8	10	112
3	F 77	1.5	3.5	5	127
4	M 24	20.0	2.9	2	99
5	M 55	0.8	4.8	1	142
6	M 49	0.9	3.1	1	125
Normal values		<1.0	>4.0	<5	(137-144)

sequel of virus hepatitis in Case 1 and of long-standing cardiac failure in Case 3; in Cases 5 and 6 it was possibly associated with alcoholism; and in Cases 2 and 4 the cause was uncertain. All except Case 6 had stigmata of chronic liver disease, and the relevant biochemical findings are shown in Table I. Case 2 gave a history of poor nutrition, and the serum albumin concentration was below 3 g./100 ml. in Cases 1, 2, and 4.

Coma was attributed to liver failure in Cases 1, 2, and 3, as all had developed ascites and two had become jaundiced shortly before the onset of neuropsychiatric disorder. The presence of a portal collateral circulation facilitating the onset and perpetuation of coma in these patients could not be excluded, but splenomegaly or superficial abdominal collateral veins were not found and there was no radiological evidence of oesophageal

varices in Case 1. Additional factors which may contribute to coma, such as high protein feeding, gross or occult gastro-intestinal bleeding, drugs, or intercurrent infection, were excluded. Ascites in Cases 2 and 3 was accumulating despite treatment, and was associated with serum sodium concentrations below 130 mEq/l., findings suggesting advanced liver damage and a poor prognosis (Hecker and Sherlock, 1956).

In Cases 4, 5, and 6 coma followed major gastro-intestinal haemorrhage. Gastro-oesophageal varices were demonstrated by barium swallow and meal, portal venography, and oesophagoscopy in Cases 4 and 5, while Case 4 also had intractable ascites, hypoalbuminaemia, and was deeply jaundiced (Table I). In Case 6 bleeding originated from a chronic gastric ulcer and there was no evidence of portal hypertension at laparotomy.

Methods

Daily assessment of the neuropsychiatric state was based on the observations of Walshe (1951), Adams and Foley (1953), and Summerskill *et al.* (1956). Because of the characteristic fluctuations in the syndrome, a distinction was made only between "coma" (absence of response to strong stimuli), "impending coma" (personality changes with objective signs, of which a flapping tremor was the most prominent), and the absence of gross psychiatric or neurological disorder.

Diets with calculated protein and sodium contents were supplied by the hospital dietetic department: antibiotics were given by mouth or intragastric drip in equally divided doses three or four times in the 24 hours; and enemas were administered when necessary to ensure daily bowel movements.

The biochemical tests, including the nitrogen balances, and bacteriological investigations reported were routine laboratory procedures.

Results

Case 1 (Fig. 1).—A woman aged 60 was admitted to hospital unconscious, and initial treatment by protein withdrawal, intragastric glucose, and enemata was followed within 48 hours by emergence from stupor, but tremor and confusion continued. Protein was added cautiously, but a daily intake of 30 g. was followed by gross neuropsychiatric disorder. Reduction of the amount to 20 g. failed to bring improvement. The patient's behaviour was incompatible with her retention in a general ward when neomycin (6 g. daily) was started, 12 days after admission to hospital. Within 24 hours normal mental function was restored and tremor and the other neurological abnormalities disappeared. The protein intake was then raised by 10-g. increments every three or four days to a total of 50 g. daily without neuropsychiatric deterioration. Simultaneously the daily dose of neomycin was reduced, and after two weeks it was discontinued. Five days later the patient again became drowsy, confused, and tremulous, but it was possible to raise the protein intake to 70 g. daily. Chlorotetracycline (2 g. daily) did not improve the neuropsychiatric state. Accordingly, neomycin (6-4 g. daily) was substituted for it without alteration in dietary protein. After three days there was a striking improvement in response to neomycin, and after a further six days it was possible to withdraw chemotherapy. There was no further relapse, the jaundice and ascites subsequently disappearing.

Case 2 (Fig. 2).—A woman aged 75 was admitted to hospital for the treatment of ascites, but her condition slowly deteriorated and she developed impending coma and then lost consciousness. She remained in deep coma for five

days despite therapy with protein withdrawal, "sigmamycin" (tetracycline and oleandomycin in proportions of 2:1) (2 g. daily) and enemata. The following day she

regained consciousness, although confusion and tremor continued for a further day. After the neuropsychiatric state had remained normal for 24 hours, 20 g. of protein was added to the diet. The next day confusion, drowsiness, and tremor reappeared, but the amount was increased to 40 g. daily. Neuropsychiatric disorder persisted, and neomycin (6 g. daily) was substituted for sigmamycin. Within 24 hours the patient had returned to normal consciousness, although remaining on 40 g. of protein daily. Neomycin was discontinued after a four-day course, being replaced by sigmamycin (2 g. daily). Two days later there was a return of drowsiness, confusion, and tremor. Chloramphenicol (2 g. daily for four days) was substituted for sigmamycin for the treatment of an infection of the urinary tract, but it had no effect on the neuropsychiatric condition. Neomycin (8 g. daily) was therefore reintroduced, and within three days there was again a striking response, the patient becoming orientated and more alert. Subsequently the dosage was reduced slowly without deterioration in her condition.

Case 3 (Fig. 3).—While in hospital for treatment of congestive cardiac failure, a woman aged 77 became confused, tremulous, and intermittently stuporous. Ammonium chloride (1 g. t.d.s.) had been included in her treatment, but its cessation failed to influence her condition. Chlorotetracycline (2 g. daily) was then given without altering the diet, and the patient regained consciousness, although confusion, apathy, and tremor persisted. Neomycin (6 g. daily for four days) was substituted for chlorotetracycline and further improvement occurred after two days. Tremor was no longer apparent and she was alert enough to sit out of bed and feed herself. Two days after neomycin treatment was stopped some tremor and apathy returned.

Case 4.—A man aged 24 was admitted to hospital with melaena and impending hepatic coma. A portacaval anastomosis, which had subsequently become occluded, had been constructed 16 months previously. Neomycin therapy (6 g. daily) was started

immediately, but balloon compression of the gastro-oesophageal region was not undertaken. Haemorrhage, with the daily passage of loose melaena stools, continued for six days and the haemoglobin concentration was 8.9 g./100 ml. (60%) after 6 pints (3.4 litres) of blood had been given during this time. A protein intake of 40 g. daily was allowed throughout, and, despite progressive liver failure, with increasing jaundice (serum bilirubin 20 mg./100 ml.), the accumulation of tense ascites, and hyponatraemia (serum sodium concentration 99 mEq/l.), there was no neuropsychiatric deterioration. Normal consciousness was re-established 36 hours after admission and subsequently maintained. After the cessation of bleeding, liver function improved quickly.

Case 5.—A man aged 55 with known portal hypertension was admitted to hospital following the passage of melaena stools. Irrational, violent behaviour prevented the immediate introduction of a gastro-oesophageal compression balloon, and neomycin (6 g. daily), together with routine treatment, was started. Bleeding continued for four days and, after 6 pints (3.4 litres) of blood had been given in this time, the haemoglobin concentration was only 10.2 g./100 ml. (64%). Grossly abnormal conduct and a "flapping" tremor persisted for three days and some confusion continued for a further two days. Protein was withdrawn from the diet for two days, but it was then introduced in

Fig. 1.—Case 1. Neuropsychiatric state in relation to treatment and protein intake.

Fig. 3.—Case 3. Neuropsychiatric state in relation to treatment and protein intake.

daily increments of 10 g. without apparently prejudicing improvement in the neuropsychiatric state.

Case 6.—A man aged 49 was admitted to hospital following haematemesis and melaena of three days' duration. The next day he developed impending hepatic coma. Although standard biochemical tests of liver function showed no abnormality (Table I), 50% of injected bromsulphthalein was retained in the blood after 45 minutes, thus supporting the possible presence of liver disease. Neomycin therapy (6 g. daily) was instituted immediately. Profuse bleeding continued, and, despite the rapid transfusion of 7 pints (4 litres) of blood, his condition deteriorated. Although impending hepatic coma had been present for 12 hours, surgical treatment was thought necessary to arrest the haemorrhage. Accordingly Mr. K. Lloyd Williams undertook a laparotomy under general anaesthesia (Dr. L. Khan) with thiopentone, pethidine, gallamine triethiodide, nitrous oxide, and oxygen. The liver was cirrhotic, but no splenomegaly or portal collateral veins were found, and three chronic gastric ulcers were present. A Polya partial gastrectomy was performed. His recovery from the anaesthetic and his post-operative progress were uneventful, and no further neuropsychiatric disorder occurred.

Bacteriological Studies

Stool cultures were examined at various stages of treatment in Cases 1-5. A "sterile" stool was obtained after four to six days' neomycin (6 g. daily) in Cases 2, 4, and 5, although faecal organisms persisted in Case 3 after the same treatment. Stools from Case 1 and 2 which were examined after longer courses of neomycin (6-14 days) grew an apparently normal faecal flora in three instances despite continued clinical improvement. The average daily dose of neomycin was less than 6 g. on these occasions. Faecal organisms were also present after chlortetracycline in Cases 2 and 3 and after both sigmamyacin and chloramphenicol in Case 2.

Additional Observations

Hepatic fetor was present initially in all patients, but it disappeared within 36-48 hours of treatment with protein withdrawal or antibiotics. Despite the subsequent addition of dietary protein and the reappearance of neuropsychiatric signs, fetor was not detected during the intermittent administration of antibiotics. The patients had loose stools with neomycin, but troublesome diarrhoea did not occur and no other toxic effect was observed.

Following a period of equilibration on the appropriate diet and antibiotic, four-day nitrogen balances were carried out on Case 1. During treatment with chlortetracycline (2 g. daily) there was a total nitrogen output of 46.1 g. with a positive balance averaging 2.2 g. daily. When neomycin (6-4 g. daily) was substituted for chlortetracycline, the urinary nitrogen loss was reduced and the positive nitrogen balance improved to 3.5 g. daily (Table II).

TABLE II.—Nitrogen Balance During Treatment with Chlortetracycline and Neomycin in Case 1

Drug	4-day Collections (g./Nitrogen)			
	Dietary Nitrogen	Urine Nitrogen	Stool Nitrogen	Balance
Chlortetracycline	54.9	34.2	11.9	+ 8.8
Neomycin	55.1	29.4	11.6	+14.1

Discussion

Treatment with antibiotics, protein withdrawal, and enemata in hepatic coma is based upon evidence that nitrogenous compounds of intestinal origin are a cause of the neuropsychiatric disorder. The object of therapy is therefore to reduce the amount of nitrogenous material in the intestines and, with antibiotics, to inhibit bacterial enzyme activity by suppression of the gut flora. The regime is of proved therapeutic value when coma results from intolerance of nitrogenous substances, such as gastro-intestinal

bleeding or high-protein feeding, in patients with adequate liver function. In coma due to liver failure there is more widespread clinical and metabolic disturbance and consequently a much poorer prognosis (Sherlock *et al.*, 1956; Summerskill *et al.*, 1957a). Moreover, the issue is rarely sufficiently prolonged or uncomplicated to permit controlled observations in relation to specific therapy.

Cases 1, 2, and 3 are of interest, as comparative studies were possible, although coma resulted from hepatic failure. In two patients relapses occurred after initial treatment when relatively small amounts of protein were added to the diet, and they responded successfully on four occasions to neomycin without alteration of the diet. In the third patient, recovery occurred when neomycin was given, despite the continued administration of protein. Other antibiotics (chlortetracycline, sigmamyacin, or chloramphenicol) proved less effective with the identical protein intake and general management, although chlortetracycline was followed by improvement in one patient. The therapeutic action of neomycin occurred within 24-72 hours and deterioration took place on withdrawing the drug after a similar interval. These results stress the importance of oral antibiotic therapy even when coma is due to hepatic failure and, in the absence of other comparative data, suggest that neomycin is the most effective of currently recommended antibiotics in hepatic coma. This accords with the experience of Dawson *et al.* (1957) with neomycin in the management of chronic or recurrent neuropsychiatric disorder due to protein intolerance in patients with extensive portal-systemic collateral circulations, and with the improvement in E.E.G. appearances following use of the drug in patients with liver disease (Parsons-Smith *et al.*, 1957).

In Cases 4 and 5, with impending coma due to bleeding varices, deterioration to coma was prevented and full restoration of consciousness occurred when neomycin was given, although the haemorrhage was not controlled. Recovery was particularly striking in Case 4, in which deep jaundice and ascites were present, especially as an adequate protein intake was allowed throughout. The improvement in Case 6 was predominately due to surgical arrest of the bleeding, but the use of neomycin before operation probably ensured the smooth post-operative course, as impending coma had been present for at least 12 hours prior to general anaesthesia and constituted an important contraindication to surgery.

The close relationship between protein feeding and hepatic coma (Phillips *et al.*, 1952) is particularly important when coma complicates liver disease associated with malnutrition. Neomycin was superior to other antibiotics tested in permitting an adequate protein intake despite neurological disorder. Moreover, the nitrogen balance was positive during neomycin therapy, whereas the tetracycline antibiotics increase nitrogen catabolism and may cause a negative nitrogen balance (Faloon *et al.*, 1954, 1957).

A nutritious diet is important in the management of many patients with cirrhosis (Patek *et al.*, 1948), and the extent to which neomycin therapy will obviate protein deprivation in the treatment of hepatic coma is not yet clear. Clinical improvement with neomycin appears within 72 hours and temporary elimination of protein from the diet for this period is still prudent if coma is established or anticipated. When consciousness returns, an adequate protein intake (40 g. daily) may be tolerated, and if protein undernutrition is thought to be of aetiological significance in the liver disease larger amounts can be tried. As the presence of blood in the intestines has an effect similar to that of protein in precipitating hepatic coma (Sherlock *et al.*, 1954), balloon compression of the gastro-oesophageal region (Sengstaken and Blakemore, 1950) is of prophylactic use in patients with bleeding varices. However, the tube is often difficult to introduce in the uncooperative pre-comatose patient, hard to tolerate, and apt to cause ulceration of the oesophagus (Sherlock, 1958). The control of neuropsychiatric complications with neomycin during bleeding in Cases 4 and 5 indicates that compression can be reserved for patients in

whom haemorrhage is catastrophic or results in progressive neuropsychiatric deterioration. The smooth recovery of Case 6, despite preoperative impending coma, suggests that neomycin is also effective as a prophylactic measure in patients with liver disease prior to operation.

The relative significance of various organisms in the production of toxic nitrogenous substances in the human intestine, and therefore the specific action of neomycin, remains uncertain. Although the faecal flora is qualitatively and quantitatively normal in cirrhosis and hepatic coma (Phear *et al.*, 1956), some organisms, particularly coliforms and *Sr. faecalis*, extend abnormally far up the intestines (Martini *et al.*, 1957). Neomycin, being poorly absorbed from the intestines, is relatively non-toxic, and doses of 8-12 g. daily were shown by Fisher and Faloon (1957) to "sterilize" the stools within 36 hours to 5 days. With the lower dosage employed in this study, the stools were "sterile" in three patients after four to six days' treatment. Reappearance or persistence of the faecal flora was not necessarily accompanied by clinical deterioration, and this agrees with the more extensive bacteriological studies of Dawson *et al.* (1957). Neomycin presumably exerts some specific effect on bacterial growth and metabolism under these circumstances that explains its clinical superiority to the other antibiotics used.

Toxic agents derived from nitrogenous material in the intestines, and of possible causal significance in hepatic coma, include methyl mercaptan (Challenger and Walshe, 1955) and tertiary amines (Butt and Mason, 1954), but evidence accumulates to incriminate ammonia in particular (Kirk, 1936), although its effect on brain metabolism has been variously interpreted (Bessman and Bessman, 1955; Summerskill *et al.*, 1957b). Ammonia from food, blood, and other nitrogenous material in the intestines can reach the systemic circulation by passing through a diseased liver or by way of portal collateral vessels (White *et al.*, 1955), and this accords with clinical experience, which relates hepatic coma to inadequacy of liver function, the extent of the portal collateral circulation, and the amount of nitrogenous material in the intestines (Sherlock *et al.*, 1954). Oral neomycin reduces portal blood ammonia levels effectively in dogs (Silen *et al.*, 1955), and Fisher and Faloon (1957) showed that both peripheral and portal vein ammonia values were lowered in patients with cirrhosis, even when protein was given. However, during long-term treatment, Dawson *et al.* (1957) found that ammonia concentrations in the blood tended to rise, although this was not necessarily associated with clinical deterioration.

Conclusion

These cases have been reported because, as is rarely possible in acute hepatic coma, objective assessment of the efficacy of a single therapeutic agent has been possible. Wider experience with neomycin in this department has confirmed its usefulness but has also emphasized two disadvantages. The first is its cost, although in these patients it was effective in doses well below the 12 g. daily used by Fisher and Faloon (1957). The second, if paradoxical, sometimes constitutes a practical dilemma and involves irreversible hepatic failure due to terminal chronic liver disease. Neomycin is sometimes so effective in prolonging normal consciousness in such patients that the distressing and unequal struggle appears to be unduly prolonged.

Summary

Neomycin was more effective than chlortetracycline, sigmamyacin, or chloramphenicol in treating three patients with hepatic coma due to liver failure under controlled circumstances. Neomycin therapy permitted an adequate protein intake, which, with the other drugs, caused neuropsychiatric deterioration.

Impending hepatic coma was precipitated by haemorrhage from gastro-oesophageal varices in two other

patients, one of whom also developed liver failure. Restoration of consciousness followed neomycin treatment despite persistent bleeding and continued protein-feeding. Balloon compression of the gastro-oesophageal region was not necessary. In another patient, impending coma resulted from massive bleeding from a gastric ulcer. Despite the neuropsychiatric disorder, general anaesthesia and surgical treatment were followed by an uncomplicated post-operative course with neomycin therapy. The influence of these findings on the management of hepatic coma is discussed.

Dr. F. Avery Jones, who also gave me his advice, Dr. A. Abdullah, and Dr. T. D. Kellock kindly allowed me to study these patients. I am grateful to them and to Dr. G. Discombe and Dr. J. D. A. Gray for biochemical and bacteriological reports; to Mrs. A. M. Dawson and Miss C. Murland for dietetic assistance; and to Dr. T. Luke, Dr. A. Pollard, and Dr. J. M. Read, house officers, for confirming the clinical findings in relation to treatment. I am also indebted to Messrs. Upjohn of England, who kindly made available supplies of neomycin.

The British Council for Rehabilitation has set up a working party under the chairmanship of Dr. ELFED THOMAS, director of education for the City of Leicester, "To investigate the needs of physically and mentally handicapped school-leavers; to study the means of meeting their difficulties, and to make recommendations." The work is expected to take about two years and will be on a nation-wide basis. The composition of the working party includes educationists, representatives of the medical services, the voluntary organizations engaged in social work of an educational and medical nature, the Trades Union Congress, industry, and observers from the Ministries of Education, Health, and Labour and National Service, and local authorities. While it is recognized that the statutory services show an enlightened approach to the problem, states the council, and, as promulgated, appear to make reasonable provision, there still remain gaps. There are, continues the council, far too many handicapped school-leavers who, for one reason or another, miss the opportunities they should have and are left in what could become a hopeless position. The British Council for Rehabilitation (Tavistock House South, Tavistock Square, London, W.C.1) would therefore welcome evidence relevant to the above terms of reference from any source.

SURVEY OF PUPILS IN SCHOOLS FOR PHYSICALLY HANDICAPPED IN LONDON

BY

W. T. PALMER

AND

DENIS PIRRIE, M.B., D.P.H.

Public Health Department, London County Council

The proper placing of the handicapped school child, particularly the physically handicapped school child, in the school community has been a matter for discussion for many years. In deciding what is best for each child there are so many variables, apart from the physical handicap, to be taken into account—age, intelligence and personality, length of stay in hospital, family care, availability of day and boarding "special" schools, transport, size of classes, and types of buildings of near-by "ordinary" schools. In recent years there has been a demand for the admission to ordinary schools of children who would previously have been regarded as too severely handicapped for anything but a special school. At the same time there are now in the special schools many children who in previous years would have been regarded as too seriously crippled for life outside a hospital or the four walls of their home.

Surveys of the reasons for admission of children attending special schools for the physically handicapped in London have been carried out from time to time, the most recent being in 1949, 1951, and 1954. The results of these surveys were not published, although the London figures for 1951 were included among those for the whole of England and Wales in the survey made at that time by the Chief Medical Officer of the Ministry of Education (1954). So far as earlier surveys are concerned, the results of one carried out in London in 1928 were published in the Annual Report of the London County Council (1928). No records are available of any such surveys which may have been carried out between 1929 and 1948.

Method

Early in 1957 it was decided that another survey should be made, and the schools were asked to submit lists of the particular defects of their pupils. In practically every case the child was under observation by a consultant or specialist at a hospital, so that the school doctor had available enough evidence upon which to give a precise diagnosis. The returns from the schools were coded, and an aggregate for London was made of the coded items. In the interests of clarity, and with a view to comparison with any other current and future surveys, the coding was based on the classifications and nomenclature of the *International Statistical Classification of Diseases, Injuries, and Causes of Death* (W.H.O., 1957). It says much for the precise nature of the information available in the schools that in only a handful of cases was it necessary to ask the school for further information before a code number could be assigned.

Results

The full tabulation given in Table I shows 93 different conditions for the 1,325 children in 17 schools at the time of the survey. The largest group is cerebral palsy, 312, but this does not represent all the children of school age in London with cerebral palsy, as a survey in 1955 (MacGregor *et al.*, 1957) revealed 526 cases between the ages of 5 and 16 years. Children crippled by poliomyelitis (240) formed

the second largest group, and congenital heart disease (127) was the only other group of more than a hundred cases. In essence Table I shows that, apart from these large categories, the children attending the special schools for the physically handicapped are suffering from a very wide range of conditions, some of which in this survey are represented by only one or two children.

From the point of view of morbidity statistics it is important to note that the figures given in Table I, which relate

only to children in special schools for the physically handicapped, cannot be used to measure the incidence of any particular condition amongst the child population, since there are many handicapped children satisfactorily placed in ordinary schools, and there are others who are not in school at all. On the other hand, from the point of view of education statistics, the figures are of importance as a measure of the need for special educational provision.

FIG. 1.—Percentage distributions of pathological conditions of pupils in schools for the physically handicapped in London, 1928, 1951, and 1957.

may possibly have been put into the wrong category, but, because of the magnitude of the differences between the successive surveys, such minor errors will not radically affect the pattern of change over the years. In Table II the numbers recorded are also shown as percentage distributions and as rates per 1,000 of the total school rolls (see also Figs. 1 and 2).

Discussion

As Table II shows, the population of the schools for physically handicapped has fallen more steeply than has the total London school population; the incidence per 1,000 of the school population of attendance at schools for the physically handicapped in 1957 was less than half what it was in 1928. The most marked decrease has been, as would be expected, in juvenile rheumatism and in non-pulmonary tuberculosis. Juvenile rheumatism (including chorea) has fallen from 1.96 per 1,000 through 0.6 to 0.16; and non-pulmonary tuberculosis has fallen from 1.14 through

0.40 to 0.16 also. It is sometimes forgotten that 30 years ago poliomyelitis was so important; in 1928 poliomyelitis was second only to rheumatism as a reason for admission to schools for the physically handicapped, with an incidence of 1.21; in 1951 the incidence was 0.53 and in 1957 it was 0.54, again the second most common cause of admission, but now second to the cerebral palsies.

The incidence of cerebral palsy has gone up from 0.49 through 0.72 to 0.77; even the actual numbers have increased from 314 to 342. We know that many very severely handicapped children are now admitted to special schools, and this may well have affected this change. The incidence of arthritis, progressive muscular dystrophy, kidney disease, and brittle bones has increased, but the numbers involved are not large. Congenital heart disease had caused 251 admissions (0.39) in 1928 and 241 in 1951, a much higher incidence (0.59), but by 1957 there were only 146 children left with congenital heart disease, a fall in the incidence to about what it was in 1928 (0.33). It would take a special inquiry to reveal the reasons for these variations. The incidence of disabilities due to injuries has fallen from 0.18 to 0.06, but this still means that 26 children are needlessly crippled. For those who do not know the special schools, it should be said that the stay of amputees, for example, is not long, and usually they soon return to ordinary schools.

The school for the physically handicapped is usually a single-storied building, too often some 30-40 years old, and not too well suited to its present function. There are usually about 100 children in the school and there are not more than 20 in a class. All children are conveyed to and from school in special coaches which call at their homes or points convenient to them. In 1928 no treatment was given in the schools, and children who required it had to attend

FIG. 2.—Rates (per 1,000 of total school roll) of pathological conditions of pupils in schools for the physically handicapped in London, 1928, 1951, and 1957.

TABLE II.—Comparison of 1928, 1951, and 1957 Surveys of Pupils in Schools for the Physically Handicapped in London

Condition	Numbers Recorded			Percentage Distributions			Rates per 1,000 of Total School Rolls

hospitals, losing valuable educational time in travelling and waiting. In 1951 a start had been made in providing physiotherapy in the schools, and by 1957 it was available in all the schools, together with speech therapy, and where a group of deaf cerebral-palsied children are gathered together a teacher of the deaf can visit them. In the old schools there is inadequate provision for these services, but in the new schools, built and building, the planning is excellent.

There are some children, too severely handicapped for the special schools of the London County Council, who may be at hospital schools or schools run by independent organizations and supported by the local education authorities, while others, about 60, receive teaching at home.

There has been a double change over the years, some handicapped children being received into the normal school community and others being drawn out of the home and the hospital into the special schools. Accordingly, it should not be assumed that all the decrease over the last 30 years is due to an improvement in the health of the child population. Much of the change is, however, due to just this. It is not that there are children with chorea or rickets in ordinary schools—there is no chorea, there is no rickets.

Summary

A survey was made in 1957 of the reasons given for admission of the 1,325 children in London's schools for the physically handicapped. The diagnoses were coded under the International Statistical Classification (W.H.O., 1957). 93 different conditions were recorded. The most common reason for admission was cerebral palsy (312), followed by poliomyelitis (240) and congenital heart disease (127).

This survey is compared with previous surveys made in 1928, when there were 4,061 children in these schools, and in 1951, when there were 1,657. The incidence of the main groups of diseases in these three surveys is examined.

The changes observed—the falling incidence of juvenile rheumatism and non-pulmonary tuberculosis, the rise of cerebral palsy—are discussed and the reasons for the general decline in the numbers in schools for the physically handicapped are examined.

Thanks are due to Mr. W. F. Houghton, education officer, and Dr. J. A. Scott, principal school medical officer, for permission to publish this report and to the staff of the schools and the public health department who helped in its preparation.

The Exhibition of Medical Records at the Royal College of Physicians of London (November 26 to December 12) covers nearly 400 years, from the end of the fifteenth to the middle of the nineteenth centuries. Among the many exhibits on view are the first ordinance book of the Fellowship of Surgeons (c. 1492-7) which contains the text of the Bye-laws of the unincorporated Fellowship of Surgeons of the City of London; and the Letters Patent incorporating the College of Physicians in London, granted in 1518. The earliest subscription book of the Archdeaconry of Chichester shows the subscription of Elizabeth Strudwicke, of Kirdford, who was licensed to practise as a surgeon in 1673; this is "probably one of the earliest examples of a female surgeon." Among the other 59 exhibits are the articles of agreement between David Irish, "prakticiner in physick," and Joseph Chitty, of Whitneys, Surrey, to cure the latter's wife of "hypocondriak melancholy madness" for £5 down and a further £5 on completion of the cure. The catalogue of the exhibition (price 2s. 6d.), with an introduction by Mr. L. M. PAYNE, assistant librarian, Royal College of Physicians, gives further details.

REMITTENT INSULIN-INSENSITIVE DIABETES

BY

RONALD WELLS, M.B., B.Sc., M.R.C.P., D.T.M.&H.

Department of Medicine, General Hospital, Singapore

Following total pancreatectomy the adult human requires about 60 units of insulin a day (Young, 1951), but this figure is probably less than the actual daily insulin secretion because the operation also presumably diminishes the production of glucagon—a hyperglycaemic hormone secreted by the alpha cells of the islets of Langerhans. Many diabetics actually require much more than 60 units of insulin daily to keep them in good health, and Bornstein and Lawrence (1951) and Bornstein (1953) have shown that some diabetics have normal serum insulin levels. In such cases diabetes is probably due to insulin insensitivity rather than to actual insulin deficiency *per se*, but the mechanism of this insensitivity is not yet clear. A number of hormones are known to counteract the hypoglycaemic effects of insulin, and it is possible that the endocrine secretions of the anterior pituitary, thyroid, and adrenal glands, and of the alpha cells of the pancreas, may each be involved to varying degrees in different cases. Several physiological and pathological processes are known to be associated with decreased insulin sensitivity, including puberty, pregnancy, thyrotoxicosis, infection, and metabolism in a high carbohydrate diet. In some cases, however, there seems to be no obvious cause for the observed fluctuations in insulin requirements.

A number of diabetics are seen in Singapore who exhibit this fluctuation to an extreme degree. Some of these patients require over 200 units of insulin daily for a period, though later their insulin requirements may fall to zero. The following eight cases are striking examples of this syndrome, and others have been observed.

Case 1. 720 Units of Insulin Daily. Over 3 Years' Complete Remission

A 52-year-old Malayalam taxi-driver was admitted to hospital on April 18, 1954, with a history of a cough for five months, and fever, polyuria, weakness, loss of weight, and excessive thirst for six weeks. He was found to be a diabetic with gross cavitating tuberculosis of the right upper lobe. His sputum contained acid-fast bacilli and his urine showed sugar and acetone. A glucose-tolerance test revealed a fasting blood sugar of 215 mg./100 ml., rising to 270, 332, 384, and 316 mg. at half-hourly intervals. Treatment was begun with streptomycin and isoniazid, and he was controlled on soluble insulin. The progress of his glycosuria and insulin administration is summarized in Fig. 1. It will be seen that ultimately 720 units of insulin were required daily to control his glycosuria. Later the insulin requirements fell away to zero, and on February 14, 1955, a glucose-tolerance test showed a fasting blood sugar of 83 mg./100 ml., rising to 120, 148, 170, and 154 mg. at half-hourly intervals. Meanwhile his pulmonary tuberculosis had also improved, and an arrangement that had been made in May, 1954, to fly him to London for a right upper lobectomy was cancelled. Anti-tuberculosis therapy was finally stopped on November 2, 1954, at which time his sputum was negative, his E.S.R. was 2 mm., and his chest x-ray film showed only mild residual fibrosis.

This patient has remained fit and well, and has never had a recurrence of his diabetes or tuberculosis. He has weathered a number of other infections, including influenza and gastro-enteritis, without any complication.

Case 2. 360 Units of Insulin Daily. 22 Months' Complete Remission

A slim Ceylonese jeweller aged 46 had a cough for nine months and was admitted to hospital on April 23, 1954, in pre-diabetic coma. He was found to have bilateral cavitating tuberculosis, and a glucose-tolerance test showed a fasting blood sugar of 181 mg./100 ml., rising to 217, 290, 385, and 363 mg. at half-hourly intervals. He was treated with insulin, streptomycin, isoniazid, and P.A.S. It was found that 360 units of insulin were required daily to control his diabetes, but after 12 days at this dosage his insulin requirements slowly began to fall, and insulin therapy was finally stopped on July 11. A glucose-tolerance test was then normal. His tuberculosis continued to improve and anti-tuberculous drugs were stopped on February 15, 1955. In May, 1956, he began to have increased thirst and polyuria, and found that he had glycosuria. He has since remained a fairly stable diabetic, and for the last year has been well controlled on tolbutamide.

FIG. 1.—Insulin administration with related urinary findings and hypoglycaemic attacks (Case 1).

FIG. 2.—Insulin administration with related glucose-tolerance tests and menses (Case 2).

Case 3. 360 Units of Insulin Daily. 27 Months' Complete Remission

A 24-year-old Indian housewife was well until August, 1954, when, in the 29th week of her first pregnancy, she noticed she had polyuria and felt very thirsty. Her urine was found to contain acetone and sugar, although at regular monthly checks these had previously been absent. A glucose-tolerance test showed a fasting blood sugar of 394 mg./100 ml., rising to 450, 455, 478, and 491 mg. at half-hourly intervals. She was admitted to hospital for stabilization on insulin, and for two weeks required 360 units of insulin daily. Yet over the course of 10 days her insulin requirements fell to zero. The baby appeared to be large, and so labour was induced at 34 weeks. During and following a normal delivery the patient's blood sugar remained within normal limits and the baby's fasting blood sugar after delivery was 52 mg./100 ml. The patient remained well and breast-fed her baby. She had no recurrence of diabetes, and regularly tested her urine without finding glycosuria until January, 1957. She was then in the seventh month of her second pregnancy and again had to have up to 360 units of insulin daily. Her insulin requirements fell just before parturition, but this time she has had to continue on a small daily dose of insulin.

Case 4. 400 Units of Insulin Daily. One Year's Complete Remission

A 52-year-old Chinese noticed the gradual onset of increased thirst, general weakness, and polyuria. He was found to have sugar and acetone in his urine. A glucose-tolerance test on January 7, 1954, showed a fasting blood sugar of 462 mg./100 ml., rising to 480, 512, 520, and 520 mg. at half-hourly intervals. The patient was 5 ft. 4 in. (163 cm.) tall and weighed 244 lb. (110.7 kg.). He was instructed to take a low carbohydrate slimming diet, and was stabilized on 400 units of insulin daily as an out-patient. His weight remained constant, and he was therefore admitted to hospital, and maintained on a slimming diet of 1,000 calories. There was an immediate reduction in his insulin requirements to 80 units a day, and as he lost weight his requirements gradually fell to zero. A glucose-tolerance test then showed a fasting blood sugar of 107 mg./100 ml., rising to 121, 148, 172, and 168 mg. at half-hourly intervals. He was discharged weighing 208 lb. (94.3 kg.) and kept at that weight for about a year. His weight then rose again and his diabetic symptoms recurred. He refused to slim again, and is now symptomatically controlled on tolbutamide.

Case 5. 240 Units of Insulin Daily. 38 Months' Complete Remission

A 42-year-old Cantonese washerwoman presented with polydipsia, loss of weight, general weakness, pruritus vulvae, and polyuria in December, 1953. There was no evidence of infection. Her urine contained sugar and acetone, and a glucose-tolerance test showed a fasting blood sugar of 405 mg./100 ml., rising to 436, 472, 506, and 512 mg. at half-hourly intervals. She was controlled on insulin, and for five months her requirements remained stable at 240 units daily. She then suddenly began to have severe hypoglycaemic reactions and insulin administration was stopped. No glycosuria occurred, and six days after being well controlled on 240 units of insulin daily a glucose-tolerance test showed a fasting blood sugar of 88 mg./100 ml., rising to 121, 148, 164, and 160 mg. at half-hourly intervals. She remained well without treatment for 38 months, and periodic urine sugar tests were always negative. Then in September, 1957, she gradually developed diabetes again, and has since been well controlled on tolbutamide.

Case 6. 320 Units of Insulin Daily. Partial Remission

A slim 31-year-old Gurkha policeman had a sudden onset of increased thirst and polyuria associated with a common cold. He was found to have sugar and acetone in his urine, and a glucose-tolerance test showed a fasting blood sugar of 163 mg./100 ml., rising to 192, 232, 226, and 196 mg. at half-hourly intervals. His cold subsided in three days and he was stabilized on insulin, ultimately receiving 320 units daily for a period of 91 days. For no apparent reason his requirements then fell to 10 units a day and he was well controlled on this dose for six weeks. Eventually his requirements slowly rose to 240 units daily. He is now well controlled on tolbutamide.

Case 7. 480 Units of Insulin Daily. One Month's Complete Remission

A 16-year-old Franco-Pakistani schoolgirl noticed the onset of increased thirst and polyuria three weeks before she was admitted to hospital on October 6, 1953. She had no evidence of infection. Her menses began five years previously and were regular and normal. She had acetone and sugar in her urine, and a glucose-tolerance test showed a fasting blood sugar of 275 mg./100 ml., rising to 320, 370, 370, and 362 mg. at half-hourly intervals. The progress of her diabetes is summarized in Fig. 2. It will be seen that she required 480 units of insulin daily at one period, and later had two remissions before finally becoming a stable diabetic requiring 140 units of insulin a day. She has remained stable on this dosage, and is now a very fit student of economics in London. Her menses were not related to the fluctuations in her insulin requirements.

Case 8. 280 Units of Insulin Daily. Three Complete Remissions, One of Over 3 Years

A Dutch business man aged 63 was admitted to hospital in July, 1953, because of an acute exacerbation of gout. Although he had suffered from gout for 30 years he had apparently never been treated with colchicine. He was therefore tried on the drug and his gout quickly improved. However, he developed glycosuria, and a glucose-tolerance test showed a fasting blood sugar of 168 mg./100 ml., rising to 186, 224, 210, and 195 mg. at half-hourly intervals. His diabetes was controlled on 240 units of insulin a day, but after six weeks at this dosage his insulin requirements began to fall and insulin administration was stopped in November, 1953. His urine remained sugar-free until March, 1954, when, following another exacerbation of gout and subsequent colchicine therapy, he was again observed to develop diabetes. On this occasion he required 280 units of insulin daily for two weeks, and then his insulin requirements gradually fell and stabilized at 80 units daily. He then went to

South Africa for a holiday, and in August, 1954, apparently had a mild coronary thrombosis followed by a severe hypoglycaemic attack. A glucose-tolerance test was reported to be normal and his insulin administration was stopped. On returning to Singapore in September his urine was confirmed to be sugar-free. However, in November he again developed acute gout, took colchicine, and developed diabetes. A glucose-tolerance test on this occasion showed a fasting blood sugar of 176 mg./100 ml., rising to 195, 220, 224, and 210 mg. at half-hourly intervals. His diabetes was controlled on 80 units of insulin daily for five weeks, and then for the third time his insulin requirements fell to zero.

It was thought possible that his attacks of diabetes might be related to his colchicine therapy, and he was therefore started on probenecid. This has been successful, and since May, 1955, he has never had severe gout, insulin, or glycosuria.

Discussion

The eight diabetic cases described above each required over 200 units of insulin daily for more than seven consecutive days. In every case this period of insulin insensitivity was temporary, seven patients later having complete remissions, and one (Case 6) requiring only 10 units of insulin a day.

Diabetes mellitus insensitive or resistant to insulin is apparently uncommon in Europe and North America. In Joslin's very large experience of diabetes he records seeing up to 1952 only 20 patients who required over 200 units of insulin a day (Joslin, Root, White, and Marble, 1952); and Smelo (1948) found records of only 29 such cases in the world literature up to 1940, and another 25 cases in the subsequent English literature up to 1948. Yet in Singapore, I have observed 38 diabetics in the past five years who each required 200 or more units of insulin on at least four consecutive days, and it is not uncommon to find that diabetics here require over 100 units of insulin daily for long periods. The average insulin requirements of 165 diabetics in Singapore, selected only to exclude advanced pulmonary tuberculosis or incipient diabetic coma, was found to be 57.5 units a day (Tan and Wells, 1957), and, although no comparable figures are available, this seems likely to be higher than the average for diabetics in Britain. If this is so, one explanation may be that a higher proportion of the diabetics in Singapore fall into the older arteriosclerotic non-ketotic insulin-insensitive group, well described by Himsworth (1936) and Lawrence (1951).

To some extent the incidence of this type of diabetes may be genetically determined, as inferred by the findings of Lister, Nash, and Ledingham (1951). Another possible explanation is that most of those who developed insulin-sensitive ketotic diabetes in Singapore prior to 1945 died during the Japanese occupation because of the insulin shortage, producing a relative scarcity of this type of diabetic in Singapore at the present day. Conversely, the non-ketotic insulin-insensitive diabetics for whom insulin administration was not essential may actually have been benefited by the food shortages of the occupation which forced them to have restricted diets.

It has been suggested that the finding of insulin insensitivity may sometimes be false, owing to deterioration of the insulin used (Palmer, 1948). In the Tropics this possibility always has to be considered; but investigations in Singapore, including comparative assays in some of the cases reported above using insulin preparations specially flown here straight from the factories, have not shown any evidence of deterioration in the Singapore insulin stocks, even when these were at their recommended expiry dates.

Over-enthusiastic insulin administration may sometimes result in confusion between maximum insulin tolerances and optimum insulin requirements. It was the practice, however, in the management of the cases reported here, to keep the insulin administered so far as possible at the minimum which would adequately control the patient's glycosuria (cf. Fig. 1).

Remissions in diabetes of the duration and degree reported here appear to be rare in the literature, but Joslin *et al.* (1952) have commented that "remissions of the disease are common when the exciting cause for onset is removed and prompt aggressive treatment, soon after the onset of diabetes . . . is instituted." In Cases 1, 2, and 6 above, the exciting cause seems to have been infection. In Case 3 diabetes developed in the seventh month of pregnancy on two occasions, and in Case 8 the onset of diabetes seemed on three occasions to be related to episodes of gout treated with colchicine. In the remaining three cases, however, no exciting cause for the onset of diabetes was found.

Experience in Singapore certainly confirms that if diabetics are rapidly stabilized on soluble insulin, raising the total dose each day by one-fifth to one-third of the previous day's dose until no more than a trace of glycosuria is present, it is very common to find some degree of remission reflected by reduction in the daily insulin requirements. Such "aggressive" treatment inevitably results in occasional attacks of hypoglycaemia, but full insulin coma is rare if the insulin dosage is reduced at the first sign of hypoglycaemia and is thereafter kept at the minimum dose which controls the glycosuria. Where insulin is given hesitantly, the dosage being increased slowly, and particularly when full control of the glycosuria is never achieved, it is most unusual to obtain a remission. The chance of obtaining a complete remission seems worth the risk of an occasional hypoglycaemic attack, and personal experience of the latter is a valuable addition to a diabetic's education.

Experience with these cases, however, confirms that patients should be warned, "once a diabetic, always a diabetic." Although in the cases here reported there have been complete remissions for 38, 27, 22, and 12 months, all the patients have relapsed except Cases 1 and 8, who have had remissions of over three years. These two patients are still regularly testing their urines for sugar, despite naturally increasing optimism.

Before the introduction of carbutamide and tolbutamide, diabetics of the type reported here always presented difficult problems in management. In hospital it was possible to adhere to the "aggressive" scheme of treatment described, but when the patient was discharged the rapid fluctuation in insulin requirements still necessitated daily consultation and adjustment of the insulin dosage. In some cases the patients learnt to adjust their own dosages safely, and others telephoned for advice every morning before taking their insulin. There appeared to be no advantage in giving several injections of soluble insulin daily, and so, once they were over the severe phase in hospital, most of these patients gave themselves a single injection of protamine-zinc insulin each morning.

It is now apparent that many of these patients can be well controlled on tolbutamide instead of insulin, and the oral treatment has the great advantage that the dosage required seems to fluctuate only slowly and over a small range. Now that a high proportion of Singapore diabetics are receiving tolbutamide therapy it is unlikely that many more of these insulin-insensitive cases will be recognized here. A few diabetics, however, have been observed to have remissions while on tolbutamide, and it may be that they would have been insensitive to insulin.

Summary

A diabetic syndrome is described in Singapore, characterized by marked insulin insensitivity and periods of complete or partial remission. During these remissions the patients may sometimes remain fit and well, with no glycosuria for long periods, without insulin administration or any other treatment for diabetes. Eight examples of this syndrome are reported, and others have been observed. It is suggested that the insulin requirements of diabetics in Singapore tend to

be higher on average than those in Britain, and that this may be partly due to selective elimination of insulin-sensitive diabetics in Singapore during the Japanese occupation.

I am grateful to Professor G. A. Ransome for permission to publish the case reports of those patients who were admitted under his care.

SEVERE INSULIN LIPODYSTROPHY AS A POSSIBLE CAUSE OF INSTABILITY IN DIABETICS

BY

RONALD G. PALEY, M.D., Ph.D., M.R.C.P.Ed.
Research Fellow

AND

MARY H. SCOTT, M.B., Ch.B.
Senior House Officer

Department of Medicine, University of Leeds

Abnormal reactions in subcutaneous fat to injections of insulin have been recorded since its discovery. Such reactions have been termed "lipodystrophy," and should not be confused with the so-called "insulin lumps" which usually result from improper injection technique. Lipodystrophic reactions have been classified thus:

(a) *Lipo-atrophy*—the usual type of abnormal reaction, the incidence varying from 33% (Yohalem and Pollack, 1949) to 55% (Paley, 1953) of an adult diabetic population receiving insulin.

(b) *Lipohypertrophy*—a less common complication in adult diabetics, the incidence ranging from 3 to 6.5%. An example of lipohypertrophy is shown in Fig. 1.

Joslin *et al.* (1952) state that insulin lipodystrophy is a harmless complication, since no important structures are damaged, and it is annoying solely on account of the cosmetic effect. Other workers believe that these lesions in the subcutaneous fat may influence the absorption of insulin. Lamar (1950) suggests that insulin "resistance" and increased insulin dosage are more frequent in atrophic lipodystrophies, apparently resulting from continuously impaired absorption. He suggested that "brittleness" is more frequent in the hypertrophic nodular type, where insulin absorption from one or more depots may at times be added to the current dose, with the production of severe hypoglycaemic symptoms.

At the diabetic clinic at Leeds General Infirmary a number of diabetic patients with severe lipo-atrophy have had great difficulty in finding a suitable subcutaneous site for insulin injections. Diabetic control has been poor, and on changing injections to a site where fat was normal, such as the abdomen or buttocks, they have experienced hypoglycaemic attacks. Clinically it appeared that the injected insulin was utilized more efficiently from the normal sites, but, as they were out-

patients at the time, all the factors influencing insulin absorption and utilization were not strictly controlled.

Diabetic patients exhibiting moderate to severe lipodystrophy as defined previously (Paley, 1953) were examined with respect to stability of diabetic control. Of 53 such patients, 28% were classed as unstable

(as defined by Fryers, Paley, and Tunbridge, 1954). The total incidence of unstable patients at the diabetic clinic at Leeds General Infirmary was 17%. Superficially it would appear that patients with lipodystrophy have a greater incidence of instability, but statistically the difference is not significant.

The evidence would suggest that lipo-atrophy is not a major cause of instability in diabetics, but in view of its frequency it seemed necessary to investigate whether it is a contributing factor.

To test this hypothesis, six patients, each showing marked lipo-atrophic changes at the insulin injection sites and each a known unstable diabetic, were admitted to the diabetic annexe, Pinderfields General Hospital.

The disease had been present for more than five years in each patient, and they had been under careful supervision in the past.

Method

The patients, all females, were observed during an initial period lasting from 4 to 10 days. During this period they were maintained on their accustomed dose and type of insulin. No change was made in the site of injection, whether this had been into the atrophic or normal fat areas. No effort was made to improve the diabetic control during the study and there were no changes in insulin dosage. Although there was great variability in blood-sugar values observed, confirming the unstable nature of the disease, no hypoglycaemic attacks occurred and there was no ketosis.

Diet and exercise were rigidly controlled. The insulin dosage was checked and insulin was injected by a nursing sister or a doctor. Times of meals and times at which blood sugar was measured were the same throughout the experiment. Capillary blood was used throughout for blood-sugar determinations, and was estimated by the method of Hagedorn and Jensen (Harrison, 1937).

Three anatomical regions for injection were selected—namely, (a) intramuscular, (b) normal fat, and (c) atrophic fat. Each patient received injections in each anatomical area for one week. The sequence of areas for injection was randomized according to the accompanying Table.

The blood sugar was estimated at 8 a.m., 11.30 a.m., 3.30 p.m., and 9 p.m. The values were then analysed to demonstrate a difference in the time of day for the occurrence of high or of low blood sugars. This daily pattern of variations was obtained by plotting the mean deviation from the daily mean at specified times of the day for each patient from the three different anatomical sites.

The experimental design was described by Crump (1952) and further elaborated by Fryers *et al.* (1954) and Paley (1954). The statistical treatment is one of analysis of variance (Fisher, 1946).

Patient	Injection Site		
	1	2	3
E.P.	a	b	c
H.S.	b	c	a
D.B.	c	a	b
M.C.	a	c	b
M.B.	b	a	c
L.W.	c	b	a

Injection regions: (a) intramuscular, (b) normal fat, (c) atrophic fat.

Similarly, three female patients with severe lipohypertrophy were investigated under these experimental conditions. In this group, insulin injections were merely alternated at a week's interval between the hypertrophic areas and normal fat.

Results

Analysis of the blood-sugar estimations in the six female patients with lipo-atrophy shows no statistical difference at any time of the day for two patients, D.B. and L.W. (Chart for D.B. is shown in Fig. 2, A). Although significant differences in mean blood-sugar levels are encountered in the other four patients, no definite pattern of response emerges.

Thus a significant depression of blood sugar is observed at fasting level when patient E.P. receives the insulin into an atrophic area (Fig. 2, B); whilst a significant depression of mean blood-sugar levels is observed at 9 p.m. in patient M.C. when the results from both intramuscular injection and those from atrophic area are compared with the response from injection into normal fat (Fig. 2, C).

Conversely, a significant depression of mean blood sugars at 9 p.m. is observed in the normal and intramuscular sites when compared with the atrophic area for patient M.B. (Fig. 2, D). As if to emphasize the completely random nature of these results, patient H.S. shows a significant depression at 9 p.m., when the results from injections into normal fat are compared with intramuscular injection and also those into atrophic fat areas (Fig. 2, E).

When the results from the three patients with hypertrophic lipodystrophy are analysed two patients show no significant difference between the mean blood-sugar levels at any time of the day for injections into the hypertrophic and normal fat areas. The two curves for each patient are almost identical. Patient F.R., with severe hypertrophic lipodystrophy, was first maintained by injections into normal fat during the pre-investigation period; the first experimental area was also normal fat.

Although marked intra-daily variations of mean blood sugars were observed from injections in this site, no hypoglycaemic symptoms developed. The second experimental area was the hypertrophic fat. Here a significantly lower mean blood sugar was observed at fasting level with insulin injections into the hypertrophic areas, and slight hypoglycaemic symptoms were noted on the last two nights of the trial in this area (Fig. 3).

Discussion

Lipodystrophy has usually been considered a harmless complication of diabetes, and it was Lamar (1950) who first suggested that alterations in insulin absorption may be influenced by both atrophic and hypertrophic lipodystrophies at the sites of injection. Only scanty references to this topic can be found in the literature—those by Aubertin (1954) and Davis (1955)—although it appears to be a common clinical impression that insulin is "absorbed" more efficiently from normal fat than from an area showing lipodystrophy.

A direct comparison of a group of patients with severe lipodystrophy and a group with no lipodystrophy did show

FIG. 2.—Mean deviation from daily mean blood sugar for five patients.

FIG. 3.—Mean deviation from daily mean blood sugar for Patient F.R.

a higher incidence of instability in the former, though the difference was not statistically significant. Such an analysis, however, does not take into account all the factors associated with diabetic control, and in fact the result could be invalid.

Three sites for injection were selected—abnormal fat area, normal fat area, and intramuscular area. The intramuscular area was selected in order to see if there was a significant change in diabetic control, and, furthermore, in patients with severe atrophic sites it could then be recommended as a temporary alternative site for therapeutic insulin injections. Previous studies (Paley, 1953), and the present investigation, have shown no muscle atrophy to be present clinically in any of these patients. Lawrence (1928) stated that there was evidence that intramuscular injections of insulin may produce local necrosis.

Since unstable diabetic patients are subject to large and rapid swings of blood-sugar levels it seemed reasonable

to suppose that this experimental design could help to solve the problem of insulin absorption from lipodystrophic sites.

This study has shown that injection of insulin into atrophic fat sites does not appear to alter diabetic control and, similarly, that intramuscular injections of insulin do not cause an increased variation in blood-sugar levels. Instability in diabetic patients therefore appears to be entirely independent of the site of injection of the insulin.

Similarly, in the three patients with hypertrophic lipodystrophy no fixed pattern of blood-sugar levels emerged. In only one patient did a significantly lower blood-sugar level occur when insulin was injected into the hypertrophic area. If this effect is due, as Lamar (1950) suggests, to the occasional flooding of insulin from these hypertrophic depots, then it is surprising that this phenomenon occurred only once in the whole study. It is more likely that this solitary episode of hypoglycaemia was entirely independent of the site of insulin injection.

Summary

Six unstable diabetic patients with severe atrophic lipodystrophy and three patients with severe hypertrophic lipodystrophy were studied to ascertain whether insulin lipodystrophy was a factor in their instability.

The experimental design was an adaptation of one used in insulin therapeutic trials, and each patient acted as her own control.

No pattern of significant differences was observed in the blood-sugar curves obtained from different injection sites, and therefore lipodystrophy cannot be regarded as a cause of diabetic instability.

In view of the belief that intramuscular injections of insulin cause tissue necrosis, it is of interest that no untoward effects occurred from such injections given for four to seven days.

We thank Dr. J. Adler and his assistant for the blood-sugar estimations, and the ward sisters, dietitian, and patients for their willing co-operation in these trials. We also thank Professor R. E. Tunbridge for permission to study his patients.

The considerable educational activities of the National Association for Mental Health are summarized in its latest Annual Report for the Year 1957-8. Its longest-established course is for school medical officers and is on the ascertainment of educationally subnormal children and mental defectives. Recent changes in the school health services and in the general approach to mental deficiency pointed "to a re-orientation of the course as a whole," but agreement on the precise nature of it in future has not yet been reached. Various refresher courses have also been held, and a new project was a residential course on "Mental Health in the Public Health Field." It was held in April this year, and was attended by ten medical officers of health from the north of England. Students who came from overseas to attend the courses included two from Malta and one from Trinidad who on returning to their own countries will set up entirely new services for the mentally handicapped. Courses for chaplains in mental and mental-deficiency hospitals were found to be useful in enabling doctors and chaplains to discuss problems of concern to both.

CONTAMINATION OF OPERATING-THEATRE AIR WITH *CL. TETANI*

BY

E. J. L. LOWBURY, D.M.

AND

H. A. LILLY, F.I.M.L.T.

From the Medical Research Council Industrial Injuries and Burns Research Unit, Birmingham Accident Hospital

Cases of post-operative tetanus have been attributed by Robinson, McLeod, and Downie (1946) and by Sevvit (1949) to dust-borne contamination. Both reports imply that such contamination of dust was probably exceptional, in one hospital because of its nearness to grazing pastures, in the other because of the use of plaster hair in repairs to the theatre suite; and in both reports it is suggested that these risks would be reduced by improvements in theatre hygiene, including the use of plenum ventilation with filtered air.

A recent study in this hospital (Lowbury and Lilly, 1958) has shown that *Clostridium welchii* could be isolated from the air at most times, and that these organisms are apparently carried into the hospital with outdoor air; a plenum-ventilated dressing station showed significantly smaller numbers of *Cl. welchii*. In this paper we report a study on the incidence of airborne *Clostridium tetani*. It shows that small numbers of *Cl. tetani* could be found usually in the street and often in the exhaust-ventilated theatres; but none were found in a dressing station which was plenum-ventilated with filtered air. A simple technique for the recognition of toxigenic *Cl. tetani* is described. Some results of examination of dust, soil, faeces, and burns for *Cl. tetani* are also reported.

Methods

Sampling

Bacterial samples from air were collected with a large slit sampler (Bourdillon, Lidwell, and Thomas, 1948), and sometimes also by settle plates, on to nutrient gelatin (20%), which was then melted at 37° C. and distributed into bottles of cooked-meat broth. These, in most of the tests, were heated at 65° C. for 30 minutes before incubation; in later tests the gelatin itself was heated before addition to the cooked-meat broth. After four days' incubation and again after 12 days' incubation at 37° C., Gram-stained films of the cultures in cooked-meat broth were carefully examined for terminal spore-bearing bacilli. When these were present the culture was examined by the methods described below for the presence of *Cl. tetani*.

Samples of faeces and soil were inoculated in cooked-meat broth, which was heated at 80° C. for 10 minutes before incubation. Road dirt, hospital dust, and burn swabs were inoculated in cooked-meat broth, which was heated at 65° C. for 30 minutes before incubation. Gram-stained films were examined, as above, after four days' and after 12 days' incubation.

Isolation and Recognition of *Cl. tetani*

Cultures in cooked-meat broth showing terminal spore-bearing bacilli were subcultured by wire loop to the water of condensation in Fildes (1925) slopes. After anaerobic incubation in a Mackintosh and Fildes jar for 48 hours, the slopes were examined with a hand lens. If a characteristic fine filamentous swarming edge of growth was present, it was subcultured to a second Fildes slope; swarming

growth on this slope, after two days' incubation, was subcultured to cooked-meat broth. All bacilli with round terminal spores were found to swarm in this manner on Fildes slopes. Cooked-meat subcultures were incubated for four days, examined for purity in Gram-stained films, and tested as follows.

(i) Pairs of mice were given injections at the root of the tail of 0.2 ml. of culture to which 2.5% calcium chloride had been added immediately before the injection; one mouse of each pair had received an intramuscular injection of 3 units of antitoxin 24 hours and again one hour before the injection of culture.

(ii) Tubes of sugar media (glucose, maltose, lactose, sucrose, and salicin) containing strips of iron were inoculated and examined for evidence of fermentation after incubation at 37° C. for five to seven days.

(iii) Loeffler's inspissated serum slopes were inoculated, incubated anaerobically for five days, and examined for evidence of digestion.

(iv) Blood-agar plates (with 4% agar), one half of which had previously been spread with 0.1 ml. of undiluted therapeutic tetanus antitoxin, were inoculated in corresponding positions on both sides with the cultures of presumptive *Cl. tetani*; a straight wire was used for the inoculation. Nine cultures and a positive control could be tested on one plate. After two days' anaerobic incubation at 37° C., the plates were examined for growth and for haemolysis inhibited by antitoxin.

Terminal spore-bearing bacilli were described as toxigenic *Cl. tetani* if, after 18 hours, they had killed or caused tetanic spasms in an unprotected but not in a protected mouse. None of the organisms which gave these reactions were found to ferment any of the sugars or to digest a serum slope. On the antitoxin-controlled blood-agar plate—an adaptation of the Nagler plate test (see Lowbury and Lilly, 1955; Lilly, 1958)—toxigenic strains of *Cl. tetani*, including 11 reference strains from the National Collection of Type Cultures, caused good zones of haemolysis on the side without antitoxin, but no haemolysis on the antitoxin-treated side of the plate (see Fig.).

Diagnostic Value of the Antitoxin-controlled Blood-agar Plate ("Bench Mouse")

Fifty strains of terminal spore-bearing bacilli from air subcultured from Fildes slopes were tested both in mice and by the antitoxin-controlled blood-agar plate test, or "bench mouse." All of these strains killed or caused tetanus in unprotected mice, and showed haemolysis only on the side of the plate without antitoxin. One strain was positive in the mouse only on a second test, the first having failed to cause tetanus or to kill the unprotected mouse; it was retested because the "bench mouse" was positive.

Haemolytic strains of streptococci (20 each of groups A, C, D, and G), of *Cl. welchii* (20) and of aerobic spore-bearing bacilli (20) were tested and found to cause haemolysis on both sides of the plate.

"Bench mouse" examined by transmitted light (on left) and by reflected light (on right). The right half of the blood-agar plate was spread with tetanus antitoxin before 10 strains of *Cl. tetani* were spotted in corresponding positions on the two sides. After two days' anaerobic incubation there was growth on both sides, but haemolysis only on the side with no antitoxin.

In view of the identical results obtained by the two methods of testing, we relied on the "bench mouse" for recognition of *Cl. tetani* in the later part of this study.

Air Samples Examined

Samples were taken in the exhaust-ventilated operating theatre on 14 days, in the plenum-ventilated dressing station of the burns unit on 8 days, and in a covered road outside the hospital on 9 days. The ventilation system of the dressing station (Bourdillon and Colebrook, 1946) had Vokes "kompak" and "multivee" filters in series. Samples of approximately 690 cu. ft. (19.5 cubic m.) (30 minutes' sampling) were taken. On six days four such samples were taken in each of the three environments. To obtain some idea of the numbers of *Cl. tetani* present, the gelatin was well mixed after melting and added in four lots each of 15 ml., 7.5 ml., 3.25 ml., and (road samples only) 1.6 ml. to cooked-meat broth. In the other samplings the entire contents of the gelatin plates—that is, 30 minutes' sampling yield—were added to cooked-meat broth. We also examined a series of cultures representing replicates of 32, 16, 8, 4, and 2 minutes' sampling in each environment.

For 23 consecutive days we exposed for periods of six hours settle plates of gelatin for *Cl. tetani* and of a selective medium for *Cl. welchii* (Lowbury and Lilly, 1955) in the theatre and in corridors.

Results

Cl. tetani in the Air of Operating Theatre, Dressing Station, and Road

Table I shows the results of sampling for 30 minutes in each of these three environments on a number of occasions. *Cl. tetani* was isolated from 24 out of 27 samples taken in the road, from 33 out of 50 taken in the operating theatre, and from none of 23 taken in the plenum-ventilated dressing station.

Table II shows the cumulative results of sampling air from all three environments on each of six days by a semi-quantitative technique. Again the air from the road is shown to yield *Cl. tetani* more often than air from the operating theatre, and none were found in the dressing station. The probable number of *Cl. tetani* in these samples cannot be assessed with accuracy. When the Poisson series is applicable, 30% of samples fertile would imply the presence of a mean number of 0.3567 organisms per sample (Fisher, 1946). Approximately 30% of air samples of 345 cu. ft. (9.77 cubic m.) from the operating theatre and of air samples from the road of 86 cu. ft. (2.43 cubic m.) contained *Cl. tetani*. This gives some indication of the range within which counts of *Cl. tetani* might be expected to fall; it is clearly much lower than the counts of *Cl. welchii* in the same operating theatres (usually between 5 and 25 per 100 cu. ft. (1.76 and 8.82 per cubic m.) of air).

There was some support for these findings in the results of settle plate culture; 18 out of 23 settle plates from the theatre yielded *Cl. welchii*, but none of the 23 comparable settle plates examined for *Cl. tetani* was positive; 4 out of 15 settle plates from a busy corridor did yield *Cl. tetani*.

The distribution of *Cl. tetani* in air was irregular: when different volumes were examined on the same day, some samples of 690 cu. ft. (19.5 cubic m.) yielded no *Cl. tetani*, but occasionally a sample of 46 cu. ft. (1.3 cubic m.) was positive. The only day on which no samples from the operating theatre yielded *Cl. tetani* was one of continuous rain. The highest proportion of positives was found in dry weather. *Cl. welchii* was previously found to vary with weather in the same way (Lowbury and Lilly, 1958).

TABLE I.—*Cl. tetani* in Samples of Air (690 cubic feet—19.5 cubic metres)

Place	Samples Yielding <i>Cl. tetani</i>	Total Samples	Days
Road	24 (89%)	27	9
Operating theatre (exhaust-ventilated)	33 (65%)	50	14
Burns dressing station (plenum-ventilated)	0	23	8

TABLE II.—Cumulative Results of Sampling for *Cl. tetani* on Six Days in Road, Operating Theatre, and Dressing Station

Volume of Sampling Medium Tested (ml.)	Corresponding Volume of Air Tested		Proportion of Samples Yielding <i>Cl. tetani</i>		
	c. ft.	Cubic m.	In Road	In Exhaust-ventilated Operating Theatre	In Plenum-ventilated Dressing Station
15.0	345	9.77	11/24	7/24	0/24
7.5	172.5	4.88	10/24	1/24	0/24
3.75	86.25	2.44	6/24	0/24	0/24
1.875	43.125	1.22	0/8	—	—

Small numbers of air-borne *Cl. tetani* were found in the environment of another city hospital and of a hospital in a rural district. The air of an operating theatre in the latter, which was ventilated by open windows, also yielded *Cl. tetani*.

Other Reservoirs of *Cl. tetani*

Cl. tetani was isolated from 6 out of 7 samples of garden soil, 5 out of 5 samples of ward floor dust, 5 out of 6 samples of street dust, 8 out of 11 trouser turn-ups of laboratory staff, and 10 out of 35 specimens of human faeces. It was not found in any of the 273 swabs from burns which we examined.

Discussion

These studies show that very small numbers of *Cl. tetani* could usually be found in the air of a city hospital; since rather more of these organisms were found in the air outside the hospital and none at all in a dressing station ventilated with filtered air, it appears that contamination was introduced from outside, and was drawn into the operating theatre by exhaust ventilation. The same source of *Cl. welchii* and exclusion of that organism by plenum ventilation with filters have been described elsewhere (Lowbury and Lilly, 1958).

In spite of the regular isolation of *Cl. tetani* from air in these studies, tetanus has not occurred in any patient following an operation in this hospital during the past nine years. The risk of clinical infection from the small numbers of *Cl. tetani* which we found in the air must therefore be extremely remote. From the data presented by Robinson and others (1946), it seems that post-operative tetanus may result from an increase in the amount of environmental contamination with *Cl. tetani*. On the other hand, the rarity of tetanus may simply reflect the sparsity of tetanus bacilli in the environment. It would be useful to know what degree of contamination with *Cl. tetani* is found in theatres in which patients are known or thought to have contracted post-operative tetanus. Spores of *Cl. tetani* can germinate and produce toxin in tissues only under special and, perhaps, exceptional conditions. Although tetanus may follow trivial injury (see Press, 1948), it is nevertheless a rare sequel even of severe lacerated wounds in unprotected patients, and tetanus following rectal operations is a rarity in spite of the relatively frequent presence of *Cl. tetani* in human faeces. As in the case of gas gangrene, we may suppose that self-infection by faecal tetanus bacilli is a possible source of post-operative infection (particularly in abdominal surgery), but, as such cases sometimes occur in small outbreaks, infection from the environment is perhaps more important.

The functions of plenum ventilation in operating theatres are (1) to remove staphylococci and other organisms liberated in the theatre, and (2) to exclude dirt and bacteria from air admitted to the theatre. The latter, as our studies

have shown, include *Cl. tetani*, and *Cl. welchii*, which can be effectively kept out by cotton-wool and fibre filters in series.

Summary

Samples of approximately 690 cu. ft. (19.5 cubic m.) of air from an exhaust-ventilated operating theatre, a plenum-ventilated dressing station, and the road outside the hospital were examined for tetanus bacilli. These were sparsely present in 24 out of 27 examples from the road and 33 out of 50 samples from the operating theatre; none were found in 23 samples from the dressing station.

Cl. tetani was found also in all specimens of hospital floor dust, in trouser turn-ups of laboratory staff, and in 10 out of 35 human faecal specimens; it was not found in any of 273 swabs from burns.

These findings are discussed in relation to the occurrence and prevention of post-operative tetanus.

A simple plate technique (the "bench mouse") for the recognition of toxigenic *Cl. tetani* is described and illustrated.

We thank Mr. W. Cater, A.I.O.T.T., for assistance in air sampling; Dr. R. E. O. Williams for suggestions on the collection of samples; the clinical director, surgeons, and nursing staff of this hospital for their co-operation; and Mr. R. Gill for the photographs.

CLEANSING OF HOSPITAL BLANKETS

BY

C. G. A. THOMAS, B.M., M.R.C.P.

Lecturer, Department of Bacteriology

J. LIDDELL, M.B., B.Chir.

Registrar

AND

D. S. CARMICHAEL, M.B., B.Chir.

Registrar, Department of Clinical Pathology

Guy's Hospital, London

Several investigators have shown that the usual methods of laundering do not effectively reduce the bacterial contamination of blankets (see Blowers and Wallace, 1955). This unsatisfactory state of affairs is tolerated only because of the great practical difficulties in devising a method of laundering which is cheap, effective, and adaptable to normal laundry procedures.

We were recently asked to report on the bacteriological efficiency of laundering blankets at Guy's Hospital. In the course of this work it was noted that the standard of cleanliness achieved was much better than expected as judged by reports in the literature and by previous observations by one of us (C. G. A. T.) in a similar investigation at another hospital.

It has been suggested that our findings may be of interest to others who are concerned with laundry hygiene.

Materials and Methods

Laundry Methods Used for Blankets.—Blankets were washed in a Tullis washing-machine fitted with interrupter gear. The machine was filled with 80–100 gallons (360–450 litres) of soft water (0° H) at a temperature of 100° F. (37.8° C.) to which was added 4 oz. (120 g.) of "Crex" (20% solution of sodium sesquicarbonate) and 8 oz. (240 g.) of "sulphanol T" paste.† Twenty blankets were washed on each occasion. The washing process lasted 10 minutes and was followed by two rinses each of 100 gallons (450 litres). Immediately after the second rinse excess moisture was removed from the blankets by the means of a Broadbent 36-in. (90-cm.) hydro-extractor. The blankets were then transferred to another floor of the laundry and dried by air at 180° F. (82° C.) for 45 minutes in a Broadbent heated tumbler. They were then stored in a secluded part of the laundry on wooden racks under cover of clean cotton sheeting.

Source of Blankets.—Samples were taken on eight separate occasions at intervals from October, 1957, to April, 1958. Blankets arriving in the laundry from medical and surgical wards were taken at random and compared with blankets which had been laundered on the previous day and which were awaiting issue to the wards.

Method of Sampling.—The sweep-plate technique was found to be satisfactory. The blanket to be tested was held flat on a horizontal surface and six to-and-fro sweeps were made over a distance of 1 ft. (30 cm.) with an inverted Petri dish. A duplicate sample was then taken from another part of the blanket. The medium employed was nutrient agar containing 0.01% phenolphthalein diphosphate. After incubation at 37° C. for 18–24 hours counts were made of (a) total colonies, and (b) colonies of *Staph. aureus*. Colonies of *Staph. aureus* were recognized when colonies of typical appearance gave a bright red colour when the plate was held over a bottle of strong ammonia (Barber and Kuper, 1951): when necessary the identity was confirmed by means of the slide coagulase test.

Studies on Antibiotic Sensitivities.—These were performed using Evans's "sented" tablets.

Studies on Air-borne Contamination.—Settle plates were used to measure the air contamination in different parts of the laundry during normal working conditions. Plates of nutrient agar were exposed for known periods of time, and after incubation for 18–24 hours counts were made of total organisms and *Staph. aureus*. The results were expressed as organisms falling on 1 sq. ft. (0.093 sq. m.) per minute.

For studying the passage of air currents through laundry machinery *Serratia marcescens* was used as a marker organism. Heavy aerosols of this organism were produced from a broth culture by means of an atomizer, and the resulting distribution of the organism was then studied: air contamination was measured by means of settle plates; dry blankets were sampled by the sweep-plate technique; wet blankets were sampled by pressing the blanket directly against the nutrient medium; and various parts of the inside and outside of laundry machinery were sampled by means of swabs moistened with nutrient broth.

Smoke produced by exposure of titanium tetrachloride was used for detecting the predominant air currents under different conditions of ventilation.

Results

Table I shows the results of a series of counts taken over a period of six months for blankets arriving dirty in the laundry compared with counts after the laundry processes were complete.

Evidently the laundering processes greatly reduce the population of both total organisms (95.7% are removed) and *Staph. aureus* (98% are removed). It should be noted.

*A preparation of sodium sesquicarbonate manufactured by Imperial Chemical Industries Ltd., designed to produce mildly alkaline conditions.

†An anionic detergent based on sulphonated fatty alcohols supplied by Skilbeck Bros. Ltd.

TABLE I.—Comparison of Blankets Before and After Cleaning

	Before Cleaning	After Cleaning
No. of blankets sampled	100	100
Total No. of organisms isolated	47,818	2,034
Total No. of <i>Staph. aureus</i> isolated	1,085	22
<i>Staph. aureus</i> isolated expressed as a percentage of the total organisms	2.3	1.1
No. of blankets yielding <i>Staph. aureus</i>	87	15

however, that even with the small number of organisms (2,034) isolated from the laundered blankets in the above experiments no fewer than 22 colonies proved to be *Staph. aureus*, and that 15 out of 100 laundered blankets were contaminated with this organism. In separate experiments in which samples of fluff from freshly laundered blankets were collected on culture plates sown with *Staph. aureus* there was no evidence that the blanket fibres inhibited the growth of this organism.

The sensitivities of 50 colonies of *Staph. aureus* isolated from dirty blankets were compared with those of 50 *Staph. aureus* isolated during the period of this survey from patients in the wards. The results are shown in Table II. It will be seen that the two groups of organisms show a similar sensitivity pattern.

TABLE II.—Comparison of the Sensitivities of *Staph. aureus* Isolated from Blankets and from Patients

Antibiotic	<i>Staph. aureus</i> from blankets % resistant	<i>Staph. aureus</i> from patients % resistant
Penicillin	68	70
Chloramphenicol	6	8
Streptomycin	40	36
Tetracycline	32	36

The results of air studies in this particular laundry were largely negative, in the sense that, although air contamination occurred at various stages in the laundering process, no significant recontamination of blankets could be detected.

Settle plates exposed to the air in the room in which incoming articles were sorted showed, as expected, that the air was heavily contaminated: it was usually found that 300–600 organisms were falling on 1 sq. ft. (0.093 sq. m.) per minute. On the other hand, in the room used for storing the laundered blankets the air was relatively clean, and, at a period of maximum activity when blankets were being issued only 23 organisms were falling on 1 sq. ft. (0.093 sq. m.) per minute.

Experiments with aerosols of *Serratia marcescens* made it possible to study air-borne contamination of blankets during the various laundering processes, but in fact no important contamination was noted. For instance, although large volumes of air were drawn into the hydro-extractors there was no evidence that this caused significant contamination of the blankets inside. Similarly, though the hydro-extractors themselves produced a moderate increase in air contamination, this was of no account, since this contaminated air had no access to that part of the laundry in which the blankets were finally dried and stored.

Discussion

The results of laundering blankets in the way here described compare favourably with the results of many other accepted methods. One factor causing a fall in bacterial counts may be the use of sulphonated fatty alcohols as the cleansing agents, since the other procedures involved are in common use in many large laundries. However, the methods described are not ideal, since large numbers of organisms, including *Staph. aureus*, can still be isolated from the freshly laundered blankets. As suggested by Frisby (1957), the ultimate solution of the problem presented by hospital

blankets may be the replacement of woollen blankets by blankets made of some material which can withstand boiling and other rigorous laundry procedures.

When considering laundry hygiene, attention should not be directed solely to the process of washing. It is clearly important to see that freshly washed articles are not recontaminated.

In sorting dirty articles of clothing in a laundry it is usual for air contamination to reach high levels. Again, large laundries have powerful appliances which by design or accident draw in large volumes of air and then expel dust or aerosols into the environment. Obviously it is important that this contaminated air should not have access to regions of the laundry where freshly laundered articles are exposed.

By very simple methods—exposing plates to the air during normal working conditions, producing artificial contamination with aerosols of an easily recognizable organism, and studying the prevailing air currents with smoke—it is possible to detect these sources of contamination.

We cannot generalize on the steps which should be taken to remove such sources of contamination, since these will largely depend on the layout of individual laundries. However, it seems likely that quite simple alterations in ventilation or the siting of machinery or sorting-rooms and store-rooms will usually improve the hygiene of laundries where these defects still exist.

Summary

Hospital blankets are often contaminated with pathogenic organisms which are not removed by accepted methods of laundering.

A simple method of laundering blankets is described which, though not ideal, appears to give better results than many of the methods in current use.

In planning methods of laundry procedure it is important to guard against air-borne re-contamination of freshly laundered articles.

We acknowledge the help received in the course of this investigation from Mr. H. Besser, the laundry manager at Guy's Hospital.

Medical Memorandum

Agranulocytosis with Thrombocytopenia following Chlorothiazide Therapy

Chlorothiazide (6-chloro-7-sulphamyl-1,2,4-benzothiadiazine-1,1-dioxide), an orally effective non-mercurial diuretic agent, has been employed extensively both in hospital and in general practice during the past year. This drug is believed to be free of toxicity, and the only side-effects observed occasionally have been mild gastro-intestinal disturbances. One case with a maculopapular rash and pruritus has been noted by C. K. V. van Dommalen (1958, personal communication) following the use of chlorothiazide, but no other toxic manifestations have been published. It is therefore worth recording a case of fatal bone-marrow dysplasia following treatment with chlorothiazide.

CASE REPORT

A man aged 70 was admitted to hospital with a history of having collapsed in the street four weeks previously. He had been treated with digoxin and chlorothiazide at home for acute congestive cardiac failure due to hypertensive heart disease. The total amount of chlorothiazide administered

was 25 g. over a period of 13 days. He had received no other drugs, and there was no history of occupational exposure to chemicals or radiation. He was transferred to hospital after four weeks' treatment because of the development of delirium and incontinence over the previous two days. On admission he was found to be mildly confused, with a generalized maculopapular and purpuric rash over the face, trunk, and extremities. A pyrexia of 100.4° F. (38° C.), mild congestive cardiac failure, left hydrothorax, and a strongly positive Hess test were noted. There was no enlargement of lymph nodes or spleen. Tendon jerks in the lower limbs were absent and proprioception and deep sensation lost. Next day his condition deteriorated, he became mildly jaundiced, and there was further extension of the rash. He died six days after admission.

Investigations.—On his admission there was a normocytic normochromic anaemia with haemoglobin of 10.1 g. per 100 ml., and 3,000 white cells per c.mm. (lymphocytes 97%, monocytes 3%). Examination of two blood films revealed only a single eosinophil polymorph, and, although a few of the lymphocytes were atypical, no primitive forms were seen. The Paul-Bunnell test and W.R. and Kahn tests were negative. Two days later the white cells numbered 900 per c.mm. (neutrophil polymorphs 14%, lymphocytes 73%, monocytes 10%, atypical cells 3%). The neutrophil polymorphs stained histochemically showed a high alkaline phosphatase content. Platelets were 76,000 per c.mm., and E.S.R. 44 mm. in one hour (Westergren). Blood urea was 140 mg. per 100 ml., serum bilirubin 1.8 mg. per 100 ml., and thymol turbidity 4 units.

The direct Coombs test and Schumm's test were negative. Electrophoresis of the plasma proteins showed an increase in α_2 globulin. Serum electrolytes were: sodium 133 mEq/l., chloride 94 mEq/l., and potassium 3.9 mEq/l. Examination of the pleural fluid showed a simple transudate containing fresh blood.

The cause of the antecedent heart failure was confirmed at the post-mortem examination as being due to dilatation of a hypertrophic left ventricle. There was extensive purpura in the skin, the white matter of the brain, and the intestine. The bone marrow was replaced macroscopically by fibro-gelatinous tissue, and histological examination of that obtained from the sternum, lumbar vertebral body, and shaft of the femur showed it to be very hypoplastic. Myelocytes and some metamyelocytes were seen, but mature granulocytes were scanty. Erythropoiesis was normal or only slightly depressed. There was a relative increase of plasma and reticulum cells and a great increase in free iron. The number of megakaryocytes present in the marrow had also strikingly increased.

COMMENT

It is impossible to avoid the conclusion that the marrow disturbance in this case was due to an idiosyncratic reaction to chlorothiazide. The dosage of chlorothiazide was high but not excessive. The maculopapular element of the rash had the familiar characteristics of a drug eruption, and the purpura was linked with a severe thrombocytopenia. The combination of a low platelet count in the peripheral blood with large numbers of megakaryocytes in the marrow is the antithetical phenomenon that has been noted by Weisfuse *et al.* (1954) in the case of quinidine. The agranulocytosis, which was almost complete at one stage, is a frequent finding in this type of reaction, and the patient had not been exposed to any other potentially toxic material.

We thank Dr. H. E. S. Pearson who was in charge of this case, and Dr. P. Darby for the histological reports.

Reviews

ROLE OF THE SOCIAL SCIENTIST

Medical Sociology: Theory, Scope, and Method. By Norman G. Hawkins, B.Ed., Ph.D. (Pp. 290+xx. 51s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications, 1958.

When asked (soon after a divorce) what she thought of men Miss Hedy Lamarr is reported to have said: "Men are fine, love is fine; it's marriage I'm a little disappointed in." If one were asked about the possible contribution of the social sciences to medicine one would be tempted similarly to reply: "The social sciences are fine, but social scientists are sometimes a little disappointing." And the reasons, one would suggest, have their origin in their attitude to the natural sciences; they have at once too much respect and too little knowledge. As a result they have taken the methods of the natural sciences but not their standards, whereas it would have been preferable to have taken the standards but not the methods.

The theme of *Medical Sociology* is the role of the social scientist in medicine. His field, it is suggested, comprises "social epidemiology, the study of cultural factors and social relations in connexion with illness, and the social principles in medical organization and treatment." His contribution to understanding of the aetiology of the disease is illustrated by reference to specific diseases: "Any social scientist who wishes to discuss tuberculosis intelligently must first disabuse himself of the notion that infection is the predominant aspect of the disease." "Demography, comparative cultural studies, research in family and occupational experience, and physiological evidence, all indicate strongly that the two diseases [schizophrenia and tuberculosis] are associated with dissolution of the supportive cultural matrix and consequent severe or prolonged stress." "The beneficial effect of milk on stomach ulcer evidences lack of emotional satisfaction as the cause of the ulcer." (If the last—a quotation from another source—is intended to be funny it is written with a very straight pen.) Although quoted out of their context these three examples are fairly representative of the style and content of this book, which can only make the reader with a biological background more than ever doubtful about the contribution to be expected from social scientists to medicine. What is least satisfactory about their approach is the confidence with which they answer difficult questions, before we know the answers to much simpler ones.

T. McKEOWN.

ULCERATIVE COLITIS

Ulcerative Colitis. By Harry E. Bacon, B.S., M.D., Sc.D., L.D., F.A.C.S., F.A.P.S. With contributions by Paul T. Carroll, B.S., M.D., and Leroy W. Krumpman, M.D. (Pp. 395+xix; illustrated. £6.) Philadelphia and Montreal: J. B. Lippincott, 1958.

The author of this monograph has had a large experience of ulcerative colitis, for he has treated more than 400 patients with the disease during the past 16 years. Although a surgeon, he believes that the majority of patients with ulcerative colitis are best treated by conservative means, and he himself operated on just over one-quarter of his patients. In other words, his approach to the disease is not narrowly surgical, and the first half of the book is devoted to a consideration of aetiology, pathology, symptomatology, diagnosis, complications, and non-surgical treatment. This part of the book is an excellent review which every doctor interested in the disease could read with pleasure and profit. It is always interesting for a physician to observe the comments of a surgeon on medical forms of treatment, and Dr. Bacon survives the test well, although it must be remarked that few specific types of medical treatments have been tried under sufficiently stringent conditions

for scientifically valid results to emerge, so that their use depends upon opinion rather than fact. There is a view, widely held in Britain but even more so in the U.S.A., that ulcerative colitis is a psychosomatic disorder, so it is not surprising that formal psychotherapy is often regarded as the essential line of treatment. Dr. Bacon does not find that this approach has much to commend it, stating that "our experience demonstrates unequivocally that psychotherapy has been entirely unsatisfactory." He advocates that the clinician dealing with the organic side of the disease should himself serve in the capacity of psychiatrist, and he gives his views on the way that this can be done.

The second half of the book is a detailed account of the surgical treatment of ulcerative colitis and the results obtained. The opening chapter, which deals with the indications for surgery, is of general interest, and the author sets out his views with clarity and good sense. The remaining chapters are chiefly of interest to surgeons, as various operations are examined in detail. In so far as I, a physician, am able to judge, these chapters are excellent in their way, even though in places the non-surgeon feels inclined to echo the sentiments of the little girl who wrote: "This book teaches me more about penguins than I wish to know." The author is in line with most other expert bowel surgeons in preferring to do a primary colectomy with ileostomy rather than carrying out ileostomy and subsequently proceeding to subtotal or total colectomy. So far as the actual fashioning of the ileal stoma is concerned—a procedure of utmost consequence for the patient's future health—it is interesting to note that he himself uses as a routine the everted, full-thickness type of stoma devised by Mr. B. N. Brooke, of Birmingham, England. It is also interesting to note that he considers that there are some patients in whom it is possible to carry out ileo-proctostomy very satisfactorily and thus preserve normal defaecation, a procedure which Mr. S. O. Aylett has championed in this country, although many surgeons judge it to be an unsatisfactory operation.

All in all, this monograph is one which can be commended to surgeons and physicians alike.

S. C. TRUELOVE.

A CENTRE OF CLINICAL INVESTIGATION

Ward 4. The Mallinckrodt Research Ward of the Massachusetts General Hospital. By James Howard Means. (Pp. 187+x; illustrated. 36s.) Cambridge, Mass.: Harvard University Press. London: Oxford University Press, 1958.

This is the story of how the first of the modern whole-time professors of medicine at Harvard built, in 1924, a ten-bedded ward with three times its area of laboratories, and so made possible one of the formative centres of clinical investigation. The book also discusses the nature of research and describes in detail the patients in the ward at one given moment; but it is mainly concerned with the results achieved. This part is very skilfully written—a most readable account which will open the eyes of every layman who has any interest in science. It gives clear descriptions of such complicated and muddling things as the interrelations between bone diseases, calcium metabolism, the parathyroids, and kidney diseases which would also clear the air for doctors. In short, there are few books better worth recommending to both lay and medical readers. But one of the chief medical interests of the book is what Dr. Means has to say about the morals of clinical investigation. He is a doctor in the best sense, and he faces honestly, and with a new constructive approach, the ethical problem involved in "subjecting patients to prolonged study both for their own benefit and that of others." He lifts the subject to the level of the concept of the active co-operation of the patient as a member of the team: "indeed, patients no less than investigators have shown both loyalty and devotion to the cause of research." The suggestions on how this may be done will be, to many doctors, the most valuable part of the book. It is a pity that the impression is conveyed that all research workers in the world were given in Ward 4.

the opportunity which enabled them to establish themselves, and that every advance in medicine in the last thirty years has come from this one source, but those who have tried to write this sort of account will sympathize with the difficulty of distributing credits fairly without being maddeningly pedantic.

CHARLES NEWMAN.

MUSCULO-SKELETAL DISEASES

Orthopedic Diseases. Physiology-Pathology-Radiology. By Ernest Aegerter, M.D., and John A. Kirkpatrick, jun., M.D. (Pp. 602+xii; illustrated. 87s. 6d.) Philadelphia and London: W. B. Saunders Company, Ltd. 1958.

The physiology, pathology, and radiology of a considerable number of diseases of the musculo-skeletal system are described. Many of the subjects considered in the greatest detail are those conditions which have attracted attention during the last quarter of a century. The authors make no pretence about any original observations, but have collected information from good papers, extracted the subject-matter suitable for their book, and illustrated it with excellent reproductions from well-chosen radiographs. It is essentially a book for postgraduates, who would look elsewhere for the clinical features of the disease, but they will find lucid reading on the blood chemistry and pathology in this text. It is hardly surprising that the authors find it difficult to group some conditions, but it is unexpected to find non-osteogenic fibroma and solitary bone cyst in a chapter on circulatory disturbance, and all types of slipped epiphyses in the category of metabolic disease, although it is agreed that all or many are of unknown origin, and it does not appear that trauma is to be considered the only cause in any cases. Hamartoma seems to be a useful term to include osteoma, enchondroma, and other suchlike conditions. There is plenty to study in this book, as chapters include congenital and developmental disturbances, abnormal vitamin, thyroid, and parathyroid function, as well as a large section dealing with many aspects of tumours of the skeleton and soft parts. Photomicrographs are well chosen and of good quality and size. The publishers have made this book very readable by the high standard of production of letterpress and illustrations.

ST. J. D. BUXTON.

PSYCHOLOGY OF MEDICAL PRACTICE

The Psychology of Medical Practice. By Marc H. Hollender, M.D. (Pp. 276+x. 45s. 6d.) Philadelphia and London: W. B. Saunders Company. 1958.

Dr. Hollender claims that his book is "grounded in psycho-analytical psychology," but he has skilfully avoided the jargon of psycho-analysis in order to appeal to the general physician, surgeon, or practitioner. He has done his work well, and there is much sound advice and food for thought in these pages. He points out that to arrive at the correct clinical diagnosis is not always enough. The patient sometimes has his own diagnosis, and if real peace of mind is to be achieved this must be uncovered and discussed. The patient will reveal his own ideas only when he feels assured of a sympathetic hearing. The author suggests that the patient wants two things from his doctor; relief from his symptoms and also the comfort of a kindly parent figure. The book is enlivened by suitable case histories and an admirable selection of quotations and aphorisms, old and new. "A patient has no more right to all the truth than he has to all the medicine in your saddle bags." "All slowly dying persons can be helped by the kindly physician."

This is a book which can be read with profit by all doctors interested in clinical medicine. It deals with the handling of many types of patients and their relations. The chapter on the use of medications is below the standard of its fellows. I would like to suggest two omissions which might well be remedied in a subsequent edition: in the chapter dealing with the cancer patient the organization of "Cancer

Anonymous" should be discussed; secondly, although hospital routine is mentioned, it is worthy of much more consideration. It is a pity such a concise book of 276 pages should cost so much.

C. A. H. WATTS.

In *The Ministry of Pensions and National Insurance* (pp. 162; Allen and Unwin, Ltd.; 18s.) Sir Geoffrey King, a former Permanent Secretary to the Ministry, gives an account of its organization and function. He describes its origins, the system of statutory authorities who decide claims and hear appeals, and the various pensions, benefits, and allowances administered by the Ministry. A chapter on reciprocity and international agreements is included.

The proceedings of the first national congress of the Società Italiana de Cancerologia, held in Milan on April 8 and 9, 1958, have been published in two parts in *Atti della Società Italiana de Cancerologia*, a supplement to the journal *Tumori* (Casa Editrice Ambrosiana, Milan). The first volume is devoted to carcinoma of the breast, the second to cancer of the oesophagus.

A Synopsis of Otorhinolaryngology, by J. F. Simpson, I. G. Robin, and J. C. Ballantyne, with a section on neurology of the ear, nose, and throat by C. H. Edwards, is a recent addition to the "Synopsis" series published by John Wright and Sons, Bristol (pp. 443, illustrated; 1957; 42s.). It is designed primarily as a revision manual, having especially in view the needs of those studying for postgraduate examinations in oto-rhino-laryngology.

Formula for Death, by Fernand Gigon (pp. 223, illustrated; Allan Wingate, 15s.), is an account of the effects of the atomic bombing of Hiroshima and Nagasaki, with case histories of some of the victims who survived but later suffered from the delayed effects of nuclear radiation. It has been translated from the French by Constantine Fitz Gibbon.

According to T. F. Schlaegel, emotional factors play a part in all conditions involving the eyes. In his *Psychosomatic Ophthalmology*, written in collaboration with M. Hoyt (pp. 523; Baillière, Tindall and Cox, 1957; 88s.), he stresses the importance of the psychological investigation of ophthalmological patients. The book is divided into five sections, in which are discussed the role of psychiatric factors in disease, general conditions involving the eyes and about which psychological factors are known, disturbances of function and structure of the visual apparatus, ocular conditions without specific anatomical location, and the psychosomatic approach to treatment.

The Chronically Ill, by Joseph Fox (229 pages; Vision Press, 25s.), is based on the author's experience over many years as administrator of a home for the aged and a small chronic-diseases hospital in the United States. He defines the chronic diseases and describes their emotional and psychological effects. Attention is paid to the sociological and economic effects of chronic illness, the types of care required, and what can be done by way of rehabilitation.

Collected Papers of the Mayo Clinic and the Mayo Foundation, Vol. 49, contains reprints and abridgments of papers published by workers at the Clinic and Foundation and received during 1957. It comprises 30 papers reprinted in full, 86 abridged, 22 in abstract form, and 608 by title only. The volume (827 pp.) is obtainable from W. B. Saunders Company, price 91s.

Medical Electrical Equipment, written by 21 contributors under the editorship of Robert E. Molloy (pp. 312, illustrated; George Newnes, Ltd., 35s.), provides information on the principles, operation, care, and maintenance of electrical apparatus used in hospitals and clinics. It is intended for those who do not possess a deep knowledge of electricity. Full information is included on the elimination of possible dangers to staff and operators.

Selected Papers from the Institute of Cancer Research: Royal Cancer Hospital, and from the Royal Marsden Hospital, Vol. 11 (1956), comprises reprints of 98 papers published by the staff and research workers on all aspects of cancer research.

The Handbuch der Neurosenlehre und Psychotherapie, edited by V. E. Frankl, V. E. von Gebattel, and J. H. Schultz, is being published in parts at approximately monthly intervals by Urban und Schwarzenberg, Munich. When completed it will consist of five volumes each of 700-800 pages. Up to the present six parts have appeared. Single parts are not sold separately; the price of those so far published is D.M. 107.

KIDNEY TRANSPLANTATION IN IDENTICAL TWINS

The immunological obstacles to a successful transplantation are probably much more severe with homografts of kidneys than with homografts of skin. A skin homograft will succeed if its recipient's tissues can be induced to accept it. Although they can be made to do so in laboratory animals by taking advantage of the principle of immunological tolerance^{1 2}—a principle which is known to apply to human beings—the problems of applying it in clinical practice have yet to be overcome. With kidney homografts, however, there is the additional problem of making the graft accept its recipient, for the experimental work of W. J. Dempster^{3 4} and of M. Simonsen^{5 6} on kidney homografts in dogs uncovered histological appearances which led to the bold inference that certain cells in the graft were reacting upon antigens present in the host.⁶ "Graft-against-host" reactions have now been demonstrated experimentally by R. E. Billingham and L. Brent⁷ and by Simonsen,^{8 9} and it is now widely believed that they are responsible for "late deaths" that occur when, for example, mice which have been given lethal doses of irradiation are protected by the injection of bone marrow cells taken from mice of different inbred strains.¹⁰⁻¹²

The existence of these two obstacles, neither yet surmounted in clinical practice—the immunological reaction of host against graft and of graft against host—makes the future of kidney homotransplantation look rather bleak. Over a period of thirteen years fifteen true homografts of kidneys have been attempted at the Peter Bent Brigham Hospital.¹³ Five of the homografts worked temporarily, and one lasted as long as five and a half months; but in the

end all failed. Nevertheless there is important surgical progress to report: J. E. Murray, J. P. Merrill, and J. H. Harrison¹³ have recently summarized their experience with the transplantation of kidneys in seven cases in which the donors and recipients of the grafts were identical twins. Four of the patients had chronic glomerulonephritis, one had subacute glomerulonephritis, and two had chronic pyelonephritis. Six were in a terminal state of irreversible uraemia; the seventh patient, a 14-year-old boy, was operated on because of the retardation of growth and psychological difficulties associated with the bilateral nephrostomies performed a year beforehand. Their respective donors, who were proved to be their identical twins by detailed blood matching and the reciprocal exchange of skin grafts, had fully normal renal function. Their willingness to sacrifice one kidney should not be passed over lightly: "A major operation on a normal person, not for his own benefit, requires a brusque re-evaluation of traditional surgical thought. Is any risk, no matter how slight, ever justified?" But the immediate and long-term risks must not be exaggerated, for "a person with one kidney can have a normal life expectancy with normal renal function: in fact, one in every thousand persons is born with only one kidney, often unknown to himself or his physician."

The kidneys were grafted not into the renal fossa, which has certain disadvantages, but into the iliac fossa, anastomosis being made between renal and hypogastric arteries and between renal and external iliac veins; the ureter was sutured to the bladder mucosa. One patient failed to develop renal function, and this was the only surgical failure. In most cases a copious outflow of dilute urine began before the operation was over. Four subjects, one operated on 3½ years ago, are essentially normal and have returned to ordinary life; one has borne a child. A fifth died after four months as a result of the reappearance of her original disease in the transplanted kidney, and a sixth, though still alive eight months after operation, has developed ominous signs of impaired renal function. The existence of a third independent example¹⁴ of the reappearance of the original kidney disease in a normal transplant gives added weight to the possibility that "there are factors in the circulating plasma capable of transmitting glomerulonephritis in the human."

These seven cases make a brilliant surgical record. They show that kidney transplantation in man can be a thoroughly successful surgical procedure, in spite of the unnatural environment and blood supply of the graft, its denervation, the interruption of lymphatic drainage, and the physiological trauma associated

with its removal. The procedure is at present applicable to the small but by no means negligible number of persons—about 1 in 180—who have identical twins. It is not of course applicable when the donor is someone other than the recipient's identical twin, because of the intervention of the immunological factors mentioned above.

Much basic experimental work has still to be done on the use of renal homografts. We most urgently need to know, for example, if the immunological reaction of a kidney graft against its host can be in itself a sufficient cause of failure, even when the reaction of the host against the graft has been eliminated. If it were surgically feasible to transplant whole kidneys successfully in rats we should not have to wait long for an answer, for rats are available in inbred strains, and it is therefore easy to devise a situation in which the graft can react upon the host although the host cannot react upon the graft. If this approach is unworkable, it will be necessary to abolish the host reaction by x-irradiation or by the induction of tolerance. By one such means or another, it is most important that the question should be answered.

INFLUENZAL PNEUMONIA

The 1957 epidemic of influenza caused by the Asian variant of type A virus had several unusual features. It reached its height in Europe and the United States in the late summer and autumn instead of in the winter. Among very large numbers of cases most were uncomplicated, but when pneumonia developed it sometimes assumed a fulminating form, and in many, although not all, of the severe pneumonias the secondary infection was staphylococcal. A survey¹ by the Public Health Laboratory Service of 477 fatal cases of pneumonia during this period—in a majority of which influenza virus was demonstrated when it was looked for—showed that staphylococci were present in the lung and sputum of 62% of all cases, but in a higher percentage among children of school age and in a much lower percentage in old persons. A fulminating course, leading to death within two days of admission, was commonest in children of under 5, and least common after the age of 45.

These findings cannot be compared directly with those of a further survey described in the opening pages of this issue by Dr. Neville C. Oswald, Dr. R. A. Shooter, and Mr. M. P. Curwen, although they agree in pointing to secondary staphylococcal infection as the most dangerous complication in this epidemic. This material consisted of 165 cases of influenzal

pneumonia in undergraduate teaching hospitals in London, of which 20 (12%) were staphylococcal, together with 135 cases of staphylococcal pneumonia occurring in other hospitals and in the armed Services. These two series enabled a searching comparison to be made between the features of staphylococcal and non-staphylococcal pneumonia during this epidemic. The mortality of the former was high in every age group, and not significantly greater in the elderly (33%) than in children (30%), whereas in non-staphylococcal pneumonia it was small in every age group but the highest. In staphylococcal pneumonia consolidation was more extensive, 37% of patients having three or more zones involved, compared with only 19% in the other cases. There were corresponding differences in the height and duration of the fever. The discussion of a separate category of gravely ill patients, possibly to be classified as examples of "fulminating" infection, is complicated by the inclusion of a further series of 79 patients, making a total of 379: there were in all 132 such patients, of whom 76 (58%) died, and they included 71 (54%) with staphylococcal infection.

Unfortunately the conclusions which can be drawn about the merits of different forms of treatment are less definite. Oswald and his colleagues discuss the indications for steroid therapy and tracheobronchial intubation, giving qualified approval to the former and granting that the latter may sometimes be advisable. Their material presumably afforded no certain information about the usefulness of staphylococcus antitoxin, old stocks of which are said to have been rapidly and unexpectedly consumed by enthusiasts for this form of treatment. None of these measures can compare in importance with chemotherapy, if effective chemotherapy is possible. This is precisely where reliable information ceases to be forthcoming. Owing to the frequency with which two or more drugs had been given, either together or successively, no valid conclusions could be drawn about the relationships between therapeutic response and antibiotic sensitivity as determined *in vitro*. This is not at all surprising: the more severe and acute an illness, the greater the urge to try every promising remedy, especially when a laboratory report suggests that some change is indicated.

Although we are told nothing about the relative merits of different antibiotics in treating these patients, we are provided with highly significant information about the sensitivities of the staphylococci to them. It is very necessary to classify these organisms into those causing infections originating outside hospital and those likely or almost certain to have been acquired since admission, and

this was done in the survey of the Public Health Laboratory Service and in the series of Oswald and his colleagues. In the former the frequency of resistance to penicillin in home infections was 35% and in the latter 49%. For staphylococci from infections developing in hospital the corresponding figures were 70% or 100% (according to the duration of hospitalization) and 93%. There are corresponding differences in Oswald's series for streptomycin and tetracycline, 62% and 74% respectively of presumably hospital strains being resistant to these antibiotics, compared with 12% and 22% of outside strains. The prospects of successful therapy with the usual antibiotics therefore seem to depend considerably on the circumstances in which the infection developed. Resistance was rare to both chloramphenicol and erythromycin, especially to the latter, and, since erythromycin is much the more active of these two antibiotics in this infection, it is probably the drug of choice. In a gravely ill patient with staphylococcal pneumonia, particularly if this has developed in hospital, it should be given forthwith, preferably by the intravenous route initially to achieve an immediate effect, without awaiting the results of sensitivity tests. Treatment with this drug, or with novobiocin, was in fact advocated by T. Simpson² on the basis of experience with 25 cases in this epidemic. Reluctance to use the later antistaphylococcal antibiotics for fear of acquired bacterial resistance may be commendable in dealing with minor sepsis, but to bring it into the argument in face of one of the most acute of medical emergencies is to lose all sense of proportion.

PRIVATE GENERAL PRACTICE

The B.M.A. has consistently recognized the importance of maintaining and encouraging the existence of private general practice side by side with the general medical services provided under National Health schemes since 1911 and 1948. The active Private Practice Committee of the B.M.A. is sufficient witness of this. Some old-fashioned socialists may hold up their hands in horror at the idea of two types of general practice being set up to meet the needs of a mythically conceived one type of human being. They admit—at least by their silence—the need for socialist Prime Ministers to have special private doctors, and for socialist Cabinet Ministers sometimes to take therapeutic advantages denied the rest of us. Even in an egalitarian world most men are less fortunate than others. Those who claim that the existence of two types of practice is wrong should be careful what they say if they imply—as they usually do—that private practice is better for the patient than public, State-provided, practice. The G.M.C. sees that

all doctors have a minimum standard of medical education. Medical schools insist that the students they accept for training have a minimum standard of general education. In this way the public is safeguarded, and can check against a public *Medical Register* the claim of a man or woman to be a qualified practitioner of the healing art. Not all doctors so registered are equal in intelligence, ability, or even in moral standards, as the biannual meetings of the G.M.C. show. But at least they have a proficiency that has been tested, and a basis for developing fresh skills.

For some doctors the idea of working in a State medical service is abhorrent. They fear the prospect of a third party coming between them and their patients. They dislike the bureaucrat and his forms, orders, and regulations. They would rather treat a patient free of charge than accept a price on his head. They are strong individualists. Out of such reactions arose the movement that found its leader in the late Lord Horder, who, while still a member of the B.M.A. Council, started the Fellowship for Freedom in Medicine. The majority of conformists in the N.H.S. probably dislike such untidy institutions, these assertions of individuality in the new society of deadly levellers. But for a sturdy nucleus the possibility of private practice means the possibility of private choice and decision and the possibility of rising by private initiative and effort, with the risk of falling by the wayside taken into full consideration.

The cost of modern medical care being what it is, some 90% of the population must have some insurance cover for the risks of ill-health. For quite a number of people the N.H.S., however excellent it may be in many respects, falls short of what they want. No one, for example, would expect a busy man like the Prime Minister or the Leader of the Opposition in the House of Lords to queue up in a doctor's surgery under the N.H.S. Just how far down the list of V.I.P.s this expectation evaporates no one has determined. (The art of V.I.P.-ship has yet to be written by Mr. Stephen Potter.) But, just as many people have insured under various provident schemes against the expense of private hospital treatment, so would many like to insure against the cost of treatment in private general practice. In its current *Bulletin* the Fellowship for Freedom in Medicine describes such a scheme now inaugurated by the British United Provident Association, and the benefits to be obtained under it.

Any movement which fosters private practice should be encouraged. It is in line with B.M.A. policy. It takes account of the fact that some doctors and some patients dislike the regimentation unavoidable in a State scheme. And any increase in private practice will lessen the heavy burden now borne by the State and its compulsory taxpayers. Many general practitioners of first-rate ability much prefer to do their work in a State-provided service. They would be the first to take into account the fact that some of their colleagues would much rather enjoy the sense of freedom that goes with the private practice of medicine, however insecure the prospects may be.

HAZARDS OF POLLEN EXTRACTS

The injection of antigens, especially pollen extracts, carries the risk of sudden death even when correctly given. The total number of deaths recorded in the medical literature following skin testing or treatment with antigens, dating back to 1911, when desensitization was introduced, hardly exceeds twenty,¹ but opinions differ on how often such cases are published. Some are known to have gone unrecorded. E. Bruun² collected five deaths following injections of antigens in Scandinavia in the "past three or four years," but had no deaths in his own clinic during fourteen years. W. T. Vaughan and J. M. Black³ listed three cases of death and ten of constitutional reactions following injections of pollen extracts; they cited an investigation by Vaughan and D. M. Pipes,⁴ who, on carefully questioning fifty doctors attending a meeting of the American Medical Association, found that twenty-five had either personally observed or had heard of cases of allergic shock or death.

F. F. Furstenburg and L. N. Gay,⁵ of the Johns Hopkins Hospital, found seventy-five constitutional reactions following 29,547 pollen injections, an incidence of 0.25%. They were unable to find any cause in one half of the fifty "clinic group," nor in two-thirds of the twenty-five "private patients." There were no deaths. Gay⁶ writes that such reactions are encountered in spite of all precautions and will occur in any group so long as our present methods of treatment prevail—a viewpoint which is still unfortunately true.

N. Hjorth⁷ has recently drawn attention to the instability of pollen solutions. He has shown that partial emptying of a vial (from 10 ml. to 1 ml. three to twenty-one days previous to testing) reduces the potency of the pollen antigen. Indeed, the last millilitre in a 10-ml. vial had approximately only the same potency as the first millilitre of a similar vial containing a tenfold lower concentration. Hjorth refers to the work previously carried out on tuberculin solutions, in which a similar effect had been attributed to adsorption on the glass surfaces. It was found that it could be eradicated by the addition of stabilizers, of which "tween 80" was the most effective, addition of 0.005% being sufficient to prevent adsorption.^{8,9} Hjorth recommends that, until the problem has been investigated and a suitable stabilizer tested, vials of antigen solutions should be discarded when they have been half emptied. This applies not only to solution used for hyposensitization but also to that used for skin testing.

Incorrect dosage and incorrect techniques increase considerably the risk of severe reactions. It is worth

emphasizing that a small-bore needle and a syringe suitable for giving the exact dose are best used, and reading of the labels on the bottles needs to be exact. The plunger of the syringe should be withdrawn for an adequate time to be certain that the needle is not in a vein. Yet even with correct techniques constant care is necessary with each individual and with each injection. Pollen solutions vary, and it is worth taking special care when changing from a used bottle to a full one. The presence of a "cold" or other infection should always be inquired for before giving an injection, for infection will lower the patient's threshold, and the dose should then be reduced or temporarily withheld.¹⁰ Most authorities are agreed that injections should be given subcutaneously and that both patient and doctor should look for any reactions. The development of a local reaction is an indication for lowering and not increasing the next dose.¹⁰⁻¹²

Pollen injections undoubtedly help a reasonably high proportion of pollen-sensitive patients,¹³ and in expert hands constitutional reactions are uncommon, while death is a very rare occurrence indeed. However, before advising pollen hyposensitization for any patient, it is worth carefully assessing the severity of the hay fever or of the pollen asthma and perhaps trying a year of symptomatic therapy first.

RESEARCH INTO TREATMENT OF TETANUS

Tetanus is now usually treated in the clinic by giving a general anaesthetic, or barbiturate, or by injecting a neuromuscular blocking agent such as D-tubocurarine. These measures affect the respiration, D-tubocurarine causing paralysis. While they have been used with success, they impose a severe burden on the nursing staff, which must be highly skilled. The time for which treatment is required may be as long as three to four weeks. In consequence there is a need for a drug which can suppress the convulsions without interfering with respiration and without causing loss of consciousness.

A useful start in this direction has been made by D. R. Laurence and R. A. Webster, who have described a method for examining drugs in rabbits.¹ By injecting tetanus toxin into the gastrocnemius muscle of a rabbit they produced local tetanus, and they recorded the electrical activity resulting in the muscle. The spontaneous activity which they observed was irregular, but they elicited bursts of activity by striking with a hammer the frame in which the animal was supported. The hammer hit the frame every minute, and the activity which resulted was measured. To decide on the testing procedure they studied the effect of two substances, mephenesin and thiopentone. Having waited until the tetanic activity was uniform during successive periods of five minutes, they injected the substance intravenously and determined the time for which the activity was suppressed. By using groups of rabbits, and determining the mean effect of each of two doses of a drug, they were able to work out a procedure for making a

quantitative comparison of one substance with another on the same rabbits.

In a second paper² Laurence and Webster have described the application of this method to the four compounds chlorpromazine, thiopentone, betanaphthoxyethanol, and mephenesin. They found that chlorpromazine was far and away the most active, the relative potencies being 266, 5, 3.8, and 1. By their method other derivatives of phenothiazine which they also tested came out as having potencies of the same order as chlorpromazine, with the noteworthy exception of acetylpromazine, which was no less than 10 times stronger than chlorpromazine. Promazine was about half the strength of chlorpromazine while promethazine was about one-third the strength. The authors say that clinical tests on acetylpromazine are in progress. The work has obviously been done critically and with great care, and provides an elegant demonstration of how an effect which would seem very difficult to measure can in fact be measured by a proper application of the principles of biological assay.

PHYSICALLY HANDICAPPED CHILDREN

The number of children in special schools for the physically handicapped is not a direct index of the incidence of malformations and crippling diseases but of those grades of disorder which would prevent a child from benefiting by attendance at an ordinary school. Thus the persistent ductus arteriosus ligated in early childhood raises no educational problems; and most children with milder acyanotic congenital or rheumatic heart disorders attend ordinary schools. The term "physically handicapped" is but one of several categories of children needing special education: for instance, children with visual, hearing, and personality defects, epileptics, and the educationally subnormal all have places of their own in the educational system. The numerous children handicapped by respiratory allergy have been traditionally grouped apart under the quaint heading of "delicate." There are two main reasons why chronic asthma might be accorded the status of a "physical" handicap: it causes an inordinate loss of schooltime, and the severely asthmatic older child, on the verge of pulmonary heart failure, presents formidable problems of care and prognosis.

Elsewhere in this issue W. T. Palmer and D. Pirrie (p. 1326) examine the reasons given in 1957 for the admission of London children to schools for the physically handicapped and compare their findings with those recorded in surveys carried out thirty years and seven years previously. The countrywide figures¹ show that physically handicapped children, in the strict sense used in this L.C.C. study, are about 10% of all the handicapped children who need special education. The experience of most school medical officers would be in accord with the findings in London. There has been a steep drop in the proportion of children with bone

and joint tuberculosis, and also of those with rheumatism and its cardiac complications. This decrease is even steeper when measured against the total school population, since the number of children in L.C.C. special schools has contracted from 4,061 in 1928 to 1,325 in 1957. This itself is a measure of success in the prevention of two major diseases. By contrast, a far greater proportion of places in the special schools are now occupied by children with cerebral palsy, and there is a small increase in those with congenital heart defects, though these, with the after-effects of poliomyelitis, show a reduction in relation to the total school population. Progress has been made in other directions also, for the special schools now educate many severely handicapped children who would formerly have been kept in hospitals or at home. And, on the other hand, many children who are less severely handicapped are retained in the ordinary schools, or are quickly promoted back to the ordinary schools after, for instance, amputation. These are changes which have done much to help children overcome their disabilities.

In London and other large urban areas most of the children with physical handicaps can attend day schools. Unfortunately in other parts of the country many of these children have to be placed in residential schools, because it would be impracticable to set up special day schools within reach of all the small groups. Another difficulty is the placing of children who have two or more handicaps: nation-wide pooling of resources leads necessarily to residential education for the majority of such children. Children with cerebral palsy may have such a multiplicity of defects—of locomotion, sensation, speech, hearing, intellect, and emotional adjustment—that their care requires especially complex provision. Here again the more densely populated areas have some advantage in convenience of organization.

COAGULATION BY LIGHT

A powerful new apparatus is now in use at Moorfields Eye Hospital, London, for the treatment of retinal detachment. It is a light coagulator which has been developed by Dr. Meyer Schwickerath, of Bonn, and is made by Zeiss. The principle is that of the burning-glass used to focus the sun's rays to ignite wood. The source of light in this apparatus is an electric arc enclosed in a quartz tube containing xenon gas under high pressure. This light is passed through an optical system of lenses and emerges via an ophthalmoscope mirror. The surgeon can direct a filtered portion of the full beam into the patient's eye, and when it is accurately placed on the fundus lesion he can switch on the full beam for a fraction of a second. The normal refractive power of the eye focuses the beam on the retina and a minute retinal burn is produced. Several applications will seal off the area under treatment.

The treatment is carried out under local anaesthetic, and the patient is aware of no more light than that of a battery ophthalmoscope. The absence of any surgical cutting, the accuracy, and the precise control of the

method make it useful in selected cases. It is at present confined to the treatment of retinal holes and thin areas not deeply detached, macular and central retinal holes, Eale's disease and retinitis proliferans, retinal haemangiomas, small malignant melanomas, iris tumours, and optical iridotomy.

THE LIVER AND DIABETES INSIPIDUS

Although not usually regarded as one of the endocrine glands, the liver plays a major part in the hormonal control of the body by virtue of its capacity to inactivate and excrete most of the natural hormones. This particular function of the liver has been intensively studied in relation to the metabolism of sex hormones,¹ but more recently it has been shown that the adreno-cortical steroids are treated likewise.² The retention of water conspicuously shown by many patients with hepatic cirrhosis and less conspicuously by patients with acute hepatitis suggests that the hormones concerned in water metabolism might also be inactivated and prepared for excretion by the liver. At least two types of hormone are active in water and mineral excretion—the adreno-corticoids, exemplified by aldosterone, and the anti-diuretic hormone of the posterior pituitary—and there is conflicting evidence as to which is involved in the water retention associated with disease of the liver. The demonstration by Ralli and colleagues³ that in acute hepatitis the urine contains an excess of some anti-diuretic principle directed attention to the posterior pituitary as the source, but subsequent work by J. J. Chart and E. S. Shipley⁴ has shown that the main anti-diuretic component of the urine of such patients is not water soluble and is probably steroidal in character.

A remarkable case recently reported from Hungary⁵ throws some further light on this problem. A young woman sustained a mild head injury resulting in concussion but no loss of consciousness. Some seven months later she developed typical diabetes insipidus and other signs of hypothalamic disorder, and her fluid intake reached 10 litres daily. Her diabetic condition progressively deteriorated until two months later, when she developed a typical attack of viral hepatitis. Her fluid intake and output fell dramatically and became stabilized at about 1 litre per day after three weeks, and at this level it has remained for the past four years apart from a temporary rise during a subsequent attack of scarlet fever.

The sequence of events in this patient can leave little doubt that as a result of the head injury the function of the posterior pituitary became seriously impaired. The coincidence of the improvement of the diabetes insipidus with the onset of the viral hepatitis does suggest that anti-diuretic hormone was being secreted by the pituitary but was insufficient, in the presence of normal hepatic

inactivation, to control the renal output of water. As soon as this inactivation was impaired by the hepatitis the renal output was again controlled. If the diabetes insipidus had again relapsed when the liver recovered, this interpretation of the facts could hardly be questioned, but in the absence of such relapse it is at least conceivable that the relationship between the events was only coincidental, not causal. Study of similar cases in the future should readily resolve this doubt and establish unequivocally the importance of the liver in the metabolism of the pituitary antidiuretic hormone in man.

FOUR PER CENT.

The Government is to increase the basic pay of doctors in the National Health Service by 4% as from next January 1. This is the second adjustment of remuneration (the first, of 5%, was in May, 1957) in the interim period before the Royal Commission on Doctors' and Dentists' Remuneration reports, which, so the Minister of Health told Parliament last week, is not expected before next summer. He added that the increase was without prejudice to the Commission's recommendations and that Sir Harry Pilkington, the chairman, had informed him "that it will not embarrass the Commission in any way." The method of distributing the money is to be discussed with the B.M.A., but the Government itself has vetoed any increase in consultants' distinction awards. Thus for the third time these awards, which are pensionable, have been excluded from pay adjustments, and they remain unchanged from the figure fixed when the Health Service began. Indeed, the value of the A and B awards was relatively reduced in 1954, when their holders did not receive as big an increase in basic pay as other consultants. It would not have cost the Treasury much to make a small acknowledgment to merit, and enterprises outside State control long ago found they could ill afford not to foster this quality. Medical officers of health are also excluded from the increase, as they were excluded from the previous one, because their remuneration did not come within the terms of reference of the Royal Commission.

The Government's decision follows repeated representations by the B.M.A. for a further interim increase, beginning over a year ago. At that time there may have been some justification for refusal owing to the country's financial state and fear of inflation. Now, when the nation's economy appears to be in bounding health, 4% is a meagre figure to dole out—at a date still to come—to a profession which has waited all too long for a fulfilment of the promise obtained by Dr. S. Wand from Mr. Denis Vosper, then Minister of Health, in June, 1957,¹ that if it seemed unlikely that the Royal Commission could report by Easter, 1958, then he "would certainly consider any representations your Council might make, including a claim for a further interim adjustment." The increase probably does no more than preserve the value of the 5% that was given in May, 1957.

Drug Treatment of Disease

INSOMNIA

BY

A. H. DOUTHWAITE, M.D., F.R.C.P.
Senior Physician, Guy's Hospital

The purpose of this article is to discuss drugs used for insomnia. That they should form only a small part of the treatment must be stressed, but the wider aspects of the problem, though of great importance, cannot be encompassed in this account. It must be noted that insomnia is one of the few states which we are called upon to control without, as a rule, any certainty that it exists. We have to accept the patient's statement that he is sleepless, but the extent of his insomnia can be determined only in the minority who are under observation in hospital. Wakefulness in the night is almost always exaggerated, though in good faith.

In the British Isles, about one in every ten prescriptions issued under the National Health Service is for barbiturates and other hypnotics. It seems improbable that justification exists for this state of affairs.

Physiology

For the human subject sleep at frequent intervals is a biological necessity. Third-degree methods of interrogation have shown that deliberate and protracted prevention of sleep can bring about a complete collapse, both mentally and physically. The insomnia which we are called upon to treat is never of this degree and duration, and is very rarely harmful. This is a point of importance to be stressed to the patient.

Many people are worried about insomnia, not because they fail to sleep at all, but because they cannot sleep when they get to bed. In other words, the conventional nocturnal rhythmicity is lacking. No fundamental law dictates that each person shall sleep from, say, six to eight hours at night. Such a habit is purposely cultivated from childhood onwards. With it is associated a series of virtually conditioned reflexes. Superimposed upon the natural physical and mental tiredness is all the ritual of preparing for bed—the bringing of the evening's activities to a conclusion, the retirement to the bedroom, the undressing, the donning of night attire, the soft light of the room, the warmth of the bedclothes, the quiet, the contentment, the relaxation, and finally the oblivion. Anything calculated to disturb this accepted procedure can defer sleep, be it a strange house, unaccustomed cold or heat, anxiety and worry, or distractions and noise outside. The alleviating of insomnia calls for much more consideration and advice than the mere proffering of a mentally obliterating drug. Despite extensive physiological research, the precise mechanism of sleep remains undiscovered.

Pharmacology

Drug treatment of insomnia remains essentially empirical. What it does, in effect, is: (1) subdue cortical activity, such as anxiety, and (2) depress the nervous system generally so that the threshold is raised to external stimuli, notably noise. What is important is that these effects should be achieved without attendant danger, either to the vital centres of the brain or to the rest of the body. The simple act of taking a tablet at bedtime may itself become incorporated in the ritual, so that it can never be discontinued.

Soporific concoctions are not exclusively a modern delusion. Apothecaries in past centuries ventured their potions, of which the mandrake is but one example, upon those tortured by sleeplessness. Lacking though many of these brews may well have been in pharmacological potency, there is

little doubt that they quite often brought about the desired result. Of the older remedies, however, one of unquestionable effect is still available—namely, alcohol. On the central nervous system this behaves not as a stimulant but as a depressant. Its progressive action from the higher centres downwards carries the subject through stages similar to those seen in general anaesthesia—induction, excitement, anaesthesia, medullary depression—the second of these being regarded as a release phenomenon. Small doses of alcohol may thus conspire to that dreamy state characteristic of anaesthetic induction and so serve as a prelude to sleep. Too much can easily give rise to excitement and thwart the purpose for which it is taken. This possibility notwithstanding, a little strong drink taken on retiring may serve in some people, especially the aged, as an appropriate "night-cap." Large draughts of weak liquor like beer, on the other hand, are to be avoided, if only for the reason that an overloaded stomach is disturbing and an overloaded bladder later may be more so.

Chloral and Paraldehyde

Trichloroacetaldehyde, $\text{CCl}_3\text{CH}(\text{OH})_2$, or chloral hydrate, is a relatively simple chemical compound which is quite easily synthesized. It was introduced as a hypnotic by Liebreich in 1869 with the idea that, in the body, it might be converted to chloroform, CHCl_3 —at that time well on its way to becoming established as an anaesthetic. In fact it is now recognized that chloral hydrate undergoes reduction in the tissues to trichlorethyl alcohol, the substance ultimately responsible for the effects on the central nervous system.

Pure chloral hydrate is a crystalline substance with a pungent smell and bitter taste. Applied externally it is an irritant, even to the extent of causing vesication. Strong solutions are similarly irritant to the alimentary mucosa, so that vomiting and purging may occur. More dilute solutions are less troublesome in this respect, but, even when sweetened, they are unpalatable, for the burning taste is very difficult to disguise. Yet after oral administration absorption of this drug is rapid and a therapeutic dose can maintain hypnosis for six to eight hours. What is more, the therapeutic ratio is very wide, so that only with very excessive doses does medullary depression occur. The cardiovascular system also escapes damage. There is consequently a good deal to be said in favour of chloral hydrate, on grounds of both efficacy and safety. Its taste is the outstanding drawback and even this may be a deterrent to habituation. Unlike the barbiturates, chloral preparations cause no "hangover."

For adults it is convenient to prescribe chloral mixture *B.N.F.*, $\frac{1}{2}$ fl. oz. (14 ml.) well diluted with water to be taken at night, this dose containing 20 gr. (1.2 g.) chloral hydrate with syrup of orange. This preparation supersedes the old draught of chloral *B.P.C.*, or haustus chloralis, $1\frac{1}{2}$ fl. oz., which contains the same amount of drug but in liquid extract of liquorice. There is no rationale at all in combining a bromide with chloral hydrate in a hypnotic mixture. For children there is the chloral elixir for infants *B.N.F.*, with 1 gr. (65 mg.) in each 60 minims (3.5 ml.), flavoured with syrup of blackcurrant. The dose can be adjusted according to age. The *B.P. Codex* also includes a chloral and potassium bromide mixture for infants which is not to be recommended.

Dichloralphenazone is a complex of chloral hydrate and phenazone which has recently been devised. It is the active

¹ Evans, J. M., et al., *J. clin. Endocr.*, 1952, 12, 495.

² Brown, H., Willardson, D. G., Samuels, L. T., and Tyler, F. H., *J. clin. Invest.*, 1954, 33, 1524.

⁴ Chart, J. J., and Shipley, E. S., *ibid.*, 1953, 32, 560.

⁵ Hankiss, J., *N.Y. St. J. Med.*, 1958, 58, 2219.

constituent of "welldorm" tablets, each of which contains 10 gr. (650 mg.) of the substance. The usual dose for an adult is two tablets before retiring, swallowed whole with a draught of water. The unpleasant taste of chloral hydrate is entirely absent, and even if the tablets are chewed they are only slightly bitter. Limited experience suggests that they are as effective, dose for dose, as ordinary chloral hydrate. No claim is made that the phenazone component is analgesic.

Paraldehyde (CH_3CHO)₃ is a polymer of acetaldehyde (CH_3CHO). Safe and effective as the drug may be, its taste and persistently penetrating smell preclude its oral administration in the ordinary course of practice. It is best avoided in cases of gross hepatic disease. In febrile states it is prone to cause excitement. There are occasions, however, when it is of considerable value. For instance, nocturnal bronchial asthma, temporarily relieved by adrenaline, may be followed by sound sleep if paraldehyde is then administered. This use is not to be confused with the intramuscular injection of 5 ml., so useful in overcoming status asthmaticus.

Furthermore, for the seriously ill patient (for example, with heart failure or carcinomatosis) who is unable to sleep except fitfully from full doses of chloral or barbiturate, the administration of 10% paraldehyde in saline (enema paraldehyde *B.P.C.*) in a dose of 30 ml. of the enema per stone of body weight (4.7 ml. per kg.) will almost always prove highly effective. It should not be given to a patient heavily narcotized with morphine or heroin, because the superimposed depression on the respiratory centre may be dangerous. It may be given with advantage at night just as the therapeutic effect of an opiate is beginning to wear off.

Ureide Derivatives

Urea is pharmacologically inactive towards the central nervous system, yet a number of its derivatives are depressants. Thus:

Monoureides

Diureides

Barbituric acid itself is not active, but many of its derivatives, formed mainly by substitution on the terminal >CH_2 grouping, are potent. These are the barbiturates.

Carbromal *B.P.* is a white, odourless, crystalline powder which is practically tasteless. The official preparation is carbromal tablets *B.P.*, usually containing 5 gr. (0.32 g.) each. The dose is 1 to 3 tablets—that is, 5 to 15 gr. (0.32–1 g.) at night. The hypnotic response is mild and of fairly short duration, but acute overdosage is unlikely to occur. Repeated administration, however, may give rise to itching of the skin, erythema, pigmentation, and widespread purpura from increased capillary permeability. Habituation occasionally arises, usually in subjects of inadequate personality. Its main value is for the light sleeper or as a weak substitute to be used in breaking the barbiturate habit. It is to be found in a wide range of proprietary preparations on sale to the public; it is not scheduled as a poison.

Bromvalerone is a mild and safe hypnotic. It appears in various proprietary sleeping tablets and tranquillizers. "Persomnia" contains carbromal and bromvalerone. Apronal ("sedormid"), the prescribing of which has been almost completely discontinued, is a fairly feeble hypnotic

and can give rise to thrombocytopenic purpura, which is more dangerous than the relatively rare purpura of carbromal.

Barbiturates

Most of the barbiturates are white crystalline solids with a slightly bitter taste. The free acids are sparingly soluble in water, but the sodium salts dissolve readily and tend to be absorbed more rapidly from the gut. With a few exceptions, like the sulphur-containing compounds, they can be taken by mouth in tablet or capsule form. Their action is almost entirely confined to the central nervous system, the higher centres appearing to be subdued first of all. But the medulla is soon involved and respiratory depression may follow. Death from overdosage is due primarily to respiratory failure, with cardiac failure ensuing in consequence. Both alcohol and paraldehyde potentiate the action of barbiturates. Such a conjunction may be dangerous.

Pharmacologically the barbiturates may be classified according to their duration of action:

Long-acting—e.g., barbitone, phenobarbitone.

Medium-acting—e.g., amylobarbitone, amylobarbitone sodium, pentobarbitone, butobarbitone.

Short-acting—e.g., cyclobarbitone, quinalbarbitone.

Ultra-short-acting—e.g., thiopentone, thialbarbitone.

To give a long-acting substance like phenobarbitone as a hypnotic is misguided. For patients who have difficulty in getting off to sleep a short-acting drug is usually chosen. For those on the other hand who fall asleep promptly but wake in the early hours of the morning, a medium-acting compound is preferable, if given at bedtime. Alternatively the short-acting quinalbarbitone may be taken on waking in the night. The ultra-short-acting barbiturates are used as intravenous anaesthetics.

The barbiturates presented in colourful capsules require no effort in prescribing and appeal strongly to patients. But overdosage, accidental or deliberate, is a real danger and accounts for many deaths annually. In theory only a week's supply should be prescribed, but this is impracticable. In any case, a determined suicide can save supplies for his terminal adventure, or indeed avail himself of the gas oven. It is our duty to warn the patient of the danger of these drugs and to advise that they be kept in a cupboard inaccessible to children. A common complaint is of "hang-over" in the morning. The explanation of it eludes us. Some patients take barbiturates nightly and yet suffer no depression in the day. Others are conscious of mental slowness and fatigue starting about 2 p.m. and lasting for 3–4 hours. Irritability, prolonged reaction-time, and lack of zest can usually be detected in the confirmed barbiturate consumer. Repeated dosage may give rise to skin rashes, and habituation is common. Despite their wide usage, therefore, the barbiturates have obvious shortcomings. To add to the confusion they are presented in great variety, with a multiplicity of proprietary names and often in a series of combinations. Their relative merits are not easy to ascertain. There is much to be said for restricting the prescribing of barbiturates to those listed in the *British National Formulary*.

Because all barbiturates are Schedule IV poisons the prescription must state in every case the name and address of the patient, the total quantity of the preparation ordered (the total number of capsules or tablets and the strength of each), the dose, the full signature of the prescriber, and the date.

Other Hypnotic Drugs

Glutethimide ("doriden") is a synthetic compound, chemically α -ethyl- α -phenylglutarimide, which is distinct from the barbiturates. It acts as a moderately powerful hypnotic, a therapeutic dose given by mouth having an onset of action within half an hour and lasting for about six hours. Tablets of doriden each contain 0.25 g. of the active principle, and the dose is one to two tablets at night. Clinical trials suggest that this preparation therapeutically is the

approximate equivalent of cyclobarbitone. Side-effects reported include nausea, skin rashes, and, occasionally, excitement. It seems a reasonable alternative to the barbiturates, with probably less likelihood of respiratory depression and certainly less "hangover." Experimentally, this drug is of great interest, for its analogue β -ethyl- β -methyl glutarimide or bemegride ("megimide") is a stimulant to the central nervous system.

Methylprylone ("noludar"), whose active constituent is chemically 3:3-diethyl-2:4-dioxo-5-methylpiperidine, is a depressant of the central nervous system. Clinical experience in Great Britain is so far limited, but a clinical trial suggested that it was therapeutically of the same order as butobarbitone and amylobarbitone sodium. The dosage is one to two tablets, each containing 200 mg., at night. No side-effects have so far been reported.

Thalidomide ("distaval") is another non-barbiturate hypnotic, discovered and developed in Germany and so far not widely tried in Great Britain. It is too early yet to say that habituation and addiction do not occur. Tablets of "distaval forte" each contain 100 mg. thalidomide. The dose for hypnosis is one tablet at night. Side-effects and toxicity are said to be absent, but there is some suggestion of interference with thyroid activity.

Many drugs might be termed indirect soporifics in that by removing a disturbing symptom nocturnal sleep follows. For instance, intestinal hypermotility with rapid filling of the colon is much commoner in the brain-worker than in those of gluttonous habits. Here dry extract of belladonna (60 mg. (1 gr.) at night, or better tricyclamol chloride ("lergine," "elorine chloride") 50 mg. may calm excessive gut movement and provide undisturbed sleep. Drugs which relieve pain and cough fall into the same category.

As emphasized at the outset, it is more important to inquire into the causes of sleeplessness than to give drugs. Such simple matters as exercise, type of meal, quantity of fluid taken in the evening, and so forth may have an important bearing on a natural approach to insomnia.

Finally, tranquillizers are not suitable as soporifics.

THE ART OF CONSULTATION

FIFTH JAMES MACKENZIE LECTURE

On November 22 the College of General Practitioners held its annual meeting in the Great Hall of B.M.A. House. During the morning Dr. G. F. ABERCROMBIE delivered the College's fifth James Mackenzie Lecture, taking as his subject "The Art of Consultation." The general theme of his lecture, said Dr. Abercrombie, was that the family doctor must learn to manage, not only the patient and his relations and friends, but upon occasion his specialist colleagues also. The family doctor must remain in control unless, with the patient's consent, he delegated his authority temporarily and for some special purpose.

A Stroll down Harley Street

Inviting his audience to accompany him on a stroll down Harley Street, he said they would listen respectfully when the talk was of Pancoast's syndrome or Schimmelbusch's disease, but they would not be impressed by statistics. As a family doctor, he was not concerned with percentages, but only with people one at a time. The average expectation of life without operation might be so-and-so, but that was not the point. The point was what would happen to his particular patient. How his heart still warmed to the surgeon who wouldn't operate. And they should take kindly to the surgeon who said, "It is rather a good idea to regard the husband as one of the physical signs," and to the physician who wrote, "But you know her better than I do, and if you have any other view I hope you will let me know."

The art of consultation was not simply a question of sending a patient away for a second opinion. It was the careful

selection of the man who by training and temperament was the most suitable for the matter in hand. His position in the profession, his standing in his specialty, his skill, his appearance, his manner, and his gift of tongues had all to be considered. When Dr. Abercrombie began in practice they knew their men pretty well, for they met them in person at every opportunity. His partner made it perfectly plain to all his patients that, if they wished, a consultation would immediately be arranged, but also that, if he himself felt the need for a second opinion, no objection should be offered. In that way, he had met many physicians and surgeons from hospitals other than his own, and had learned a great deal from them.

Absolute Equality

When a consultant and a general practitioner met, no matter how distinguished the one or how obscure or different the other, they met on terms of absolute equality, the one to give, the other to receive, but not necessarily to adopt, the advice tendered. The consultant had to be careful here. He should be patient while the practitioner told his tale; he should not wave away, as of no account, the x-rays that had been brought; and he should not, with a brisk, "Well, I don't think we need discuss this together, need we?" deprive the practitioner of the opportunity to consider what was to be said to the patient, before it was said. Beyond all doubt a consultation was of immense value to the general practitioner, for it afforded him priceless opportunities of keeping up to date.

Consultations were arranged, generally speaking, either for information or for action, though often of course for both purposes. Dr. Abercrombie then gave some admirable examples of the first, often the "reassuring" type. "These men," he commented, "gave their opinions with absolute assurance. I may have had an idea, but their reasons were so convincing that they converted the idea into a certainty." Such opinions were first class; there was nothing woolly about them. He then recounted a rather different experience.

"A lady, 14 weeks pregnant, and her 4-year-old daughter, simultaneously developed German measles. The mother knew all there was to be known at that time about pregnancy and German measles, and I immediately obtained confirmation of the diagnosis from a dermatologist. Thence to an obstetrician, who, though clearly in favour of terminating the pregnancy, asked that his opinion be confirmed by a colleague. The second was just as hesitant as the first, and I had finally to take her to a physician before the operation could be done. This physician simply said, 'You can't do anything else.'"

Often, of course, one got no help at all from a consultation. Harley Street, in his experience, was reluctant to confess itself stumped. "It would be better sometimes if it did, and the exceptions are refreshing."

A Chance for the College

Cases of cancer of the breast were always distressing, for if at all possible there had to be a mutilating operation. The question was, "How much?" and the practitioner would know his surgeons well enough to be able to forecast what operation any of them would recommend in an individual case. The practitioner's responsibility was not lessened but rather increased thereby. But at any moment now, it seemed, continued Dr. Abercrombie, some pharmaceutical firm would announce a new drug for the treatment of cancer, and, if the history of antibiotics and of tranquillizers was any guide, that announcement would be followed within a matter of months by a dozen such discoveries. Their College would then have an immense opportunity if they were ready for it. "Have we a plan for the immediate investigation of such new remedies?" Their new building was to be alongside the Royal College of Surgeons and the Imperial Cancer Research Fund. They ought now, in anticipation of something revolutionary in the treatment of cancer, to have a consultation with those bodies, and prepare a scheme for assessing the value of new therapy.

"No man should die of acute or obscure disease without a consultation," Sir Clifford Allbutt had said as long ago as 1889. They would notice he had not said "without a second opinion"; it was "without a consultation." That surely was a right and fundamental principle in the practice of medicine. They all saw from time to time exceedingly rare conditions, of which they had had no previous experience—so rare, perhaps, that even the specialist they proposed to call had never seen such a thing before. Even so, and no matter how confident they might be that they had arrived at the correct diagnosis and had instituted the best possible treatment, they should always hold to the principle that no man should be allowed to die of acute or obscure disease without the benefit of a consultation. Allbutt, whose regard Sir James Mackenzie especially valued, had gone on to say—to the students at Charing Cross Hospital—"It is you touchy young men, just out of the schools, who give us the trouble—who bridle up at the suggestion of a consultation and declare that nothing more can be done."

Modern investigations were not an unmixed blessing, and sometimes their specialist colleagues were hypnotized by them. A physician had even refused to see a child patient with him outside his hospital, for fear that his opinion would be valueless before she was "investigated." Some years ago he had shown a child with a congenital heart lesion to a consultant. The consultant told him that his hospital had just started a clinic for such cases, and his answers to a question or two convinced Dr. Abercrombie that he had temporarily lost sight of what might be best for his patient in the desire to add another case to the new venture. He had become for the moment a collector, and the patient a rare and interesting specimen.

Captain of the Team

He had said that the family doctor received, but did not necessarily adopt, the advice given. He might feel convinced that a particular line should be taken, but be unable at first to find anyone to agree with him. He must then bide his time, advocating his plan, here a little, there a little. The family doctor really came into his own when specialist opinions differed. In this dilemma, all looked to him to find the right solution, and he must take his courage in both hands and rise to the occasion. Heaven knew he would not always be right, but he would by that time have specialized on that particular patient to such an extent, and have thought so deeply about him, that he might fairly claim that his advice should be followed. What should be done in the not very uncommon situation when pathological investigations drew blank, x-rays were indecisive, and specialists uncertain? The family doctor must accept the responsibility and make a decision, and to do that he should state the problem to himself in the simplest possible terms.

A great deal of the art of consultation could be very simply stated, said Dr. Abercrombie in conclusion. "Choose your man well, meet him yourself, remember that he is not infallible." A second opinion was a very poor substitute for a consultation. How much better to meet, to discuss, to agree, to explain to the patient and obtain his consent! It was now somewhat out of fashion to describe family doctors as the spearhead or backbone of the profession. Teamwork was the slogan; but he hoped they would agree with him when he said that if the family doctor was to be a member of the team he must be its brains and captain.

Reporting on the progress of the Perinatal Mortality Survey on November 12, Dr. NEVILLE BUTLER, its director, said that the return of completed questionnaires received by the Survey up to October 31 had now reached 95% of the 18,005 live-births notified between March 3 and 9, and 91.3% of the 8,316 perinatal deaths notified in March, April, and May. At least 85% of the 2,700 perinatal deaths notified in March had come to necropsy.

COLLEGE OF GENERAL PRACTITIONERS SIXTH ANNUAL MEETING

The sixth annual general meeting of the College of General Practitioners was held at B.M.A. House on November 22. Some 250 members and associates attended.

Dr. F. M. ROSE, chairman of the College council, presenting the annual report, described the College's progress. More than 5,000 members and associates had joined the College since its foundation, an increase of 554 during the year. One new overseas faculty had been formed, in South Australia, making 36 regional faculties in all—25 in the United Kingdom and Eire, and 11 overseas. On July 1, the six faculties in Australia founded their own

Presidential Chain of College of General Practitioners: Detail of the Links. The chain, designed by Mr. A. G. Styles and made in white and yellow gold by Messrs. Garrard and Co. Ltd., was presented to the College on November 22 by the Geigy Pharmaceutical Co. Ltd. It is 40 in. (102 cm.) in length and made of 19 matching pairs of links. The links are alternate medallions portraying a poppy entwined with foxglove and two entwined serpents.

Australian College of General Practitioners based on the constitution of the parent College, and planned with its encouragement and blessing. In the autumn the president paid a successful visit to South Africa to discuss the problem of setting up faculties in that country.

Education and Research

The undergraduate education committee (Dr. RICHARD SCOTT, chairman) has prepared a General Practice Teaching Register of members and associates in the United Kingdom and Eire who are willing to take students into "On practices"; and it has published a handbook "On Undergraduate Education and the General Practitioner." The postgraduate education committee (Dr. GEORGE SWIFT, chairman) has sponsored the work of the College's medical recording service, pioneered so successfully by Drs. John and Valerie Graves, which is proving of special value to doctors living in areas remote from medical teaching centres. That committee has also adjudicated the Upjohn travelling fellowships, supervised the arranging of the Pfizer lectures, and published "Problems of Stress in General Practice." The widespread activities of the research committee (Dr. R. J. F. H. PINSENT, chairman) have continued and 632 members and associates of the College are now on the Research Register. Careful thought is being given to the financial aspects of research in general practice, including the possibility of founding research registrarships. Four issues of the new *Journal of the College of General Practitioners* (Dr. R. M. S. MCCONAGHEY, editor) have been published during the year.

New Premises

In March the College moved into new premises at 41, Cadogan Gardens, Sloane Square, S.W.3, generously provided by its anonymous donor. All meetings of council and its committees are now held there. A college library (Dr. J. P. HORDER, honorary librarian) is being developed, and the practice equipment and premises committee (Dr. J. C. T. SANCTUARY, chairman) is preparing a demonstration

room. There are bedrooms for members and associates visiting London.

Elections and Presentations

Dr. I. D. GRANT was unanimously re-elected president for 1958-9. His portrait by Mr. Norman J. Miller Miller was presented to the College by the chairman of the Scottish Council (Dr. W. S. GARDNER) on behalf of members and associates in Scotland. A magnificent presidential chain of office (see Fig.) was presented by Mr. H. L. ADDLESHAW on behalf of Geigy Pharmaceutical Co. Ltd.

Dr. Albert Schweitzer, O.M., Dr. W. N. Pickles, C.B.E., Dr. W. A. Conolly (Australia), Dr. A. Barrett Jameson (New Zealand), and Dr. M. R. Stalker (Canada) were appointed honorary fellows of the College. Dr. J. K. Paterson (Upton, Huntingdonshire) was presented with the Butterworth gold medal (1957-8) for an essay on "Second Opinions," the second prize being awarded to Dr. S. G. Gang (Cardiff). The subject for the 1958-9 Butterworth gold medal will be "The Child is Father of the Man." (Essays must be submitted to the chairman of the awards committee not later than September 19, 1959.) Seventeen Upjohn travelling fellowships (up to £200 each) were presented to: H. W. Ashworth, M. H. S. Bound, Margaret P. Coshaw, W. G. Daynes, V. G. Doyle, T. S. Eimerl, R. N. R. Grant, D. M. Hughes, A. J. Laidlaw, J. B. Longmore, W. J. H. Lord, D. W. MacLean, D. H. McVie, A. E. de la T. Mallett, Charlotte Naish, E. J. R. Primrose, and F. H. Staines. Six Public Welfare Foundation prizes (£40 each) were presented to the following final-year students: E. E. Barnard, J. C. Burn, W. J. C. Conn, Christine E. J. Dandie, P. W. Kershaw (all of Edinburgh University), and C. Venning (Charing Cross Hospital Medical School).

The following faculty representatives were appointed to the Sixth College Council (1958-9): L. W. Batten (North London), R. H. A. Elder (South London), E. A. W. Marien (East London), R. Cove-Smith (West London), George Swift (South-east England), J. C. T. Sanctuary (Northern Home Counties), W. G. Tait (Thames Valley), D. Scott Napier (East Anglia), R. M. S. McConaghey (South-west England), D. L. Crombie (Midland faculty), K. M. Foster (North Midlands), R. A. Murray Scott (Yorkshire), S. Freeman (North-west England), R. Harkness (North-east England), W. L. Selkirk (Merseyside and North Wales), J. N. M. Parry (Welsh faculty), Richard Scott (South-east Scotland), W. S. Gardner (West of Scotland), J. M. Henderson (East Scotland), G. Swapp (North-east Scotland), G. H. Clement (North Scotland), A. S. Boyd (Northern Ireland), V. G. Doyle (East of Ireland), J. P. J. Little (West Ireland), J. C. Walsh (South Ireland), A. B. Jameson (Auckland), H. E. W. Robertson (Canterbury), H. E. M. Williams (Otago), E. J. Marshall (Wellington), Mary Robertson-Glasgow (Kenya). Four elected members of council, to replace those retiring, were appointed: J. Fry, J. M. Hunter, R. J. F. H. Pinsent, and G. I. Watson.

College Business

The report of the criteria committee (Dr. K. McD. FOSTER, chairman), on a possible examination on the conduct of general practice as one of the criteria for future membership of the College, was discussed. A motion that no action be taken about this for five years was lost, and the report was referred to the faculties for their consideration. The College by-laws were amended, and, by almost unanimous agreement, the annual subscription for members was raised from three to five guineas. The chairman thanked the B.M.A. for its generosity in allowing the College the use of its Hall; and Dr. G. F. ABERCROMBIE moved a vote of thanks to Dr. Rose.

At a meeting of the new council held later, Dr. F. M. Rose was appointed chairman, Dr. Annis Gillie, vice-chairman, Dr. H. L. Glyn Hughes, hon. treasurer, and Dr. J. H. Hunt, hon. secretary. Drs. G. F. Abercrombie, H. N. Levitt, and Charlotte Naish were appointed additional members of the council.

Symposium on "Dyspepsia"

On Sunday, November 23, under the chairmanship of Dr. I. D. GRANT in the morning and Sir FRANCIS FRASER in the afternoon, 180 members and associates of the College attended a symposium on "Dyspepsia." The trustees of the Wellcome Foundation generously provided the

auditorium, and also morning coffee, lunch, and tea for the whole audience. The main speakers were Drs. S. J. Carne, Desmond O'Neill, Richard Scott, R. R. Bomford, H. N. Levitt, and Mr. H. Daintree Johnson.

MEDICINE ON TELEVISION

ITS PRESENTATION TO THE PUBLIC

A discussion on "Presenting Medicine to the Public on Television," arranged by the Scientific Film Association, was held at the Royal College of Surgeons on November 19. The principal speaker was Mrs. MARY ADAMS, who until her retirement this year was assistant to the Controller of Television Programmes at the B.B.C. Her talk was followed by short telerecordings of admittedly controversial sequences from five B.B.C. programmes, including *The Hurt Mind*, *Your Life in Their Hands*, and *On Call to a Nation*, and then by a general debate. Dr. R. F. WOOLMER, chairman of the medical section of the S.F.A., was in the chair, and the audience comprised doctors, a number of whom were those directly concerned, as advisers, in medical television to the public; health educationists; and directors, producers, and technical staff from the B.B.C. and I.T.A.

Mrs. Mary Adams on Televising Medicine

"On the whole," said Mrs. ADAMS, immediately putting her audience on its mettle, "people in professional circles tend to talk about television without having seen it." It was said that only about 10% of a professional audience would be found to have a set. She believed, however, that in presenting medicine to the public, television had a future which could be both healthy and constructive. Many ingredients were involved. First there was the question of the health of the individual as well as the health of the individual in society. Then there was the medium itself, and not only the techniques, which were themselves complicated, but also the people who manipulated them, with their anxieties and attitudes, and the predilections of individual producers. There was the ingredient of the authority by which these programmes reached the public, authority which came from Parliament and the Postmaster-General and through the board of governors of the B.B.C. and the governing body of I.T.A. Another ingredient, often forgotten, was the audience. It was a mixed audience, and there was something queer about television whereby people seemed to have to view. So, although one talked about people being able to switch off if they did not want to see an operation, they did not in fact do so. There were also the assessors of programmes—Mr. Dickson Wright and some of his colleagues in the B.M.A., as well as the professional critics in the press and elsewhere, and scientific assessors working in viewer research.

"Medicine has always been a satisfactory and 'good' subject for television from the earliest days," continued Mrs. Adams. This was not surprising, because medicine exercised a striking fascination for people; no doubt it had something to do with Western ideas about death. It was true in all countries with television, even behind the Iron Curtain. Exactly the same kind of controversy as that in the *British Medical Journal* and the Press had been aroused in Prague recently by the same kind of programme, and it had elicited the same kind of response—the mass of viewers agreeing, the medical profession somewhat divided, a few being worried about consequences which they did not know about.

Pros and Cons

Television was an entertainment medium, and every programme had to be considered in that light, or at any rate in that context.

The main argument against these programmes was the charge of sensationalism. "I do not know what 'sensationalism' is quite," said Mrs. Adams. "I think it only means that the people behind the programmes are being immoral in their motivations. If so I have not met any of them. They are only anxious to do their best." On superficiality, she agreed that television was in some

ways a very superficial medium. Those inside were extremely anxious that the doctor-patient relationship should not be disturbed in the wrong way. Yet it might be right to disturb it. Turning to the arguments in favour, Mrs. Adams said that there was now a "climate" for the scientific and medical, and to let medicine opt out of this general climate would be quite unthinkable. One also had to remember that a large number of other agencies were doing the same thing, so it was difficult to disentangle the effect of television. Research into the effect should be asked for by all, including the medical profession. It was important also to experiment with new techniques and personalities in programmes. Mrs. Adams had been impressed by the argument of Dr. M. Keith Thompson in the *British Medical Journal** that there was a tendency for television as it existed now and under its present authorities to put on the screen the most orthodox methods. "We come down fairly heavily on the side of the orthodox," she agreed. Television had received much help and stimulation from the medical profession, but on the whole the ideas for programmes had come from the television people. She would like to see the reverse process—the medical profession saying, "This is a subject which ought to be aired and we will help you."

The audience were then shown the five short sequences from B.B.C. television programmes.

Discussion

Mr. A. DICKSON WRIGHT, who opened the discussion after the film sequences, said he did not realize this was going on: it seemed to have developed to a tremendous degree. Hypochondriasis was running through the world. He was appalled by it.

Dr. C. M. FLETCHER, who has appeared in a number of the programmes, replied that hypochondriasis had existed in the 15th and 16th centuries, for example; these programmes did not produce it, though they might transfer it to a new organ. He suggested that the College of General Practitioners might help in research on the effects of the programmes. For people to know what medicine could do to-day was nothing but reassuring. He had thought it a mistake to include the operation of portocaval anastomosis in *Your Life in Their Hands*, but he had been convinced of his mistake. Some builders had remarked they never thought surgeons were as good as that—"they're as good as plumbers." Here was something they could understand.

A psychiatrist, while agreeing that the general public had always been interested in medicine, felt that television, which reached millions, had a special responsibility. Programmes like that on smoking and lung cancer and those dealing with the prevention of illness were useful, but whom was a film about ether abreaction going to help? He had seen people who were not willing to be treated by E.C.T. and ether abreaction, because they had been frightened.

Dr. M. WARE said he had read the report on the effects of *The Hurt Mind* programmes, and thought it scientifically unreliable. Standards of assessment should be more stringent. When questions of treatment arose, a doctor might need to spend much time preparing some patients, while others could be told quickly. A programme going to an enormous audience could not make that sort of allowance. On television personalities, Dr. Ware commented: "I am not sure it would be a good thing in medicine if there were a lot of 'radio doctors.'" In *On Call to a Nation* he had been rather shocked at a consultant's comments that, if the general practitioner had sent the patient earlier, more could have been done. Did it do good to say that in that type of programme?

Dr. D. STAFFORD-CLARK also agreed that much more "feed back" was needed on the effect of programmes.

The general practitioner who acts as medical adviser for I.T.V.'s *Emergency Ward 10* said that Tessa Diamond, sitting next to him, who originated the feature, had reacted very unfavourably during the sequences of the operation and the ether abreaction. He thought these might be suitable

*March 8, 1958, p. 578.

when there was "lock and key" television for specialized audiences. He had found no increase in hypochondriasis as a result of *Emergency Ward 10*, although he understood that, following a programme in the series in which a man died after a wasp sting, 20 minutes later two people with wasp stings had presented themselves on the doorstep of a St. John's Wood doctor.

RESEARCH DEFENCE SOCIETY

MR. RICHARD FORT'S STEPHEN PAGET LECTURE

For the jubilee of the Research Defence Society this year the Stephen Paget lecturer was Mr. RICHARD FORT, B.Sc., M.P., the representative of the House of Commons on the Medical Research Council. He chose for the subject of his lecture, delivered at the Zoological Society of London on November 18, "Irrationality in Public Life." At its conclusion he made two suggestions: First, that it would be worth considering the setting up of a new research council to promote research—which would include research on irrational behaviour—in the field where medical and social science meet; and, second, that workers in this scientific borderland should be invited to give future Stephen Paget lectures, so as to foster the application of scientific method to the study of human behaviour.

Irrationality in Public Life

Mr. Fort said the subject of his lecture had been suggested to him by the irrational basis of the appeal of anti-vivisection: irrationality was also the basis of much that happened in public life, as any politician knew. Most of the knowledge we had of the extent and causes of irrationality was derived from practical experience rather than theoretical study, which demanded difficult techniques of interviewing and mathematical analysis in order to get scientifically satisfying results. He thought much more fundamental research was needed to describe and analyse irrationality.

Sir Alan Herbert had drawn our attention to certain "witch words," words that aroused emotions without making people think what they meant. "Vivisection" itself, "puppy" and "kitten" for "dog" and "cat," were examples from the anti-vivisectionists. In public life there were many others, ranging from "democracy" to "victimization." Fifty years ago Graham Wallas, in his book *Human Nature in Politics*, had emphasized how irrational was most people's approach to politics despite the façade of self-interest or other rationalist arguments often used in political debate. Despite absurdities and obsolete ideas Graham Wallas's analysis of political behaviour was still broadly true. The closed mind was almost as common in politics as in anti-vivisection.

One of the features common to politics and other activities in which the irrational is an obviously powerful force was that people were stimulated to act. Those so stirred often showed by their arguments or writings that their emotions had been aroused by some stereotype which simplified thinking, so far as their action was based on conscious thought at all. In politics there was the long-haired, ranting radical and the top-hatted, pot-bellied capitalist. Many Conservatives still resented Mr. Bevan's "vermin" speech of ten years ago. "The reality behind these stereotypes, if any, is surely drawn from some long-past abuse or situation by now overcome." Another feature of the irrational in public life was the importance of the small pressure groups which specialized in arousing to action those only mildly interested. There was also an apparent parallel between the intensity with which irrational causes were pursued and what was usually described as the "climate of opinion."

Mr. Fort believed that people would continue to act on the irrational as they always had done. Because of this, he suggested, there was need for much research into irrationality.

To-day's Drugs

With the help of expert contributors we publish below notes on a selection of drugs in current use.

Histadyl E.C. (Eli Lilly and Co. Ltd.).—Each fluid ounce (30 ml.) contains codeine phosphate 1 gr. (65 mg.), ephedrine hydrochloride $\frac{1}{2}$ gr. (32 mg.), thenylpyramine fumarate $1\frac{1}{2}$ gr. (87 mg.), ammonium chloride 10 gr. (650 mg.), chloroform 1 minim (0.05 ml.), with alcohol 5% and menthol and flavouring agents.

This is a combination of a cough suppressant, a bronchodilator, an antihistamine, and an expectorant. It will no doubt be fairly effective in relieving irritating cough, and probably has much the same effect as codeine phosphate alone or with ephedrine. It is worth bearing in mind that ephedrine given at night may keep the patient awake.

N.H.S. basic price: 16 fl. oz., 10s. 5d.

Dequadin Pessaries (Allen and Hanburys Ltd.).—Each pessary contains 10 mg. of dequalinium chloride (deca-methylene bis-(4-aminoquinolinium chloride)), and they are offered for the treatment of vaginitis caused by monilia (*Candida albicans*) or trichomonads. Dequadin, which is not an antibiotic, is effective against a wide range of bacteria and yeasts. Its value in the treatment of oral thrush has been reported on, but its efficacy as a trichomonocide has not yet been confirmed. Two clinical observations are here pertinent. First, when vaginal moniliasis is diagnosed, glycosuria should be excluded, as it is a frequent predisposing cause. Secondly, the cure of trichomonas vaginitis seems to depend more on the length of time for which treatment is conscientiously carried out than on the use of any individual trichomonocidal drug.

N.H.S. basic price: 30 pessaries with applicator. 6s. 8d.

Correspondence

Antibiotic Therapy for Bronchitis

SIR,—Dr. A. H. Luscombe (*Journal*, November 15, p. 1226) need expect no guidance from the Ministry of Health as to the propriety of prescribing prophylactic antibiotics to his chronic bronchitics. He should, however, translate his moral obligation to his patients into practical therapeutics. The case for prescribing these drugs is irrefutable. In this industrial practice in 1956, 5,318 working days were lost and £2,128 paid in sickness benefit because of acute and chronic bronchitis. At £50 per annum I can therefore afford to treat 40 patients regularly with antibiotics and still save the country 5,318 working days at £2 a day, i.e., £10,000 per annum.

Dr. Luscombe's dilemma is in fact a false one. His moral duty to the patients—to treat them as well as possible—in no way conflicts with his duty to the community—i.e., to make sure that his patients contribute of their best to the common welfare.—I am, etc.,

H. W. ASHWORTH.

Darbishire House Health Centre,
Manchester, 13.

SIR,—Dr. A. H. Luscombe (*Journal*, November 15, p. 1226) describes in his letter a problem common to many of us at the present time. The evidence accumulates that tetracycline, whether in short or long courses, benefits many patients with chronic bronchitis. To my mind there can be no doubt that our first duty is to the patient and that we must risk conflict with the costing department of the Ministry of Health. It would be wrong if we withheld a treatment because of the cost, if the treatment is demonstrably the best. Moreover, if there is benefit, it does not seem right to select on economic grounds only those patients who work.

Our dilemma would be lessened if the two pharmaceutical companies which make the tetracyclines found it possible to

reduce the price. We ourselves can usefully study the natural history of the disease in order to discover in due course whether some patients are benefited more than others, and whether prolonged prophylaxis or treatment in the exacerbation is more appropriate.—I am, etc.,

London, N.W.1.

J. P. HORDER.

Antibiotics in Acute Tonsillitis and Otitis Media

SIR,—Dr. John Fry's article (*Journal*, October 11, p. 883) does not seem to have attracted the attention it deserves. It suggests among other things that rheumatic fever is now so rare (he has seen no cases in ten years) that there may be no point in treating sore throats with antibiotics in the hope of averting rheumatic fever. In this area it is not quite so rare and there have been six cases in this practice in 12 years, but of these four did not seek medical advice for a preceding sore throat and of the two who did one was treated with a sulphonamide and the other with penicillin; as they developed rheumatic fever it would seem possible, therefore, that the damage may be done in the very early stages of the sore throat and that by the time the patient seeks treatment it is too late for penicillin to alter the outcome. The same appeared to be the case in Dr. Fry's patients with acute nephritis. It would be interesting if other practitioners could produce figures on this point. Patients whose sore throats are treated with penicillin for ten days are said not to get rheumatic fever,¹ but is there adequate evidence that treating them for the four or five days which Wheatley² found to be customary in general practice is equally effective?

Regarding otitis media, I think one can be fairly certain that the results reported in the M.R.C. trial³ are due not to penicillin but to decreased virulence of the organisms. As Dr. Fry points out, the results were much the same whether antibiotics were used as a routine or not, and in my own practice in which penicillin is used in less than 10% of cases without perforation, the results are virtually the same as those found in the M.R.C. trial. Once perforation has occurred, it seems reasonable to give antibiotics if the discharge does not rapidly cease, as Poulsen⁴ found that residual deafness was more or less proportional to the length of time the discharge persisted; discharge lasting less than a fortnight did not result in hearing loss, while discharge for eight weeks or more always led to some degree of deafness.

If one could be sure that the antibiotics were harmless, the main issue involved would be that of expense. But are they harmless? In examining the new boys at a public school, I have found that unilateral deafness is both commoner and more severe among them than among the local children. When the latter get otitis media they are not given routine antibiotics; on the other hand the deaf new boys at the public school almost invariably give a history of otitis media treated with antibiotics. This unfortunately proves nothing, but now that it seems to be accepted that the sulphonamide treatment of otitis media can be the cause of deafness, is it not time to consider whether antibiotics may not sometimes do the same, and whether their use should not be confined to selected cases? Whatever treatment is used a certain percentage of cases always have slight residual deafness, provided that the tests employed are sensitive, though when a whispering test is used the incidence of deafness is commonly reported to be nil. Wilson,⁵ for instance, found that after penicillin treatment 18% showed some degree of hearing loss, while on inadequate dosage of penicillin the figure rose to 35%. Popper,⁶ who claims to have seen 93 cases of such antibiotic deafness, states that the fluid in the middle ear, sterilized by antibiotics, often becomes a jelly-like mass which may eventually organize into fibrous tissue, with consequent loss of hearing.—I am, etc.,

PETER A. WALFORD.

Case of Penicillin Reaction

SIR,—The following case illustrates the value of chloropropenpyridamine maleate in the treatment of penicillin reactions.

A woman aged 62 was admitted to hospital with fractures of both malleoli. A blister developed over the lateral malleolus which became septic. It was treated with five daily injections of 500,000 units of "penaquacaine." Nine days after the last injection the patient developed a rash resembling prickly heat. Next morning there was localized swelling of the upper lip. Other clinical features were shivering, urticaria, redness of the eyes, swelling of the eyelids, face, scalp, back of neck, wrists, buttocks, and backs of hands, pallor, generalized aching pains, mistiness of vision, tachycardia to 112 beats per minute, and pyrexia to 101° F. (38.3° C.). Injections of adrenaline 5 min. (0.3 ml.) temporarily alleviated the pruritus. Ephedrine, phenobarbitone, and anti-pruritic lotions caused only slight improvement. On the third day, chloropropenpyridamine maleate was begun in doses of 8 mg. orally two-hourly to three doses, followed by gradual reduction in frequency of administration. This caused rapid and complete alleviation of all symptoms, but when the drug was stopped severe generalized urticaria recurred, and persisted until after three days' further treatment with the above drug and cortisone acetate. The condition was finally cured by the arrival of rain, associated with a drop in temperature from 105° F. (40.6° C.) to 65° F. (18.2° C.).

Another patient was admitted at the same time with severe urticaria following penicillin injections, and she also responded to chloropropenpyridamine maleate.—I am, etc.,

Administrative Hospital
Naurn, Central Pacific.

S. V. HUMPHRIES.

Poliomyelitis Vaccines

SIR,—The review of the present position regarding poliomyelitis vaccines by my friends Professor G. W. A. Dick and Dr. D. S. Dane (*Journal*, November 15, p. 1184) must carry great authority, and yet it seems doubtful whether they have presented a balanced analysis of the present position. Thus they consider that trials of the oral vaccines now available are only justified in countries which cannot afford the Salk type. In coming to this conclusion they infer confidence in the ultimate success of the Salk type of vaccine, though I can hardly believe that they are entirely happy about the ultimate prospects of this method. Both methods of protection have a long list of theoretical advantages and disadvantages, and it is surely unrealistic to condemn one method without also considering the disadvantages of the other.

Further, in taking such a strong line against clinical trials of the live poliovirus vaccines now available, they may be condemning a method which, for all they know, might prove to be both safe and effective. This is surely a very defeatist attitude to a problem to which the whole world requires an answer. It seems to be vital to discover quickly whether oral vaccines can be used safely, and it is at least doubtful whether the laboratory tests for increased virulence *en passage* mean very much.

Professor Dick also raises the possibility that virulent polioviruses may be largely eliminated from communities which are efficiently immunized with potent formalized vaccines. He has shown, however, that attenuated strains may become more virulent, so he is in fact suggesting that the Salk type of vaccine might lead to the disappearance of polioviruses in this country. Such a situation might well become dangerous, and I would have thought that this suggestion throws doubt on the prospects of our national programme. If on the other hand our experts think that the maintenance of a flourishing alimentary canal infection with polioviruses is a desirable accompaniment of the present programme, then the sooner we find out which strains to encourage the better. Perhaps Professor Dick would clarify his own hopes and fears a little further on these points.—I am, etc.,

W. RITCHIE RUSSELL.

Medicine on Television

SIR,—The long-awaited discussion between Mrs. Mary Adams (pro) and Mr. Dickson Wright (contra) regarding medical television programmes took place at the Royal College of Surgeons last Wednesday (see p. 1351). It was a disappointing occasion, with an over-lengthy apologia from Mrs. Adams, a dreary but partly necessary interim of film recordings of sample programmes, and a witty rejoinder by Mr. Dickson Wright. He evidently, like many of us, distrusts anything new. There followed a disjointed statement of various views, sometimes amusingly put; but this scarcely went beyond allusions to audience reactions and criticisms of the technique and representativeness of certain programmes.

Some must have gone away feeling that this highly important topic had received merely superficial attention. One was left with the impression that nothing had been achieved, for nothing had been altered. Two schools of thought departed as they had arrived, each to dig its heels in deeper, the one to preserve the dignified secrecy of its craft, the other determined to serve further half-baked doses of medical fare.

For it must be admitted that the programmes shown were poor, and quite unworthy of the magnificent means of communication put into our fumbling hands by the brilliance of television inventors and engineers. In this one must side with Mr. Dickson Wright, whose censures were largely just and wise. Yet one must agree with Mrs. Adams in her assertion that television has come to stay, as indeed it has, like nuclear physics. The question is, Who knows how to use them for the public weal? In regard to both few would disagree that a constructive use is desirable, and constructive of happiness as well as pleasure, for the two are not the same. We clamour for entertainment, and often miss happiness in our greed for it. Like the Press and radio, television is under endless pressure to entertain its audience; and as Mrs. Adams said, the audience does find medical matters entertaining. Mankind at large is attracted by gruesomeness, perhaps by his fear of death (the only basic point made by Mrs. Adams). It is a curious foible, and television will be forced to decide whether to encourage it or not; and if it decides to do so it will further have to examine its own motives. Unless its present mode of presentation of some medical affairs changes, it will have to decide between hypocrisy and sensationalism.

To present complex operations and problems of disease with the scantiest of preliminary acquaintance with normal arrangements is to invite a charge of hypocrisy, for this is not education but entertainment. It is like presenting an intricate repair job in the innards of a motor-car to an audience completely ignorant of even the normal workings of the mechanical beast. And how ignorant that audience is of its body's healthy activities—and this includes most television producers! A medical man spends two or three years of intense study of the normal chassis before he ever begins to learn damage and repair. How then can the public be other than baffled and perhaps queasy over some of the medical programmes already shown—just like a young medical student who goes to an operation out of curiosity long before he has the knowledge to appreciate clearly what is going on? Medicine is not fittingly turned into a peep-show, and, if it is, the public will be filled with misapprehensions unless a more intelligent policy is forthcoming.

However, and even if one agreed with the restrictive views of Mr. Dickson Wright, one must face the inevitability of television at least dabbling in medicine, even in the gore and Grand Guignol. Already other medical men of a supposedly more liberal persuasion are offering their services. One must hope their more liberal views of the nature of medicine itself will triumph, and that a healthier policy will prevail. It is a sad, and perhaps unwise, thing to encourage mankind to dote on gruesome spectacles of disease and death. Man is born into the life with health, energy, and hope to achieve what he can. Some attention to disease is the

common lot; but let it be limited to what is necessary. Any probing by the public into the arcana of disease must be balanced by an equal knowledge of the healthy normal, if things are to be seen in proportion. Otherwise the procedure is merely morbid and quite unlikely to add to human happiness, however much it panders to dubious pleasures. This is the challenge which faces television: if it brings the problems of disease to the public, is it also prepared to show enough of healthy human biology to make disease intelligible entertainment or enlightenment?—I am, etc.,

Guy's Hospital Medical School.

ROGER WARWICK.

Qualified Pen-names

SIR,—I was not surprised to read in the *Lancet* (November 15, p. 1065) the protest from Dr. H. M. Sinclair about the issue by the B.M.A. of a booklet by "John Clyde, M.D., M.A., Ph.D., B.Sc."—apparently "one of the foremost nutritionists in the world." Dr. Sinclair accuses the B.M.A. of misleading the public, because this great expert's name cannot be found in the *Medical Register*—published, I may add, to enable the public to distinguish the qualified from the unqualified. The booklet, it appears, is issued under the auspices of the popular health journal, *Family Doctor*, published by the B.M.A. On other occasions I have noticed strange names given a pseudo-authority by respectable degrees and diplomas in this magazine. Such a habit seems to me as reprehensible as putting phony degrees after real names.

What surprises me is that you, Sir, as Editor of the *British Medical Journal*, can countenance such a practice. In view of the fact that you periodically restrain innocuous outbursts of the fact that you periodically restrain innocuous outbursts of naughtiness on my part from appearing in the *British Journal of Ophthalmology*, I assume that you have some overall responsibility for all B.M.A. publications, even although you may not be concerned with the details of their editing. We look to you to preserve standards—not to let them down; and the profession and the public with them.—I am, etc.,

STEWART DUKE-ELDER.

Institute of Ophthalmology,
University of London.

* The Editor of the *B.M.J.* has no responsibility whatsoever in connexion with *Family Doctor* and its associated publications. We would therefore prefer to make no comment on the practice to which Dr. H. M. Sinclair and Sir Stewart Duke-Elder draw attention.—Ed., *B.M.J.*

Wider Scope for Gluten-free Diets

SIR,—We have been interested in the report by Dr. John W. B. Forshaw (*Journal*, October 25, p. 1020) of a considerable improvement in his patient suffering from post-gastrectomy steatorrhoea with the use of a gluten-free diet. We have experience of a further surprising benefit from such a diet. The following is a brief account of the case, which will be published in greater detail later.

The case we refer to is one of chronic relapsing pancreatitis with extreme calcification of the gland. Steatorrhoea of a marked degree was present which was associated with gross nutritional disturbance. We considered that his steatorrhoea might conceivably be partly pancreaticogenous, partly due to malabsorption. He was placed on a gluten-free diet, with resultant dramatic improvement shown, for example, by a weight increase, maintained over the past three years, of about 40 lb. (18 kg.) from his previous weight of 100 lb. (45 kg.) and a change over these years of the vitamin-A absorption curve from that characteristic of extremely poor intestinal absorption to that characteristic of a pancreatic deficiency. We have been unable to persuade this patient to use gluten again on a trial, but he has asked to be excused, for he ascribes all his present good health to a gluten-free regime.

Both our case and Dr. Forshaw's indicate that gluten sensitivity or toxicity may play a part in the clinical manifestations of disorders, other than certain forms of idiopathic steatorrhoea. They also suggest that dietary adjustment of this somewhat unusual sort may help some cases of pan-

creatic disease. This would appear to be a more reasonable approach than a current tendency which would link in the mind gluten (or its by-products) with idiopathic steatorrhoea and nothing else.

The vitamin-A absorption studies have been carried out as part of a study on this problem with the help of a grant-in-aid from the Medical Research Council of Ireland, which we wish to acknowledge with thanks.

Early Diagnosis of Mental Defect

SIR,—I was very interested to read Dr. Brian H. Kirman's paper (*Journal*, November 15, p. 1215) on the diagnosis of mental defect in young children. I would agree with him that it is usually quite unjustifiable to ascertain a child under the age of 5 years as ineducable. I agree, too, that a diagnosis of mental deficiency should never be made on the basis of bad or abnormal behaviour in a young child. No paediatrician would think of such a thing.

I disagree, however, with Dr. Kirman's comment that "it is possible to recognize only severe mental defect at an early stage. . . . The predictive value of tests under the age of 5 years is very low." I have now completed a study which proves that exactly the opposite is the case, indicating that mental retardation can be diagnosed with a high degree of accuracy in the first two years and in many cases long before the first birthday. It is true that "even in severe defect early accomplishments are sometimes normal for the age." Except in the case of degenerative diseases, this applies to gross motor development only, and all should know that this is the least useful field of development by which to assess a child.—I am, etc.,

Department of Child Health,
University of Sheffield.

R. S. ILLINGWORTH.

Detection of Ovulation

SIR,—I have only one helpful criticism to make of your very excellent annotation (*Journal*, November 15, p. 1213) on the modern problem of how to estimate the exact time of ovulation by the "clintix" method. I would emphasize that in my experience any result of putting a clintix, on or without a holder, into the vagina with a view to observing the glucose concentration is faulty and very often entirely negative when done by the patient, or in the consulting-room. The test is, however, of great assistance and importance if the clintix is inserted *via* a Fergusson or other speculum directly into the cervical canal.

I am drawing attention to this latter manoeuvre because this test has proved of even more value than the Spinnbarkeit test, the occult blood test, and the repeated DaPaz test of the cervical mucus.—I am, etc.,

London, W.1.

V. B. GREEN-ARMYTAGH.

N-Phthalyl Glutamic Imide

SIR,—N-Phthalyl glutamic imide is a drug with sedative properties and very low toxicity sold in this country under the proprietary name of "distaval." It has been found impossible to calculate the traditional LD50 because a dose of 5 g. per kg. is well tolerated by mice. The suggested dose range in man is 25 to 50 mg. two to four times daily as a sedative, and 50 to 100 mg. as a hypnotic at night. Its effects have been described by Jung,¹ Kunz *et al.*,² Esser and Heinzler,³ and Stärk.⁴

Jung reported that the drug lowered the B.M.R. of thyrotoxic patients, but did not determine whether the depression was due to thyroid suppression. Kunz *et al.* failed to obtain depression of the metabolism of mice. Murdoch and Campbell⁵ studied the effect of varying doses on the uptake of ¹³¹I by the thyroid of nine euthyroid patients. 50 mg. in one patient produced no effect; 100 mg. in one patient had a questionable effect; 150 mg. in two patients had a questionable effect in one and produced partial suppression in another; 200 mg. given to four patients had a questionable

effect in one, produced partial suppression in two, and complete suppression for less than four hours in one; finally 400 mg. (four times the highest recommended hypnotic dose) produced complete suppression for less than four hours in a single patient. They concluded, perhaps rather pessimistically, that "it would seem unjustifiable to use the drug for long-term sedative or hypnotic therapy, pending the results of a more detailed study . . . [in] hyperthyroidism." At the time of the publication of this paper we had begun such a study, and in a letter (*Journal*, February 1, p. 280) expressed the view that in thyrotoxic patients the effects of distaval were negligible compared with those of carbimazole. We have now extended our observations.

Nine thyrotoxic patients have been given single doses of 400 mg. of distaval, and the effects on the immediate uptake of radio-iodine by the thyroid have been measured by the method described by Farran.⁶ No definite effect on the uptake could be demonstrated in any of the patients. In two patients soporific effects were produced by this dose, which is far greater than that suggested by the manufacturers. One patient was treated for a week with a dose of 400 mg. daily. No effect on the thyroid was demonstrated by the above method or by that of Arnott *et al.*⁷

We do not question the accuracy of the observations of Drs. Murdoch and Campbell, and are prepared to believe that in the occasional patient, treated with doses far beyond the suggested range, antithyroid properties may be demonstrated by highly sensitive methods. Such findings are of no practical importance. We have, for instance, found antithyroid properties by the above method in the milk of cows fed on ordinary pasture.⁸ If distaval has a goitrogenic effect no greater than that of cow's milk, we feel that the drug may be given without fear of any damage to the thyroid gland.—We are, etc.,

Blood Groups of Mummies

SIR.—The establishment of a laboratory to investigate the blood groups of mummies and the consequent development of new techniques should prove of great value to clinical and forensic haematologists as well as anthropologists. In your annotation on the subject (*Journal*, November 1, p. 1091) you suggest that it is doubtful whether it will ever be possible to detect antigens other than those of the ABO system in post-mortem material which has not been specially preserved. In our view, this suggestion is too gloomy. Antigens which appear to be of the Rh system were demonstrated by us in muscle obtained from South American Indian mummies,¹ and pre-dynastic Egyptian mummies,² using the "inhibition" technique, slightly modified, of Boorman and Dodd.³ These workers have checked the accuracy of their technique against recent post-mortem material and we have confirmed their results. The proof that what we detected were really Rh antigens cannot, of course, be complete, because of the impossibility of carrying out experiments, to test the technique used, on mummified tissue from subjects of known Rh group. However, our protocols indicate that the results are difficult to explain on any other basis.—We are, etc.,

Trypanosoma rhodesiense in a Bushbuck

SIR.—Dr. R. B. Heisch, Mr. J. P. McMahon, and Dr. P. E. C. Manson-Bahr are to be congratulated in proving at long last (*Journal*, November 15, p. 1203) that Rhodesian sleeping sickness is a zoonosis. In 1925, under the auspices of the Rockefeller Institute, I visited Tanganyika and was asked by the Governor, Sir Donald Cameron, while watching a cricket match at Tabora, how I viewed the problem. I replied that two things were necessary. First, an aerial survey of the Territory to decide what was to become man-cattle country, and what should remain for the time being fly-game country. Second, some human volunteers, now that "Bayer 205" was available, to discover which game harboured strains pathogenic to man. I pointed to the gang of prisoners who acted as groundsmen. "Impossible," was his reply. It was a Mandated Territory. But a few years later Dr. J. F. Corson offered himself as a guinea-pig and dozens of Africans followed. Now Mr. C. W. A. Guggisberg has provided in his own person the last link in the chain of liberation.

I was informed during my last visit in 1952 that the aerial survey was just completed.—I am, etc.,

London, W.1.

CLEMENT C. CHESTERMAN.

Tuberculous Meningitis after B.C.G.

SIR.—The paper on "Tuberculous Meningitis Following B.C.G. Vaccination," by Dr. Mary Kerr and Dr. J. M. Dunbar (*Journal*, October 25, p. 1019), is less remarkable for the failure of B.C.G. vaccination to protect from tuberculous meningitis than for the circumstances in which the vaccine was used.

A baby aged 2 months was vaccinated on a single unspecified tuberculin test while living in a caravan with her mother, father, and brother, all of whom suffered from pulmonary tuberculosis. The state of the mother's disease at the time is not recorded, the father's disease was "believed to be inactive, though it was still being observed at three-monthly intervals," and the brother had sputum-negative cavitation in the year of the birth and was still receiving chemotherapy. It can therefore justifiably be said that the baby was in contact with one or more actual or potential infectors.

It is an axiom of tuberculosis control that contact between a susceptible infant or other child or young person and an infector should be broken immediately, and where B.C.G. vaccination of a non-reactor is contemplated there should be an interval of six to eight weeks between break of contact and the final pre-vaccinal tuberculin test and a similar or longer interval before resumption of contact. Such safeguards appear to have been omitted in the case reported, and their omission requires explanation, for in the absence of recalcitrance by the parents or brother (of which there is no evidence) it is hard to understand not only why the infant was left in such an environment but also why she was vaccinated in it.

As to the rarity of tuberculous meningitis in children vaccinated with B.C.G. it can be said that in Northern Ireland in 1953-7, 40,274 infants under 1 year were successfully vaccinated, many of whom were contacts. None has yet developed tuberculous meningitis.—I am, etc.,

Whitehead, Co. Antrim.

H. G. CALWELL.

Informing the Hospital

SIR.—With regard to identification of tablets in general practice the problem is a common one. Apart from the rare case of poisoning, one is often asked to re-prescribe tablets in which the patient has great faith when, for various reasons, records are not available of the tablets previously prescribed. Similarly, in cases sent from hospital when patients are on two lots of tablets which are similar, it is often difficult to differentiate between the two. This is particularly the case with small white unmarked tablets such as digoxin, B.P., and phenobarbitone, B.P., a not

uncommon combination. The *Chemist and Druggist* have only partially met the situation with the charts mentioned by Dr. Jane M. Fullerton (*Journal*, November 1, p. 1105). It cannot possibly hope to cover all tablets, including all white unmarked ones.

My idea to solve the problem is simple. All tablet manufacturers, irrespective of whether they are pharmaceutical chemists or merely tablet manufacturers, should be allocated a two- or three-code-letter combination, and this should be stamped on the tablet, followed by (or on the other side in the case of small tablets) the number of the product.

I am told that it is now possible to mark coated tablets. For capsules I suggest a similar marking, or a system of differential colour bands, somewhat akin to that used by the electrical industry for resistors. This would mean that both the source and the name of the product would be readily identifiable by means of a code book (or cards) which could be distributed to chemists and doctors.

With therapeutic advances the problem is getting more chaotic every day, and it is to be hoped that the industry will embark on an overall code system rather than an individual one for each firm.—I am, etc.,

London, W.12.

JOHN D. W. WHITNEY.

Oesophageal Stricture

SIR.—I was most interested in Mr. K. S. Mullard's letter (*Journal*, November 1, p. 1101) but regret that he has failed to grasp the main point in my paper on "Oesophageal Stenosis after Partial Gastrectomy" (*Journal*, October 4, p. 819). The paper related the case histories of two patients both suffering from duodenal ulceration, who for the very first time developed oesophageal obstruction, at an interval of three weeks following Polya gastrectomy. The various theories regarding the possible cause of this were discussed fully in the text. The well-recognized reflux oesophagitis due to acid pepsin was of course considered as a possible causative factor, but was ruled out because the gastric content was neutral in reaction and its peptic activity nil.

The main thesis in the paper was to suggest the possibility of oesophagitis with stenosis due to the reflux of a jejunal secretion of pH 6.5-7.0 in which trypsin could act as the irritant factor. This suggestion was supported by the fact that, when jejunal contents were excluded from the stomach and lower oesophagus by the conversion of the Polya and Billroth I type, the symptoms of oesophagitis disappeared completely. Had the oesophagitis been due to the presence of "gastric mucosa lining the lower oesophagus," as suggested by Mr. Mullard, then the oesophagitis would have persisted. The fact that it did not persist but cleared up completely and the patients have both remained perfectly well ever since demonstrates that Mr. Mullard's views regarding aetiology in these two cases are untenable.—I am, etc.,

Darlington, Co. Durham.

K. C. McKEOWN.

Buzzers for Bed-wetters

SIR.—The Staffordshire County Council have provided for the past year electrical nocturnal alarms for schoolchildren suffering from enuresis.

In view of Dr. Margaret White's letter (*Journal*, November 8, p. 1165) reporting 45 children successfully treated with no failures, it is interesting to compare the results in another area. In Staffordshire a total of 48 cases have been treated, of whom 38 have been greatly improved or cured, and in several of these the child has now been dry for a period exceeding six months. There have been four cases where the child was not improved following the treatment, and one case relapsed. There were three cases where there was lack of co-operation on the part of the parent or the child. In one of the remaining cases, the child would not persist with the use of the machine owing to fear caused by the sounding of the bell during the night. The average duration of the treatment as mentioned by Dr. White is some two or three months. On the whole the results were con-

sidered very encouraging by the parents and medical staff, and the scheme is being extended.

In passing it may be noted that the "improved or cured rate," i.e. 79%, with the enuresis alarms, compares very favourably with the improvement using pituitary snuff reported by Holt¹—i.e., 8 out of 60 cases improved.—I am, etc.,

School Health Service,
Stafford.

Foreign Body in Endotracheal Tube

SIR.—Accidents and near calamities due to blocked endotracheal tubes are probably not as rare as may be thought. There must be a natural reluctance on the part of many anaesthetists to report their mishaps, valuable though such reports should be to their colleagues.

The letter by Dr. K. A. Stewart (*Journal*, November 15, p. 1226) brings to mind a similar occurrence some months ago. The patient, an obese middle-aged woman, was being anaesthetized for reduction of a nasal fracture. A rubber endotracheal tube was passed, which had been taken from a tray containing a number of such tubes with Rowbotham connexions attached. Manual inflation with oxygen from the reservoir bag met with resistance, and the patient became cyanosed. She was resuscitated with difficulty after the tube had eventually been removed. Inspection of the endotracheal tube afterwards showed it to be completely blocked by the top of a glass ampoule, firmly wedged in the Rowbotham connexion. No satisfactory explanation could be found as to how it had got there.—I am, etc.,

London, W.1.

E. H. RAINER.

Sweet Tooth and Decay

SIR.—In view of the conflicting impressions of Mr. F. T. Ransom (*Journal*, September 6, p. 638) and Dr. V. M. Osborne (*Journal*, November 15, p. 1229) on the effects of chewing sugar-cane and of the incidence of dental caries it is desirable that a large-scale inquiry should be undertaken to determine the dental health of the children in the West Indies. Meanwhile may I draw attention to the small survey made in 1948 by the late J. D. King in the sugar- and non-sugar-cane producing areas of Trinidad and British Guiana, among children aged 12-14 years? The non-cane districts had an insignificantly larger percentage of carious permanent first molars than the cane districts in both colonies, and the children in British Guiana had a significantly larger proportion of carious teeth than the children in Trinidad. The incidence and extent of caries in the upper first and second permanent incisors—these teeth are generally the most susceptible of those in the anterior part of the denture and their labial surfaces are accessible to friction during the consumption of sugar-cane—was significantly larger in the cane districts of Trinidad than in the non-cane districts, but in British Guiana the non-cane districts had an insignificantly larger value than the cane districts. The incidence of caries in these teeth was greater in Trinidad than in British Guiana. The incidence of caries in all the fully erupted permanent teeth was high and the activity of the disease was of a similar order to that in the urban district of the Isle of Lewis and in South-East London children. In Trinidad the children from the non-cane districts had more gingivitis than those from the sugar-cane areas, and in British Guiana the incidence and extent of gum lesions was greater in the non-cane than in the cane districts. There was a large association between gingivitis and calculus deposits, and the advantage of the cane districts was probably due to the extent to which cane was able to dislodge dental calculus and counteract any other source of irritation. Susceptibility to parodontal disease or dental caries was little, if at all, affected by sex or race, Negro and East Indian.

An investigation to discover the effect of increased sugar intake on caries in children over a period of two years was described in a Medical Research Council *Special Report*.² The conclusion arrived at was that, "provided a child is

In spite of his busy life, Haultain seemed, until recently, quite tireless, so marked was his enthusiasm for all he undertook. His friends were legion, and to them the kindly hospitality of Haultain and his wife was freely offered and will be recalled with deep gratitude. That never-failing, happy greeting from Theodore will be greatly missed—we are the poorer for his loss. To his widow, daughter, and two sons is extended the deepest sympathy.—E. C. F.

S. LOUISE FRASER, M.B.E., M.D.

Dr. S. Louise Fraser, formerly honorary obstetric surgeon to the York Maternity Hospital, died at a Bournemouth nursing-home on October 14. She was 84 years of age.

Sarah Louise Fraser was born at Inverness on January 28, 1874, and was educated at Inverness and Notting Hill High Schools and at Bedford College, London. She studied medicine at the London (Royal Free Hospital) School of Medicine for Women, and graduated M.B., B.S. from London University in 1900, proceeding to the M.D. in 1908. Part of Dr. Fraser's early professional experience was gathered at the York Dispensary, which then employed three resident doctors whose work in effect was to provide a free domiciliary service for the poor of the city. In 1906 she started her own practice in York, and soon afterwards she was elected to fill a vacancy on the honorary staff of the dispensary, where she held a weekly clinic for women and children, and became an *ex officio* member of the board of directors.

At that time York had no maternity hospital, but Dr. Fraser persuaded her fellow-directors to launch a public appeal for subscriptions, and as a result, in 1908, the Ogleforth Maternity Home came into being in a house capable of accommodating five patients. As time went on neighbouring houses were added to the home until, in 1923, it was handed over to the local authority. From Dr. Fraser's concern about the health of the babies born in the home came her idea of an infant welfare scheme in York, and again she was fortunate to have the support of the board of directors of the dispensary. At first the results from the scheme seemed disappointing to her, but, when steps were taken to provide free meals for the mothers attending the infant welfare centre, the good effect on the babies' health was soon discernible.

During the first world war Dr. Fraser was medical officer at the Nunthorpe Hall auxiliary hospital, and for her services was appointed M.B.E. in 1920. From 1926 she began to spend much of each year abroad, but in 1938 she returned to England and thenceforward lived at various places, ultimately at Bournemouth. Even at an advanced age she still retained a keen interest in medical matters and in the profession which she had served so well.

F. G. LESCHER, M.C., M.D., F.R.C.P.

Dr. F. G. Lescher, consulting physician to the Derbyshire Royal Infirmary, died at his home at Mackworth, near Derby, on November 12. He was 70 years of age.

Frank Graham Lescher was born on May 19, 1888, and was educated at Stonyhurst and at Caius College, Cambridge, where he obtained a second class in the Natural Sciences Tripos in 1910. From Cambridge he went on to St. Bartholomew's Hospital, qualifying in 1913 and graduating M.B., B.Chir. in the following year. At Bart's he was house-physician to Dr. (later Sir Walter) Langdon-Brown and he was also senior house-surgeon at the West London Hospital. Having joined the R.A.M.C. in 1914, he gave distinguished service as a medical officer to a field ambulance, winning the Military Cross with two bars and attaining the rank of major. In 1918 he was taken prisoner. On return to civilian life he proceeded to the degree of M.D. and settled in practice in Derby, where he was appointed assistant physician to the Derbyshire Royal Infirmary. Becoming full physician in 1931, he continued to serve the hospital until his retirement in 1954. In his later years he was consulting physician to the Burton-on-Trent General Infirmary and to the Derby City Hospital. Having gained the Membership of the Royal College of Physicians in 1934, he was elected to the Fellowship ten years later. A Territorial officer, he was for a time A.D.M.S. to the 46th North Midland Territorial Division, and during the second world

war he was a group medical officer in the Emergency Medical Service. Dr. Lescher leaves a widow and two daughters.

A colleague writes: Beginning in general practice, Dr. Graham Lescher later confined himself to consulting work, in which his ability was recognized and valued throughout a wide area. But essentially he put his hospital work first. He was a sound physician with a leaning towards neurology. Many resident medical officers profited by his teaching, and his colleagues could always benefit by discussing medical problems with him. He published a number of valuable papers. From 1922 to 1927 he was honorary secretary of the Derby Division of the B.M.A. and eventually chairman (1935) and also president of the Derbyshire Branch (1937). But he directed his main energies to the work of the scientific medical societies in Derby and the East Midlands, in whose meetings he frequently took active part. He was particularly good at demonstrating a clinical case. A man of considerable energy, he did not let his outside duties interfere with his hospital or private work. He played golf with his colleagues and later on became an enthusiast for fishing.

H. M. WILSON, O.B.E., M.B., B.Chir., F.R.A.C.S.

Mr. H. M. Wilson, consulting surgeon to the Hastings Memorial Hospital, New Zealand, and a former president of the New Zealand Branch of the B.M.A., died at his home at Havelock North on November 12. He was 82 years of age.

Harry Montefiore Wilson was born in the province of Hawke's Bay in New Zealand, the son of Mr. H. C. Wilson, of Napier, who fought in the Maori wars as a member of the armed constabulary. From the Collegiate School, Wanganui, Harry Wilson entered Trinity Hall, Cambridge, in October, 1895, obtaining his B.A. three years later. He then went on to St. Mary's Hospital for his clinical training, and graduated B.Chir. in 1902 and M.B. in 1906. Before returning to New Zealand he held the appointments of house-physician at St. Mary's Hospital and house-surgeon at the Birmingham General Hospital and the Hospital for Sick Children, Great Ormond Street. In 1903 he became assistant medical officer at the Wellington Public Hospital, New Zealand, and two years later resident medical officer at the Napier Hospital. From 1908 to 1911 he was in practice, first at Waipukurau and then at Waipawa, both in the province of Hawke's Bay. He settled at Hastings in 1911, becoming honorary surgeon to near-by Napier Hospital and helping to found the Memorial Hospital at Hastings. During the first world war he served as a captain in the N.Z.M.C. In 1927 he became a foundation Fellow of the Royal Australasian College of Surgeons. A member of the British Medical Association for 53 years, he was chairman of the Hawke's Bay Division in 1922-3 and again from 1948 to 1950, and president of the New Zealand Branch in 1941-2. He was appointed O.B.E. in the 1951 Birthday Honours. He is survived by a son and four daughters.

A. E. HAY, M.R.C.S., L.R.C.P.

Dr. A. E. Hay, who was in general practice in the Isle of Wight for most of his professional life, died at his home at Brading, in the island, on October 19, the day after his 80th birthday.

Arthur Edgar Hay was born at Felpham, Sussex, and was educated at the Elizabeth College, Guernsey, King's College School, Wimbledon, and King's College, London. Qualifying in 1904, he held the appointments of house-surgeon, house accoucheur, and house-physician to the women and children's department at King's College Hospital and house-surgeon and casualty house-surgeon at the Queen's Hospital for Children, Bethnal Green. He then settled in Cowes, in the Isle of Wight, where he built up a large family practice and acted as an honorary medical officer to the Frank James Memorial Cottage Hospital. He

was also the local Poor Law medical officer and public vaccinator. He lived and worked at Cowes until 1944, when continuing ill-health compelled him to curtail his activities considerably, and he went to live in the village of Brading. There he soon established himself just as successfully as in Cowes, though of necessity on a much smaller scale. Ten years later, in 1954, a further deterioration in health forced him to retire completely. He leaves a widow, one son, and three daughters, to all of whom we offer our sympathy.

J. J. O'D. writes: Dr. Hay was a shining example of all that is best in the family doctor tradition of this country. To hundreds of families and for many years he was not only "the doctor" but also the guide, philosopher, and friend, and he achieved that enviable position by the simple process of mixing, quite subconsciously, the ingredients of competence and conscientiousness with those of cheerfulness and generosity. His large practice was matched only by his own capacity for hard work: though he led an extremely full and busy life, he was never too rushed to spare a few moments for conversation, never too tired to be cheerful, and never too irritated to be good-tempered. Despite his own heavy commitments he was ever ready to come to the aid of a harassed colleague, especially one junior to himself; and his arrival, almost invariably accompanied by an amusingly told and reassuring tale of a similar occurrence in his own practice, raised morale and relieved the situation. He was devoted to his family and they to him, and within the family circle he attained a happiness and contentment of mind that were a joy to witness. He will be sadly missed by them as well as by a multitude of patients who will mourn the passing of a fine doctor and a truly great character.

IVOR CHANCE, M.B., B.S.

The obituary of Dr. Ivor Chance was published in the *Journal* of November 15 (p. 1234).

A friend writes: Ivor Chance possessed an amazing capacity for friendship. He endeared himself to all who knew him, irrespective of class or background. His Christian faith was simple and childlike and expressed itself in a life that was truly dedicated to his fellow-men. He loved people and always aimed to heal the whole man. He entered wholeheartedly into the life and work of his Church. Whatever he undertook, whether in his professional sphere or in private life, he did with the utmost enthusiasm, and he had the capacity for infusing in others a comparable zeal. Fearless in his denunciation of injustice of any kind, he had a particular dislike for anything that savoured of cant or hypocrisy. He was blessed with a great capacity for fun: aided by his sense of humour he was able to meet and overcome many difficult situations. A true man of God, he lived out in his daily life his own inward personal faith, and he earned for himself the designation given in the Scriptures to St. Luke—"A beloved physician."

D. B. G. and D. W. D. write: It was our privilege to meet Ivor Chance when he commenced his medical studies with us at the Middlesex Hospital medical school in 1941, and our lifelong friendship which followed was inevitable. He had an unflinching sense of duty to his patients and friends, and was fundamentally sincere in all he said and did. He had an extraordinary ability to make friends in all walks of life, regardless of age, creed, or colour. His firm Christian faith, tireless energy, and great sense of humour enabled him to live a full, though sadly short, life and to overcome cheerfully all obstacles and disappointments. These qualities, coupled with his clinical ability and perseverance, inspired the love and respect of colleagues and patients alike. The memory of Ivor Chance's way of life is sure to remain a refreshing example to those who knew him. We extend our sincere sympathy at his untimely passing to his family, and especially to his wife, who shared his many ideals and Christian conviction and was able to contribute so much to his work as a medical missionary during their three years in Uganda.

Medical Notes in Parliament

INTERIM PAY AWARD

Sir HUGH LINSTAD (Putney, Con.) asked the Minister of Health on November 20 what action, in the light of his recent estimate that the Royal Commission would not report until next summer, he proposed to take in respect of the remuneration of doctors and dentists employed in the Health Service. Mr. D. WALKER-SMITH stated that the Government proposed to make a further interim increase of 4% in the current basic remuneration of doctors and dentists in the National Health Service with effect from January 1, 1959. This interim increase would, of course, be without prejudice to the recommendations of the Royal Commission, but he had consulted the chairman and he had informed him that it would not embarrass the Commission in any way. The method of distributing the additional remuneration would be discussed with the two professions.

Mrs. LENA JEGGER (Hölborn and St. Pancras South, Lab.) referred to this reply on November 24, when she said it had given in the country the impression that these rather stingy and *ad hoc* handouts to the medical and dental professions indicated a complete lack of Government policy for the Health Service. Could the Minister of Health say that in these days of expanding economy this concession could be taken as encouragement by all the other ancillary workers who had claims before the Minister and who were entitled to better treatment from the Minister? Mr. WALKER-SMITH said that if the country had formed any such impression it would be an erroneous one through a wrong understanding of the facts. This was neither stingy nor piecemeal. It was a 4% increase costing £5m., and was given because the Royal Commission was taking longer to report than was originally thought probable.

OTHER ANSWERS TO QUESTIONS

Queen Mary's Hospital, Carshalton

Mr. ERIC FLETCHER (Islington, East, Lab.) asked the Minister of Health on November 17 whether he was aware of the feeling among parents and others against the proposal to close Queen Mary's Hospital for Sick Children, Carshalton; and whether he would reconsider the matter. Mr. WALKER-SMITH said that he had received representations from several sources about the proposal to change the use of this hospital, and he would certainly take these and all relevant factors into account before coming to a decision.

Mr. FLETCHER asked if the Minister would bear in mind that for many years this hospital had enjoyed a high reputation among parents for its special work among children. There would be great concern among parents if it were closed. Mr. WALKER-SMITH said there was no proposal to close the Queen Mary's Hospital, as might appear from Mr. Fletcher's question. The proposals were merely concerned with the change of use. He readily accepted that the hospital had a high reputation, but it was nearly half empty because of the welcome fall in the need for the accommodation for children. Mr. KENNETH ROBINSON (St. Pancras, North, Lab.) said there was a desperate need at Fountain Hospital, which had an equally high reputation, for decent, modern accommodation. Mr. WALKER-SMITH said he had that very much in mind.

Crawley Hospital

Mr. F. GOUGH (Horsham, Con.) asked what progress had been made in the building of Crawley Hospital; and on what date it was anticipated the hospital building would be completed. Mr. R. H. M. THOMPSON, Parliamentary Secretary to the Ministry of Health, stated that tenders had been invited for the first stage of building, with a view to work starting before the end of the financial year. It was estimated that this work would take about two years.

Mr. GOUGH described the whole story of Crawley Hospital as a real public scandal, and an epic of bureaucratic muddle, stubbornness, and stupidity. He had been given assurance after assurance and promise after promise since September, 1954, during which time the population of Crawley had grown by 26,000. Would the Minister instigate an interdepartmental inquiry to look into the matter? Mr. THOMPSON replied that the Minister did not feel that an inquiry was called for. This was a very large and costly scheme, and involved planning on a most extensive scale. The first stage was under way.

Edinburgh Hospital Schemes

Details of the schemes for new hospital building, and for the modernization of hospitals in Edinburgh, were given on November 18 by Mr. J. NIXON BROWNE, Under-Secretary of State for Scotland, in answer to questions by Mr. J. HOY (Leith, Lab.). Building schemes, amounting in all to £1,400,000 already submitted and approved, were in hand or about to start, he said. These are:

New Hospital Building in Edinburgh

Hospital	Scheme	Estimated Building Cost	Provision made in 1958-9
Western General Hospital	Neurosurgical unit	£ 341,000	£ 100,000
	Theatre block (phase I)	97,000	23,200
	suite (" II)	95,750	1,000
	New boilerhouse	108,429	850
Edinburgh Royal Mental Hospital	bacteriology laboratory	126,000	3,000
	Reconstruction and development	522,925	10,000
Gogarburn Institution	New ward block	52,000	6,000
Edinburgh Royal Infirmary	New biochemistry laboratory	51,000	15,000
Queen Mary Maternity Home	12-bedded maternity unit	17,540	2,000
		£1,411,644	£161,050

In addition details of modernization schemes provided for during the current financial year and costing £364,487 were also tabulated.

Future of Royal Infirmary

Mr. A. WOODBURN (Clackmannan and East Stirlingshire, Lab.) called attention to the need for a more speedy redevelopment of the Royal Infirmary, Edinburgh; and asked whether the Secretary of State was satisfied that its bed accommodation was not being too much diverted to non-medical cases. Mr. NIXON BROWNE replied that the Secretary of State was well aware of the problem, which was being urgently examined at his request by a joint planning committee representing hospital and teaching interests and the department. This hospital, like other large teaching hospitals, faced the problem of the continuing care of patients who no longer required highly specialized facilities. The planning committee would have this problem very much in mind in laying down the lines for future hospital development in Edinburgh as a whole.

Mr. WOODBURN said this was one of the most famous hospitals in the world. Accusations that it was being used as a home for old people were causing great perturbation. Questions had appeared in the press about whether the hospital would be diverted from its proper purpose to become a home for old people. Mr. BROWNE replied that the Secretary of State would not wish any such impression to get abroad. This was a big problem, and there were many views on it. It would be wise to await the decision of the planning committee.

Scottish Cancer Services

Mr. W. HANNAN (Glasgow, Maryhill, Lab.) asked what progress had been made in giving effect to the circular setting up the organization of Scottish cancer services;

and, in particular, what means had been adopted for the earlier diagnosis of malignant disease. Mr. NIXON BROWNE told him that a registration and follow-up system for all cases of malignant disease had now been instituted in each of the five hospital regions in Scotland, and regional cancer committees had been established to keep facilities for diagnosis and treatment under review. Early diagnosis was possible only if medical advice was sought at the earliest possible stage, and the Secretary of State had no doubt that the regional committees would consider the best means of securing this.

Mental Defectives in Scotland

Mr. HECTOR HUGHES (Aberdeen North, Lab.) asked the Secretary of State how many mentally defective patients were detained in Scotland, what steps were being taken to ensure that the condition of each was periodically reviewed with a view to release; and how many had been released. Mr. J. S. MACLAY stated that at September 30 there were 5,732 patients under detention and 2,542 under guardianship. Patients were detained on the initiative of the parents or of the local authority with the parents' consent, or by order of the Sheriff. The need for detention was subsequently reviewed by the General Board of Control. He had no statutory authority in these matters. In the first nine months of 1958, 100 patients were discharged and 127 released on licence.

Classified by age groups, the figures are:

Number Aged								Total
Under 16	16-24	25-34	35-44	45-54	55-64	Over 64		
On Institution Registers								
Male	577	804	669	532	350	118	53	3,103
Female	375	569	527	505	388	182	83	2,629
Total	952	1,373	1,196	1,037	738	300	136	5,732
Under Guardianship								
Male	26	420	294	269	204	109	24	1,346
Female	15	307	232	244	218	133	47	1,196
Total	41	727	526	513	422	242	71	2,542

Deaths from Leukaemia

Mr. FRANK ALLAN (Salford, East, Lab.) asked the Prime Minister what investigation had been undertaken by the Atomic Energy Research Establishment or the Medical Research Council to inquire to what degree any significant difference had been found in the content of strontium-90 in the bones of children dying from leukaemia or bone cancer compared with those dying from other causes in Great Britain; whether he would request such investigations if not already undertaken, and whether the results would be published. Mr. H. MACMILLAN stated on November 18 that in the course of a nation-wide survey of the strontium-90 content of human bone a certain number of specimens of bones of children who died from leukaemia had been examined. The results obtained from the survey so far had not demonstrated a difference between these bones and comparable specimens obtained from children dying from other causes. None of the bones examined had come from a case of bone cancer. Should any significant relationship be observed between the level of strontium-90 and the cause of death a special report would be published.

Atmospheric Pollution

Mr. S. SWINGLER (Newcastle-under-Lyme, Lab.) asked on November 18 what progress was being made in reducing the causes of atmospheric pollution. Mr. J. R. BEVINS, Parliamentary Secretary, Ministry of Housing and Local Government, said that dark smoke from chimneys was, with certain exceptions, now prohibited; there was a statutory obligation in force to take all practicable means to minimize grit and dust from industrial furnaces; the number of smoke control areas in operation or preparation was growing at a steady rate; and pollution by noxious or

offensive cases, which was controlled under the Alkali Act, was showing a significant fall. The department was directly responsible for giving technical advice only where the process was subject to control under the Alkali Act. Information indicating where local authorities, industry, and householders could obtain technical advice was given in the three memoranda on the Clean Air Act published by the department.

Mr. G. NABARRO (Kidderminster, Con.) wanted to know what progress had been made by the Department of Scientific and Industrial Research and other research agencies in ascertaining means of purifying exhaust fumes of diesel-powered road vehicles, prior to emission; and, having regard to the rate of increase of carcinogenic diseases commensurate with the increase of such vehicles, and also support for clean air policy, what further Government action in the matter was proposed. Mr. HARMAR NICHOLLS, Parliamentary Secretary, Ministry of Works, said the department had done no research on the purification of exhaust fumes from diesel-powered road vehicles; but results of work carried out elsewhere had shown that the greater part of the smoke from diesel engines could be prevented by proper adjustment, running, and maintenance. The Medical Research Council had no evidence at present to suggest that exposure to diesel fumes was a contributory factor in the causation of cancer.

Doctors' Emigration

Dr. DONALD JOHNSON (Carlisle, Con.) asked the Minister of Health on November 24 if he was aware of the increasing numbers of established doctors who were leaving general practice under the N.H.S. to emigrate; and whether he would make appropriate inquiries into this trend. Mr. WALKER-SMITH stated that he had no reliable evidence of any increase in the emigration of general practitioners, but would gladly study any which Dr. Johnson could produce. Information on the emigration of doctors and dentists generally submitted by the Government to the Royal Commission was published in the Commission's Minutes of Evidence 14-15 for 17-18 April, 1958. Dr. JOHNSON said there was a feature in the *B.M.J.* which showed this trend. If he sent it to the Minister would he consider it? Mr. WALKER-SMITH replied that he would. He would be glad to consider any evidence. Mr. J. TILNEY (Liverpool, Wavertree, Con.) said that, if such emigration was to parts of the Commonwealth that were short of doctors, should it not be encouraged? Mr. WALKER-SMITH said that his responsibility was to provide a Health Service in this country. He was not unmindful of the considerations referred to by Mr. Tilney.

Addiction to Unrestricted Drugs

Mrs. HARRIET SLATER (Stoke-on-Trent, North, Lab.) asked if the Minister's attention had been drawn to the article in the *B.M.J.* on "Addiction to Unrestricted Drugs,"* and what action he proposed to take on the problem raised. She also asked if any further consideration had been given to the restricting of carbromal drugs. Mr. WALKER-SMITH—the Secretary of State for Scotland and I have invited the Interdepartmental Committee on Drug Addiction to consider and advise us upon the problem of preparations, including carbromal preparations, which are outside the scope of the Dangerous Drugs Act but which may be liable to produce addiction or to be habit-forming. The committee have not yet concluded their consideration of this question. Mrs. SLATER said the article was a responsible one, which gave case histories of people who had been affected. Would the Minister speed up both the consideration by the committee and some action to place the drugs on the Poisons List? Mr. WALKER-SMITH—it is certainly a responsible article, but it does not add to the information before the committee, who are proceeding as rapidly as their wide duties permit. Making a drug a poison was a matter for the Poisons Board.

**British Medical Journal*, October 18, p. 950.

Dr. EDITH SUMMERSKILL asked if the Minister would consider enlarging the terms of reference of the committee with a view to improving the machinery devised to examine the various products that were coming on the market. Surely the machinery was not adequate to cope with the increasing number of products being put out by the proprietary houses. Mr. WALKER-SMITH pointed out that the terms of reference were already wide, in that they required the committee to consider whether any revised advice they gave on narcotic drugs should extend to other drugs which were liable to produce addiction or were habit-forming.

Mr. SOMERVILLE HASTINGS (Barking, Lab.) asked that the Minister should keep in mind the possible danger to patients of unnecessarily restricting the freedom of action of medical practitioners. Mr. WALKER-SMITH said that was another question. Guidance was given, he thought acceptably, to the medical profession.

Medico-Legal

ERROR IN DIAGNOSING CANCER

[FROM OUR LEGAL CORRESPONDENT]

A principle, of which out of sympathy it is easy to lose sight, is that a mistake, medical or otherwise, which causes injury is not necessarily negligent. This was illustrated by the recent dismissal in the Court of Appeal (*The Times*, November 19) of an appeal by Mrs. Crivon, of Offham Slope, Finchley, from the dismissal by Mr. Justice Hilbery of an action in which she had alleged negligence against the Barnet Group Hospital Management Committee, the North-west Metropolitan Regional Hospital Board, the late Mr. H. R. Segar, and Dr. D. M. H. Cogman.

Mr. Segar had operated on Mrs. Crivon in May, 1950, for the removal of a small lump in her breast. Dr. Cogman made a pathological examination of a specimen of the lump and reported that he thought it to be cancer. In consequence Mrs. Crivon went to Mount Vernon Hospital and was subjected to deep x-ray therapy for a considerable time. Meanwhile further pathological examinations were made. Senior pathologists at Wellhouse Hospital found no evidence of cancer, and the pathologist at Mount Vernon did not think there was any malignant cancer. The deep x-ray therapy was therefore stopped, but Mrs. Crivon's skin was marked and the surface destroyed, she was exposed to the possible consequences of deep x-ray therapy, and was subjected to the distress, pain, and worry which it involved.

Mrs. Crivon, who conducted her appeal in person, complained that in a matter of such importance to her Dr. Cogman should have taken a second opinion before his diagnosis was acted on. But the evidence of Professor R. W. Scarff was that he was not prepared to say the diagnosis had been wrong, and he might on the slide in question have come to the same conclusion himself. Once a carcinoma had been diagnosed speed of treatment was essential, said Lord Denning delivering the Court of Appeal's judgment, and the fact that a second opinion was not taken and that no further check was made when she went to Mount Vernon did not in the view of the Court of Appeal make out a case of negligence. A wrong diagnosis was unfortunate, but on the evidence the judge had been justified in finding that there had been no negligence in the diagnosis or consequent upon it.

Mrs. Crivon's appeal was accordingly dismissed.

CLAIM AGAINST NORTHERN IRELAND TUBERCULOSIS AUTHORITY

[FROM OUR LEGAL CORRESPONDENT]

On October 20 Lord MacDermott, the Lord Chief Justice of Northern Ireland, dismissed an action by Dr. Joseph Norris Whyte, of Antrim Road, Belfast, against the Northern Ireland Tuberculosis Authority (*Northern Whig*,

October 18). Dr. Whyte, one of the Authority's consultants, had claimed that his contract with the Authority did not entitle them to assign to him the duty of examining for tuberculosis candidates for the Royal Ulster Constabulary, and that he was entitled to receive fees for so doing.

Until 1954 candidates were examined by the Constabulary's doctor, and certain of them were then sent for chest x-ray. By informal arrangement with the secretary of the Authority Dr. Whyte read the x-rays and reported on them. The reports went to the police, and the Authority received one-third and Dr. Whyte two-thirds of a guinea for each report. After 1954 the police ceased paying the Authority, and the two-thirds payment to Dr. Whyte stopped in consequence. Dr. Whyte's case was that his function in making the x-ray examinations and reports was not the prevention of tuberculosis and promotion of public health but simply to see whether the candidates were fit to be recruited into the Constabulary. The Authority's case was that the work fell within the scope of the hospital and specialist services which the Authority was required to provide under the Public Health (Tuberculosis) Act (Northern Ireland), 1946, and that, since under his contract Dr. Whyte's duties were those which might be assigned to him for the purpose of discharging the Authority's obligation under the Act, Dr. Whyte was not entitled to any additional remuneration for carrying it out.

Lord MacDermott held that the work which was done by Dr. Whyte was work covered by his contract which the Authority was entitled to require him to do. It fell within the Authority's statutory duty, and Dr. Whyte was not entitled to additional remuneration for performing it.

The Act which the Glasgow doctor contravened when he signed a medical certificate of incapacity for work without seeing his patient (*Journal*, November 1, p. 1111) was the National Insurance Act, 1946, not the National Health Service (Scotland) Act.

Vital Statistics

Gastro-enteritis in Yorkshire

An infectious disease characterized by gastro-enteritis and pneumonia has recently broken out among young infants in the region of Thorne, near Doncaster. 6 deaths had been reported by November 25. The Thorne area consists of two mining communities, Thorne-Moorends and Stainforth-Dunscroft, with a population of 34,000 and a birth rate of 21.3 per thousand population. On October 21 a child of 2 months with gastro-enteritis was admitted to hospital from a caravan site in Thorne. After two weeks the child suddenly developed pneumonia and died in hospital on November 9. A second child, aged 3 weeks, was admitted on November 2 in serious condition and died from pneumonia within 36 hours. This child had had mild gastro-enteritis for some days before admission and had shown no response to thorough drug therapy. At this stage there was no suspicion of any epidemic in progress. Routine stool examination had isolated staphylococci from the stools of these two cases. On the admission of a third case on November 4 investigations were started into finding a common factor. Gastro-enteritis was found to be prevalent among both adults and children.

During November 12 and 13, 3 more deaths were notified in children aged 6 weeks, 6 months, and 1 year. All were admitted in moribund condition and died quickly. All gave a history of mild gastro-enteritis before suddenly developing a rapidly fatal bronchopneumonia. It was now evident that a serious infection was about, especially so as the symptoms preceding the pneumonia were of only a mild nature. The fourth death was reported to the coroner to enable specimens to be obtained for virus research and identification. Inquiry

showed that practically all these patients had been fed on a well-known brand of dried milk, and in view of the isolation of staphylococci from the patients investigations were undertaken to see whether this was a possible source, though it was thought to be unlikely. At the time of going to press a further 11 babies all under 1 year old had been admitted to hospital from this area, 4 from adjacent areas, and 1 (which died) from Hemsworth, a district 20 miles away.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases (deaths for influenza) of certain diseases notified weekly in England and Wales (great towns for influenza). Highest and lowest figures reported in each week during the years 1949-57 (influenza, 1953-7) are shown thus ———, the figures for 1958 thus ———. Except for the curves showing notifications in 1958, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending November 8 (No. 45) and corresponding week 1957.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the whole of England and Wales (London included). London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES	1958					1957				
	Eng. & Wales	London	Scot.	N. Ire.	Eire	Eng. & Wales	London	Scot.	N. Ire.	Eire

Venereal Diseases: Gonorrhoea Increasing

In England and Wales during the quarter ending June 30, 1958, 1,055 new cases of syphilis were reported as attending the clinics as compared with 1,244 the previous year. Of these, 163 were classified as primary, secondary, or latent in the first year of infection. 4 cases of congenital syphilis in children aged under 1 year were reported, and 105 cases in persons over that age. New cases of gonorrhoea (with corresponding 1957 figures in parentheses) numbered 6,855 (5,880), of chancroid 64 (51), and of non-gonococcal urethritis (males only) 4,326 (4,280).

New cases of gonococcal infection have sharply increased in both men and women. After the war new cases decreased, and in 1954 reached a record low level of 17,536. Since then they have risen annually, and in 1957 numbered 24,381. This is about the same as the 1949 figures. The increase continued in 1958, and in the first six months of this year 12,911 new infections were seen, compared with 10,953 in the first half of 1957.

Week Ending November 15

The largest fluctuations in the notifications of infectious diseases in England and Wales during the week ending November 15 were increases of 464 for measles, from 5,315 to 5,779, 162 for whooping-cough, from 643 to 805, 63 for scarlet fever, from 912 to 975, and a fall of 196 for food-poisoning, from 392 to 196.

The largest rises in the incidence of measles were 112 in Cheshire, from 262 to 374 (Congleton M.B. 89), 112 in Yorkshire West Riding, from 691 to 803 (Halifax C.B. 197), 84 in Staffordshire, from 156 to 240 (Brownhills U.D. 56), 75 in Lancashire, from 650 to 725 (Liverpool C.B. 138, 75 in Manchester C.B. 81, Preston C.B. 71), and 60 in Surrey, from 120 to 180 (Croydon C.B. 77). No large changes were reported in the local trends of scarlet fever. The largest increase in the number of notifications of whooping-cough was 24 in Lancashire, from 46 to 70. 6 cases of diphtheria were notified, being the same number as in the preceding week.

The notifications of acute poliomyelitis numbered 66, and these were 9 fewer for paralytic and 7 fewer for non-paralytic cases than in the preceding week. The largest returns were Lancashire 12 (Manchester C.B. 5, Denton U.D. 3), Yorkshire West Riding 11 (Huddersfield C.B. 3, York C.B. 2), Harrogate M.B. 2, Hampshire 5 (Southampton C.B. 4), Warwickshire 5 (Birmingham C.B. 4), and Devonshire 5 (Plymouth C.B. 5).

Notifications of dysentery, 614, were 12 fewer than in the preceding week. The chief centres of infection were Yorkshire West Riding 97 (Leeds C.B. 49, Hemsworth R.D. 19), Lancashire 80 (Deptford 14, Lewisham 11, Islington 10), Lancashire 63 (Eccles M.B. 29, Liverpool C.B. 19), Glamorgan-shire 49 (Cardiff C.B. 17, Rhondda M.B. 13), Warwickshire 49 (Coventry C.B. 39, Birmingham C.B. 10), Cambridgeshire 41 (Cherterton R.D. 34), Nottinghamshire 30, Hampshire 26 (Southampton C.B. 18), Essex 24 (Leyton M.B. 15), and Cumberland 20 (Carlisle C.B. 16).

The largest outbreak of food-poisoning was 20 cases in Droylsden U.D., Lancashire.

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenza pneumonia.

‡ Includes puerperal pyrexia.

Medical News

Travelling Fellowships for 1959-60.—The Medical Research Council invites applications for Rockefeller Travelling Fellowships in Medicine, which are intended for graduates resident in this country who have had some training in research work in medicine, surgery, or medical science; Dorothy Temple Cross Research Fellowships in Tuberculosis, which are offered to suitably qualified British subjects "intending to devote themselves to the advancement by teaching or research of curative or preventive treatment of tuberculosis in all or any of its forms"; Alexander Pigott Wernher Memorial Travelling Fellowships in Ophthalmology and Otolaryngology, which are intended for medical graduates in the United Kingdom and Commonwealth who wish to study the prevention and cure of blindness and deafness. These fellowships are for the academic year 1959-60. Further particulars and forms of application may be obtained from the Secretary, Medical Research Council, 38, Old Queen Street, London, S.W.1, to whom applications should be sent not later than December 31, 1958.

Fulbright Travel Grants.—The United States Educational Commission in the United Kingdom announces that, under the provisions of the Fulbright programme, travel grants are available to citizens of the United Kingdom and dependent territories to go to the U.S.A. for academic or educational purposes, such as study, research, or lecturing. All awards are competitive and are made by the Board of Foreign Scholarships in Washington upon the recommendations of the Commission. All applicants must possess a guarantee of adequate financial support in dollars for their visit, and afterwards they are expected to return to reside permanently in their home countries. Those in the graduate student category are expected to go to the United States for the academic year beginning in September, 1959. For those in the lecturer/research scholar category, travel grants are available between June 1, 1959, and April 1, 1960. The closing dates for applications are March 14 for those travelling between June 1 and August 15, 1959; and June 1 for those travelling between August 16, 1959, and April 1, 1960. Further details may be obtained from the Commission, 71, South Audley Street, London, W.1.

Rockefeller Grants.—For the third quarter of 1958 Rockefeller Foundation grants totalled \$1,777m. Grants for medical education and public health accounted for \$480,107, and for biological and medical research \$232,557. Major grants were provided for research on genetics (in Switzerland and Sweden) and on the mode of action of insecticides (U.S.A.). In Britain the department of chemistry at King's College, Newcastle upon Tyne, receives \$15,000 for work on the chemistry of biologically important compounds, under the direction of Professor J. BADDILEY. Sir HAROLD HIMSWORTH, F.R.S., Secretary of the Medical Research Council, receives a grant to allow him to confer with scientific colleagues in the United States; and Professor C. H. WADDINGTON, F.R.S., professor of animal genetics at Edinburgh, receives support for a study of the influence of science on the visual arts during the twentieth century.

"International Pharmacopoeia."—The W.H.O. expert committee on the *International Pharmacopoeia* met in Geneva last month to discuss the preparation of the second edition. Volumes I and II of the first edition were published in French, English, and Spanish and subsequently translated into German and Japanese. A supplement to these two volumes is being printed, and the committee, which included Mr. T. C. DENSTON, secretary of the British Pharmacopoeia Commission, also discussed the publication of information sheets about new pharmaceutical preparations.

General Optical Council.—Mr. G. G. BAKER, Q.C., Recorder of Wolverhampton, has accepted the invitation of the Privy Council to be chairman of the General Optical Council, which will be established under the Opticians Act, 1958, on January 1. The full membership of the Council is expected to be announced shortly. Mr. A. T. GERARD, of the Ministry of Health, has been appointed registrar of the Council.

Edgar-Gentili Scholarship.—The council of the Royal College of Obstetricians and Gynaecologists invites applications for the Edgar-Gentili scholarship (up to a total value of £1,000 per annum). Its primary object is to encourage research on chorionepithelioma, although work on the trophoblast, its interaction with maternal tissue, or on the placenta may be regarded as relevant. Further details are to be found at p. 52 of the advertisements. The closing date for applications is December 31, 1958.

Lalor Foundation.—For its programme of grants next year the Lalor Foundation offers grants in support of research on the basic biochemical and biophysical mechanisms affecting fertility and reproduction in various species. The grants range from a nominal amount up to \$8,000 a year, and they are designed primarily to assist younger academic research workers. Awards may be granted to nationals other than U.S. citizens, though usually on condition that the research is done at an American institution. The final date for applications is January 14. Further details are obtainable from the Lalor Foundation, 4400, Lancaster Pike, Wilmington, 5, Delaware, U.S.A.

Medical Psychotherapy.—At the International Congress of Psychotherapy, held in Barcelona in September, it was decided to set up an international organization to promote co-operation and the exchange of views between medical psychotherapists, irrespective of their school. The *Acta Psychiatrica* was adopted as the organization's official journal, and it was decided to hold an international congress every three years, the next to be in Vienna in 1951. The following were elected to the committee: *president*, Professor M. Boss (Zurich); *vice-president*, Professor R. SARRO (Barcelona); *hon. secretary*, Dr. H. K. FIERZ (Kreuzlingen, Switzerland); *hon. treasurer*, Professor E. CARP (Leyden); and Dr. J. BIERER (London), Dr. R. EGG-OLFSSON (Stockholm), Professor V. FRANKL (Vienna), and Mrs. E. WEIGERT (U.S.A.).

Society for Psychosomatic Research.—The annual dinner was held at the Royal College of Physicians of London on November 20. The guest of honour was Dr. KURT HAHN, formerly headmaster of Gordonstoun School.

Honorary Degrees at Leeds.—The court of Leeds University has decided to confer the honorary degree of D.Sc. on Mrs. DOROTHY HODGKIN, F.R.S., reader in x-ray crystallography at Oxford, and on Sir RUDOLPH PETERS, F.R.S., at a congregation on May 14.

Dr. R. S. Aitken, Vice-Chancellor of Birmingham University, had conferred on him recently the honorary degree of Doctor of Laws of McGill University.

Sheffield University.—Dr. M. A. WILSON, deputy director of the Public Health Laboratory, Sheffield, has been appointed an honorary part-time lecturer in bacteriology.

Faculty of Medicine, Bristol.—Dr. E. W. BRADFORD, senior lecturer in preventive dentistry and parodontal diseases at St. Andrews, has been appointed to the chair of dental surgery from March 31, 1959. Professor A. I. DARLING will assume the title of "professor of dental medicine."

Guy's Hospital Medical School.—The title of "reader in orthodontics in the University of London" has been conferred on Mr. W. J. TULLEY in respect of his post at Guy's Hospital Medical School.

COMING EVENTS

St. Bartholomew's Hospital.—The 13th Decennial Club will meet on December 6 at the Connaught Rooms, London, W.C.2. Further details may be obtained from the secretaries of the club, St. Bartholomew's Hospital, London, E.C.1.

FitzPatrick Lectures.—Dr. W. S. C. COPEMAN will lecture at the Royal College of Physicians on December 9 and 11 at 5 p.m. His subject will be "Medical Practice in the Tudor Period."

Harben Lectures.—Sir SAMUEL P. BEDSON, F.R.S., will lecture on "The Psittacosis-Lymphogranuloma Group of Infective Agents" on December 8, 9, and 10, at 4 p.m. at the Royal Institute of Public Health and Hygiene, 28, Portland Place, London, W.1.

British Records Association.—Exhibition of medical records (see p. 1328) in the library of the Royal College of Physicians of London until December 12 (weekdays 10 a.m.-5 p.m.; Saturdays 10 a.m.-1 p.m.).

Stubbs's Anatomical Drawings.—A collection is on view in the gallery of the Arts Council, 4, St. James's Square, London, S.W.1, until December 13, from 10 a.m. to 6 p.m. including Saturdays (Tuesdays and Thursdays, 10 a.m. to 8 p.m.).

NEW ISSUES

SPECIALIST JOURNALS AND ABSTRACTS

The journals listed below are obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

Abstracts of World Medicine.—Issued in the first week of each month, this journal contains abstracts of important papers selected from the current medical literature of the world. Annual subscription £4 4s.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, December 1

DENTAL AND MEDICAL SOCIETY FOR THE STUDY OF HYPNOSIS.—At Royal Society of Medicine, 8 p.m., Dr. A. G. Davies: Hypnosis, Sex, and Sexual Disorders.
GUY'S HOSPITAL.—At Anatomy Lecture Theatre, 5.15 p.m., lecture-demonstration in endocrinology by Dr. P. M. F. Bishop: Hypopituitarism.
● INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—At Chelsea Hospital for Women, 4.30 p.m., Guest Lecture by Mr. Frank Denny: Carcinoma and other Disorders of the Vulva.
LIVERPOOL UNIVERSITY: FACULTY OF MEDICINE.—At Large Lecture Theatre, New Medical School, Ashton Street, 12 noon, Mr. D. P. Choyce: Onchochercal Eye Lesions.
MARLBOROUGH DAY HOSPITAL.—8.15 p.m., film: Aspects of Childhood Psychosis. A discussion will follow.
UNIVERSITY COLLEGE LONDON.—At Physiology Lecture Theatre, Gower Street, W.C., 5.30 p.m., special university lecture in pharmacy by Professor Z. M. Bacq (Liège): Substances Which Protect Against Ionizing Radiations.

Tuesday, December 2

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. C. N. Armstrong: Intersexuality.
ILFORD MEDICAL SOCIETY.—At King George Hospital, 8.45 p.m., Squadron Leader P. Howard: "Some Physiological Aspects of High Speed Flight." Members of Stratford Division, B.M.A. are invited.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. B. Russell: Bacteria on the Skin Surface.
MANCHESTER UNIVERSITY: DEPARTMENT OF OCCUPATIONAL HEALTH AND NORTH-WEST ENGLAND FACULTY, COLLEGE OF GENERAL PRACTITIONERS.—At Theatre 1, Clinical Sciences Building, York Place, 8.30 p.m., Professor R. E. Lane: Some Industrial Diseases.
ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Sir James Paterson Ross: Changing Scene of Surgery.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor G. S. M. Bothe: Closing Mechanism Between Stomach and Oesophagus and its Importance in Surgery of the Gastro-oesophageal Junction.
ST. ANDREWS UNIVERSITY.—At Physiology Department Lecture Theatre, 5 p.m., Dr. J. Iball: Investigating the Molecular Structure of Biological Materials.
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Institute Theatre, 5 p.m., Mr. E. A. J. Alment: Foetal Distress and Resuscitation of the Newborn.
UNIVERSITY COLLEGE LONDON: DEPARTMENT OF PHARMACOLOGY.—At Physiology Theatre, Gower Street, W.C., 5.30 p.m., Dr. W. S. Feldberg, F.R.S.: Some Physiological Aspects of General Anaesthesia.
WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Dr. E. H. Larkin: "Physical" Treatments in Psychiatry.

Wednesday, December 3

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. A. Tickner: Some General Aspects of the Biochemistry of the Skin.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Mr. W. P. Cleland: Secondary Lung Tumours.

INSTITUTE OF LARYNGOLOGY AND OTOLARYNGOLOGY.—5.30 p.m., Dr. I. Friedmann, Dr. D. A. Osborn, and Dr. A. L. Jeames: clinical pathological conferences.

INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Mr. A. W. Badenoch: Haematuria.

MANCHESTER MEDICAL SOCIETY.—At Large Anatomy Theatre, Manchester University, 4.30 for 5 p.m., Dr. J. D. Spillane: The Cervical Spine.

MIDLAND MEDICAL SOCIETY.—At Birmingham Medical Institute, 8.15 p.m., symposium by Dr. M. J. Meynell, Dr. S. Sevit, and Mr. H. C. McLaren: Prevention and Treatment of Pulmonary Embolism.

● NATIONAL COLLEGE OF RUBBER TECHNOLOGY, Northern Polytechnic, Holloway Road, N.—6.30 p.m., Mr. W. C. Favager: Plastics in Hospital Equipment.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Guest Lecture by Dr. R. I. S. Bayliss: Laboratory Investigations in Endocrinology.

UNIVERSITY COLLEGE LONDON.—(1) At Physiology Lecture Theatre, Gower Street, W.C., 5.30 p.m., special university lecture in pharmacy by Professor Z. M. Bacq (Liège): Substances Which Protect Against Ionizing Radiations. (2) At Anatomy Theatre, Gower Street, W.C., 5.30 p.m., special university lecture by Professor O. E. Lowenstein: Sensory Function and Qualitative Information.

Thursday, December 4

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. E. F. Scowen: Hyperoxaluria.

FOUNTAIN HOSPITAL.—5.30 p.m., symposium: Psychological Research in Mental Deficiency. Papers by Dr. Mary Woodward, Mr. F. Orford, Mr. J. Lyle, Mrs. Lydia Mundy, and Mrs. M. W. Gillian Brandon.

LIVERPOOL MEDICAL INSTITUTION.—8 p.m., Mr. L. H. Savin: Facies in Disease.

ROYAL COLLEGE OF SURGEONS OF ENGLAND AND INSTITUTE OF LARYNGOLOGY AND OTOLARYNGOLOGY.—At Royal College of Surgeons of England, 5.30 p.m., Otolaryngology Lecture by Sir Stanford Cade: Cancer of the Tongue.

ROYAL SOCIETY OF HEALTH.—At Wulfrun Hall, Wolverhampton, 10 a.m., Dr. P. Phelps and Mr. G. W. Mullett: Radiation Hazards and the Local Authority; Miss Hilary Clark: Some Human Aspects of Over-spill Housing.

ST. ANDREWS UNIVERSITY.—At Physiology Department Lecture Theatre, 5 p.m., Professor J. I. P. James: Early Treatment of the Injured Hand.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Sir Paul Mallinson: postgraduate demonstration in psychiatry.

UNIVERSITY COLLEGE LONDON.—At Anatomy Theatre, Gower Street, W.C., 5.30 p.m., special university lecture by Professor O. E. Lowenstein: Sensory Function and Qualitative Information.

Friday, December 5

● INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. A. D. Porter: clinical demonstration.

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. N. S. Plummer: clinical demonstration.

INSTITUTE OF LARYNGOLOGY AND OTOLARYNGOLOGY.—3.30 p.m., clinical discussion for general practitioners by Mr. Wallace Black: Swellings in the Neck and their Management.

PLYMOUTH MEDICAL SOCIETY.—At Freedom Fields, 8.30 p.m., Professor Alan Moncrieff: Marasmus in Young Children—a new outlook.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—(1) 10 a.m., Guest Lecture by Mr. R. V. Cooke: More About Biliary Tract Surgery. (2) 4 p.m., Guest Lecture by Professor N. H. Martin: Myelomatosis.

ROYAL MEDICO-CHIRURGICAL SOCIETY OF GLASGOW.—At Royal Faculty of Physicians and Surgeons of Glasgow, 8.30 p.m., short papers by Dr. W. A. J. Crane, Dr. W. G. Whyte, and Dr. R. Fife.

UNIVERSITY COLLEGE LONDON.—At Anatomy Theatre, Gower Street, W.C., 5.30 p.m., special university lecture by Professor O. E. Lowenstein: Sensory Function and Qualitative Information.

WHIPPS CROSS HOSPITAL MEDICAL SOCIETY.—8.30 p.m., joint meeting with East Metropolitan Branch of Pharmaceutical Society. Lecture by Superintendent G. E. Salter (New Scotland Yard): Scientific Detection of Crime.

Saturday, December 6

INSTITUTE OF LARYNGOLOGY AND OTOLARYNGOLOGY.—11.30 a.m., special lecture by Mr. J. A. Sullivan (Toronto): Modern Temporal Bone Surgery.

KENT PAEDIATRIC AND CHILD HEALTH SOCIETY.—At Children's Department, Farnborough Hospital, 3 p.m., Dr. A. Elliott: New Development in Child Health.

MIDLAND THORACIC SOCIETY.—At Birmingham Medical Institute, 3 p.m., Dr. C. W. D. Cole: The Working Foundryman and his Chest.

SOUTH-EAST METROPOLITAN REGIONAL TUBERCULOSIS SOCIETY.—At St. Bartholomew's Medical College, 10 a.m., joint meeting with North-East Metropolitan Regional Tuberculosis Society.

Sunday, December 7

UNIVERSITY COLLEGE HOSPITAL.—10.15 a.m., meet in Rowland Ward Hall, St. Pancras Hospital, St. Pancras Way, N.W. Lecture-demonstration for general practitioners. Clinical demonstration by Lord Amulree: Care of the Aged.

BIRTHS, MARRIAGES, AND DEATHS

DEATHS

Barton.—On October 24, 1958, at his home, Douglas Elliott Barton, M.B., B.S., C.P.H., D.I.H., of Bexley Heath, Kent.
Crabtree.—On November 7, 1958, at Scarborough Hospital, Jane Crabtree (formerly Bamford), M.B., Ch.B., of 2, Holbeck Court, Scarborough, Yorks.
Lewis.—On November 9, 1958, in hospital, Glyndwr Morison Lewis, T.D., M.R.C.S., L.R.C.P.
McLean.—On November 7, 1958, at Eastwood, Notts, Leslie George McLean, M.M., M.B., Ch.B., of 59 Nottingham Road, Eastwood.
Masters.—On November 7, 1958, Edgar James Masters, M.B., B.S., D.C.H., D.R.C.O.G., of Cornerways, The Boulevard, Worthing, Sussex, aged 30.
Porter.—On November 5, 1958, at Godalming, Surrey, Douglas Porter, M.B., Ch.B., D.P.H.
Roberts.—On November 9, 1958, in a nursing home, Wilmslow, Cheshire, Hubert Shearwood Roberts, M.D., late of Southport, Lancs.
Waller.—On November 7, 1958, at The Croft, The Street, Rustington, Sussex, Wathen Ernest Waller, M.D., M.R.C.P.
Whitley.—On November 4, 1958, in hospital, William Frederic James Whitley, M.D., D.P.H., of 44, Church Burn Drive, Morpeth, Northumberland, aged 84.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Serum Lipase and Protease

Q.—What are the normal values of serum lipase and protease (the various trypsin-like enzymes), and what are the approximate values of significance in pancreatitis?

A.—Normal values of serum lipase are up to 12 units. A definition of the units and details of the method are given by Cherry and Crandall¹ and also by Maclay.² Little of the lipase normally present in serum is derived from the pancreas, but in pancreatitis the pancreatic contribution, and hence the total serum lipase, rises—the latter being roughly parallel to the serum diastase—though declining more slowly as the pancreatitis subsides. On the whole lipase estimations add little information to that supplied by diastase estimations, and for this reason, and also because estimation of lipase is not simple, the method has been little used as a diagnostic test.

Methods for estimating serum trypsin have hitherto proved unsatisfactory. But recently Nardi³ has devised a method in which a synthetic polypeptide (α -benzoyl-L-arginine amide hydrochloride) is the substrate, the amide group being split off: the ammonia so formed is a measure of tryptic activity. Nardi's control group (8 normals and 27 patients without pancreatic disease) is small and needs extending to include a group with extensive tissue necrosis. In this control group serum trypsin varied between 0 and 120 units, except in one case of cholecystitis, where the figure was 260 units. In 14 of 16 cases of pancreatitis serum trypsin exceeded 240 units, although in 6 of these cases serum diastase and lipase were normal. In 7 cases of carcinoma of the pancreas serum trypsin was greatly raised in 6, although in 4 of these serum diastase and lipase were normal. Nardi's data suggest that estimation of serum trypsin provides a more reliable test for pancreatitis and carcinoma of the pancreas than estimation of diastase or lipase. In chronic sclerosing conditions of the pancreas all these tests are likely to be negative.

Disinfecting Vehicles

Q.—What is the most effective method of disinfecting a vehicle after transport of infectious diseases?

A.—The best method, to leave the inside of the vehicle in an acceptable state, is to use a "white" disinfectant (stable emulsions of crude cresol and the higher phenolic constituents of coal tar in water; on dilution they form weaker emulsions) with a fine spray two or three times, or 25% formalin in industrial spirit with oil of lavender *q.s.* The interior is then wiped down and the doors left open.

Wintering Abroad

Q.—Would wintering abroad help a patient who has attacks of bronchitis each winter, and, if so, where?

A.—A sufferer from winter cough of this character would certainly benefit from avoidance of the climatic conditions that are usual in this country during the first quarter of the year. There is a wide choice of suitable residences abroad. If there is an asthmatic element or any considerable degree of emphysema, altitude demands some attention, since for some indefinite reason, whether physical or biochemical, asthmatic subjects are most comfortable at a critical height, and those with emphysema and any cardiac disability should avoid situations above three or four thousand feet (914–1,219 m.). With these exclusions, the elevated valleys of Davos and Arosa—about 5,000 feet (1,524 m.)—are satisfactory at this time of the year. The banks of the Lake

of Geneva—1,200 feet (336 m.) or so—which are well protected from wind, are also suitable. Of entirely different type are Madeira, the Canaries, Gibraltar, Majorca, the British West Indies, Algiers, and Assouan. The last-named, on the edge of the desert, appeals strongly to me.

There is thus no difficulty in nominating desirable residences: the choice is dependent upon a number of factors apart from climate. Expense may be of crucial importance both in transport and—since a long-term arrangement is contemplated—in residence. Social and psychological considerations demand attention, and into these enter individual tastes and habits. One may be easily reconciled to comparative solitude, and in fact prefer to be left to his own resources, while another suffers intolerable boredom without the provision of social contacts, distractions, entertainments, and recreations. It is clear, therefore, that it is necessary to decide what the patient desires apart from change of climate and to make appropriate inquiries about the circumstances of the various places mentioned, especially if his experience as a traveller has been limited. If I place Assouan in the forefront it is from recollection of my own visits during the months of January–February. I preserve the impression of a perfect climate. This, however, was many years ago and inevitably much alteration in accommodation and other matters must have occurred. Algiers, especially Mustapha Supérieur, has attractive features apart from climate, which, although satisfactory, cannot compete with that of Assouan. By the end of March it is sometimes rather uncomfortably hot. The journey is much shorter than that to Assouan. Transport to all places mentioned is naturally a variable feature.

Cresol Vapour

Q.—Is there any likelihood of cresol vapour being carcinogenic when inhaled frequently in the treatment of some respiratory conditions?

A.—There is no evidence that pure cresol is carcinogenic, and the fraction from coal tar which contains cresols would be unlikely to contain any of the known carcinogenic hydrocarbons in any quantity. Although it is difficult to be certain, it would seem to be unlikely that cresol vapour used in the treatment of respiratory conditions would cause cancer.

NOTES AND COMMENTS

Fibrinosol.—In experimental work to devise a serum test for the early diagnosis of carcinoma use is sometimes made of an organic substance called fibrinosol. Ashe Laboratories Ltd., Ashetree Works, Kingston Road, Leatherhead, Surrey, inform us that fibrinosol is a by-product of their chemical manufacture, and they are willing to supply it free of charge to any hospital on request.

Disclaimer by Professor Aird.—Professor IAN AIRD writes: Would you be kind enough to inform our profession through your columns that the illustrated article which appeared on November 23 in a Sunday newspaper, and in which my name featured, was prepared and published without information from me and without my knowledge, nor did I furnish the illustrations for it.

Correction.—The fifth sentence of Mr. H. H. Nixon's letter on extra skin creases ("Notes and Comments," November 15, p. 1244) should read: "He did not mention that they also had symmetric skin creases . . ." not " . . . asymmetric skin creases. . ."

D. G. MELROSE, M.A., B.M., AND L. J. TELIVUO,† L.M.

From the Departments of Surgery and Medicine, Postgraduate Medical School of London, Hammersmith Hospital, London, W.12

The natural history of ventricular septal defect (V.S.D.) is such that few patients survive past the third decade (Brotmacher and Campbell, 1958). It is therefore fortunate that the introduction of the cardio-pulmonary bypass has permitted effective surgical treatment. This bypass is now current practice in the U.S.A. (Kirklin *et al.*, 1957; Warden *et al.*, 1957; Gerbode *et al.*, 1958). The object of this paper is to present a series of 21 patients with V.S.D.s, operated on under total cardio-pulmonary bypass with the Melrose-N.E.P. pump-oxygenator at Hammersmith Hospital. These patients form the major group of a total of 40 operated on in this way for the correction of congenital cardiac defects during the last 18 months.

The Patients.—The ages of the 21 patients ranged from 2½ to 25 years, the average being 8½ years. Of these patients with V.S.D. four had in addition a patent ductus arteriosus. Of the cases without a duct three were unusual. One had a single ventricle, one had two V.S.D.s, and in one the V.S.D. was in an unusual site in relation to the tricuspid valve (Case 13).

Clinical Picture

Symptoms

Infancy is known to be a hazardous period in patients with large V.S.D.s, and over half of the 320 patients of Keith *et al.* (1958) died before the age of 1 year. Similarly, in our cases there was often a history of feeding difficulties, with breathlessness and cyanosis, and very slow weight gain in infancy. After the age of 1 year they did better, though frequent chest infections were still common, and when seen by us they were often remarkably asymptomatic and active. Dyspnoea on exertion was no more than slight in two-thirds and was severe in only one case (Case 2).

Signs

These children were commonly undersized for their age, being on average 18% below the expected weight. Chest deformity with uniform or asymmetrical bulging of the sternum and Harrison's sulcus was frequently noted (Fig. 7). Clubbing was never seen, but slight cyanosis was occasional and was usually peripheral.

*Nuffield Research Assistant.
†In receipt of British Council Bursary.

the arterial oxygen saturation being always above 88%. No patient had congestive heart failure at the time of operation.

Jugular Venous Pulse.—This was abnormal in eight, consisting usually of a moderately dominant *a* wave; a really conspicuous *a* wave was seen only once (Case 13).

Arterial Pulse.—The volume was usually normal or slightly small and the rhythm regular. A slight-to-moderate waterhammer quality was found in 11. A striking suprasternal arterial pulsation was found in Cases 14 and 15, which had in addition a patent ductus.

Cardiac Pulsation.—The type of pulsation varied according to the size of the left-to-right shunt and the pulmonary resistance. When the shunt was considerable there was a localized hyperdynamic thrust at the apex, indicating left ventricular enlargement, and a diffuse parasternal heave due to enlargement of the right ventricle. When the shunt was smaller and the pulmonary resistance appreciably raised (around 9 units) the left ventricular thrust was less impressive and the dominant pulsation was that of the right ventricle.

Auscultation

V.S.D. Thrill and Murmur.—These were usually maximal at the left sternal edge, and in most cases the murmur was loud and long, indicating a substantial flow through the defect (Fig. 1A). In the patients with a pulmonary resistance of 9 units or more the murmur and thrill were softer and shorter, owing to reduction in flow through the defect (Fig. 1C).

Apical Diastolic Murmur.—A low-pitched delayed murmur at the apex attributed to a torrential mitral blood flow (Wood, 1956) was heard in all cases. When loud and long the left-to-right shunt was always large (Fig. 1A). We expected, when the murmur was soft and short, that the shunt would be small and the resistance high, but this was not always so. Of the six cases with this type of murmur, four had a large shunt and in two the shunt was small.

Basal Diastolic Murmur.—An early blowing diastolic murmur was heard in the left second to third spaces in eight patients. At operation three were shown to have a ductus, one was proved to have aortic incompetence, and one to have pulmonary incompetence. The cause

of the murmur was not determined in the remaining three and disappeared after operation in one. In these three it was presumed to be due to aortic or pulmonary incompetence.

FIG. 1.—Phonocardiograms taken at the left sternal edge (L.S.E.) and at the mitral area (M.A.). (A) Loud long systolic murmur (S.M.) and long mitral diastolic murmur (M.D.M.) in a patient with a large left-to-right shunt and low pulmonary resistance. (B) Same patient as (A) showing disappearance of significant murmurs after closure of defect. A soft ejection systolic murmur is shown. Note appearance of right bundle-branch block. (C) Short soft systolic murmur in a patient with only a small left-to-right shunt and high pulmonary resistance. The second heart sound is very loud and virtually single, and the mitral diastolic murmur is soft and short.

FIG. 2.—Postero-anterior and lateral views of the heart in Case 4 with a large left-to-right shunt and only slightly elevated pulmonary resistance. The right ventricle and pulmonary artery are enlarged and there is pulmonary plethora. Definite left atrial enlargement is seen in the lateral view.

Second Heart Sound.—This was loud and narrowly split in all patients except three. One of these was found to have definite organic pulmonary valve stenosis at operation, one had aortic incompetence and infundibular obstruction and the other (Case 13) had an unusual defect, referred to later.

Other Sounds.—Two cases had a pulmonary ejection click and high pulmonary pressures, but with a substantial shunt. An ejection click at the apex, thought to be aortic, was heard in one patient who had also a patent ductus. No other abnormal sounds were heard in any patient.

Associated Non-cardiac Anomalies

These were usually absent, but one patient had stigmata of the "rubella syndrome" and also a patent ductus. Another patient had right basal bronchiectasis.

Methods of Study

Radiology

The heart was enlarged in every case, being usually moderate in degree with a cardio-thoracic ratio of 55–65%. Enlargement was considerable in two and slight in three. Both ventricles were enlarged in every case. The left ventricle tended to be less prominent in the cases with a high pulmonary resistance. Left atrial enlargement, of slight-to-moderate degree, was present in all save two, of whom one had substantial infundibular stenosis and the other a high pulmonary resistance (14 units). Impressive right atrial enlargement was seen only twice. One of these patients (Case 13) appeared at operation to have tricuspid incompetence; in the other patient (Case 21) clockwise cardiac rotation was found at operation.

Enlargement of the main pulmonary artery was invariable, as was plethora of the lung fields. Intrinsic pulsation of the small branches was well marked in all. The size of the aorta was unremarkable.

Fig. 2 shows the radiological features in a typical case.

Aortography was performed on two patients and one was shown to have a patent ductus (Case 20).

Electrocardiography

Right atrial P waves were found in six cases and were gross in only one (Case 13). Left atrial P waves occurred in 11. Direct evidence of right ventricular hypertrophy (Hollman, 1958) was found in 11, and 7 of these had an RSR pattern in VI and one had complete right bundle-branch block. Direct evidence of left hypertrophy (Cabrera and Monroy, 1952) consisting variously of deep Q waves, tall R waves, or tall peaked T waves was found in 19 (Fig. 3).

Lone right hypertrophy was found in only one (Fig. 4), while solitary left hypertrophy occurred in six. Thus 14 patients had combined hypertrophy. In six of these the right ventricle appeared dominant and in three the left. We had expected that when the left ventricle dominated the

right the pulmonary flow would be higher and the resistance lower than when the right ventricle was dominant. This was not the case, for there was no clear relationship between the cardiographic and haemodynamic findings. Further, it was anticipated that when the right ventricle dominated the

FIG. 3.—Electrocardiogram of Case 19, showing dominant left ventricular hypertrophy with deep Q waves, tall R waves, only small S waves, and tall T waves in V5-V7. Slight right ventricular hypertrophy is present too.

FIG. 4.—Electrocardiogram of Case 1 showing dominant right ventricular hypertrophy with no clear evidence of left ventricular hypertrophy at all. There is a monophasic R wave in V1 with S waves across to V7 and a dominant R wave in lead aVR. There are no Q waves in V5-V7.

FIG. 5.—Post-operative electrocardiogram of Case 4 showing complete right bundle-branch block with the secondary R wave present even in V7. Well-marked T-wave inversion is present across to V5.

left a smaller fall of right heart pressure would occur than when the left ventricle was dominant, but we were disappointed in this also. Nevertheless we continue to use the cardiogram in the assessment of individual patients in the belief that the presence of left hypertrophy is a favourable sign.

Cardiac Catheterization

This was carried out in every case, and the data were used to estimate the size of the defect, the severity of the pulmonary vascular disorder, and the presence of associated anomalies. The size of the left-to-right shunt was expressed as the ratio of pulmonary to systemic flow.

$$\frac{\text{Pulmonary flow}}{\text{Systemic flow}} = \frac{\text{Systemic A-V O}_2 \text{ difference}}{\text{Pulmonary A-V O}_2 \text{ difference}}$$

The pulmonary arteriolar resistance was expressed in arbitrary units (Wood, 1956), and in cases where the oxygen consumption was not measured an average value for age and surface area was obtained from tables.

The results of this investigation are summarized in Table I.

TABLE I.—Haemodynamic Studies at Catheterization, at Operation, and Results

Case No.	Age	Pulmonary Artery Pressure (mm. Hg)	Pulmonary Systemic Flow Ratio	Pulmonary Arteriolar Resistance (Units)	% Fall in R.V.P.† L.V.P.	Result

* = O₂ consumption assumed.

† R.V.P. = right ventricular systolic pressure. L.V.P. = left ventricular systolic pressure.

% fall in R.V.P. = R.V.P. % before closure minus R.V.P. % after closure.

% fall in L.V.P. = L.V.P. % before closure minus L.V.P. % after closure.

Also see text.

The pulmonary artery pressures ranged from 17/5 to 120/70, and were mostly of the order of 70/50 mm. Hg. The left-to-right shunt was large in all but three cases, the ratio of pulmonary to systemic flow ranging from 1.1:1 to 5:1, with an average of 2.4:1. The pulmonary resistance was usually only moderately elevated, but in four patients it was high. The average for all cases was 7.4 units. An infundibular gradient, usually slight, was found in nine patients and ranged from 7 to 40 mm. Hg. One patient had a 30 mm. Hg gradient at valve level. The oxygen saturation was higher in the pulmonary artery than the right ventricle in four patients, of whom two had an associated patent ductus. In two cases proved to have a ductus the saturation in the two sites was equal. The arterial oxygen saturation was always above 88%, and averaged 93%.

The pulmonary wedge pressure when determined ranged from 5 to 16 mm. Hg (measured from 5 cm. below the sternal angle).

Associated Lesions and Unusual Features

Patent Ductus Arteriosus.—The classical signs were absent, although suspicion was raised by an early diastolic murmur at the left sternal edge in two. Cardiac catheterization

revealed a further rise in oxygen saturation in the pulmonary artery as compared with the right ventricle in only two, even though in another the ductus was found at operation to be large and the ventricular defect small. On x-ray examination the pulmonary artery was always at least moderately dilated. Our experience indicates that when the ductus is patent in the presence of a V.S.D., it is difficult to diagnose pre-operatively with certainty without the aid of retrograde aortography. The importance of the patent ductus in relation to perfusion is discussed below. Patency of the ductus should be suspected if there is a basal early diastolic murmur, if the catheterization data suggest a further left-to-right shunt at pulmonary artery level, or if there are any other features associated with patent ductus, as in one of our patients who had stigmata of the "rubella syndrome" (Heiner and Nadas, 1958).

Obstruction to Right Ventricular Outflow.—Nine patients were found to have infundibular obstruction at cardiomy, while another had definite valvular stenosis. In no case was the obstruction severe enough to reverse the left-to-right shunt, and the pulmonary artery pressure was elevated in all but one.

Pulmonary Valve Lesions.—Two patients had abnormal valves. In Case 5 the cusps were fused and the orifice reduced to 1 cm. in diameter. In Case 18 the cusps were adherent to the pulmonary ring, and this gave rise to pulmonary incompetence with a diastolic thrill.

Atypical Ventricular Defects

Case 6.—This boy of 7 years with a single ventricle was of exceptional interest, for pre-operatively all the signs were those of a straightforward ventricular defect apart from the cardiogram. This showed gross left-axis deviation with extreme clockwise rotation and absent Q waves over the left ventricle.

Case 9.—This patient, a girl aged 2½ years, had two ventricular defects, and pre-operatively the only hint of an associated lesion was a very large diphasic complex in lead I of the cardiogram.

Case 13.—In this girl of 9 years the defect was a low one beneath the septal cusp of the tricuspid valve, and the jet from the left ventricle was directed partly into the right atrium. Clinically the patient was unusual because she had a tall a wave, a widely split second sound, a very large right atrium, and the systolic thrill was near the apex.

Indications and Contraindications to Operation

In view of the known poor prognosis it is clear that all patients with a moderate-sized or large defect should be considered for surgery unless there is some contraindication. It is equally clear that the main hazard regarding closure is the presence of severe pulmonary vascular disease, because patients with this complication have a very high operative mortality and also may derive uncertain benefit if they survive. Thus the difficulty in selecting suitable cases for operation is experienced mainly in those patients who have an elevated pulmonary vascular resistance.

If the pulmonary resistance is so high as to cause an obvious right-to-left shunt with an arterial oxygen saturation below 85%, with or without cyanosis and clubbing, then closure of the defect should not be recommended. Such cases will have only a small left-to-right shunt with pulmonary flow less than 1.5 times the systemic, and the clinical features previously mentioned of a substantial shunt will be absent. The whole clinical picture, in fact, will be dominated by evidence of extreme pulmonary hypertension.

Cases less severe than this first group but with a substantially elevated pulmonary resistance (9 units or more) present the greatest difficulties in selection and a careful consideration of all aspects of the patient is essential. It is doubtful whether any one parameter is of overriding importance. Evidence for the presence of an appreciable left-to-right shunt with only a small or absent right-to-left shunt must be sought, so that a fall in pulmonary artery pressure after closure can be anticipated.

Case 3 can be cited as an example of a patient in this group, for she had a pulmonary artery pressure of 100/35 mm. Hg and a pulmonary arteriolar resistance of 13 units. We were encouraged to operate on her by finding a definite left ventricular thrust at the apex even though the right ventricular pulsation was prominent too, by a long loud V.S.D. murmur and thrill with a moderately loud mitral diastolic murmur, by the presence of a qR pattern in V6 even though R was monophasic in V1, and by a pulmonary flow 1.8 times the systemic. At operation a good drop in pulmonary artery pressure after closure was obtained. On the other hand, a girl of 9 with a pulmonary artery pressure of 80/40 mm. Hg and a pulmonary resistance of 14 units was thought to be unsuitable because of the following features. Clinically the left ventricle was doubtfully palpable, the V.S.D. murmur was not full length, and the thrill rather weak, there was no mitral diastolic murmur, the cardiogram showed deep S waves with no Q waves over the left ventricle, and the pulmonary flow was only 1.2 times the systemic.

The ideal case for operation is typified by Case 12. This boy of 10 years had a pulmonary resistance of 3.5 units, with a pulmonary artery pressure of 60/30 mm. Hg and a pulmonary blood flow 2.4 times the systemic. Clinically there was a quite forceful localized thrust at the apex, a loud long V.S.D. murmur with a strong thrill, and a loud long mitral diastolic murmur. The cardiogram showed a small Q, tall R, and small S in V6 with a prominent peaked T wave, and the predominant deflection in aVR was negative. On x-ray examination he had well-marked pulmonary plethora. At operation his pulmonary artery pressure dropped from 50/20 to 27/20 mm. Hg after closure of the defect.

Anaesthesia

The patients are made very drowsy by premedication, and we have found it best in children to give quinalbarbitone per rectum (4–5 mg./kg., maximum 200 mg.) with intramuscular promethazine (1.5–2 mg./kg., maximum 50 mg.) and pethidine (3–4 mg./kg., maximum 100 mg.). This allows the patient to be weighed without disturbance immediately before induction of anaesthesia by a minimal dose of thiopentone (25–50 mg.). After curarization (tubocurarine 0.5 mg./kg.) the trachea is intubated. Very light general anaesthesia is maintained with nitrous oxide and oxygen, using intermittent positive-pressure ventilation by a pulmoflator.

In the theatre a cannula is placed in a left arm vein for blood transfusion; a nylon catheter is passed from a right arm vein into the thorax for measurement of superior vena caval pressure and serves as an alternative route for intravenous therapy. Blood lost during surgery is estimated by weighing swabs and measuring suction loss, continuous balance being maintained by transfusion with citrated blood. All other intravenous fluids, including those used in manometry, are restricted to a minimum. Intermittent pethidine and tubocurarine are given as needed, with an additional dose of these two drugs before perfusion to anticipate the sudden dilution of circulating anaesthetic agents by blood from the pump oxygenator.

During the period of total bypass the lungs are held in a position of partial inflation with a mixture of helium and 20% oxygen at a steady pressure of 5–8 cm. of water to prevent pulmonary collapse.

After perfusion, ventilation is resumed with 100% oxygen until nitrous oxide is needed to maintain anaesthesia. Usually no more anaesthetic drugs are given; 18 patients spoke as soon as the endotracheal tube was removed, two others gradually returning to full consciousness in two hours. In only one instance was it necessary to reverse residual curarization.

Bronchial secretions have not been increased and aspiration has been unnecessary, but before the end of the operation a Ryle tube is passed through the nose to empty the stomach and is left in place.

Surgical Technique

Approach to the Heart and Great Vessels.—A vertical sternum-splitting incision is made, using a Gigli saw to divide the bone in the midline. The left internal mammary artery is isolated and catheterized with a fine elastic nylon tube for arterial pressure recording. After reflection of the lower pole of the thymus the pericardium is opened vertically in its full extent. Traction sutures hold the pericardium over the edges of the sternum, thus protecting the pleural cavities. A self-retaining retractor spreads the incision. Whilst the heart is being exposed the left common femoral artery is prepared for later cannulation, and through the same incision in the groin the saphenous vein is catheterized for recording pressure in the inferior vena cava.

Examination of the Heart.—Confirmation of the diagnosis is next sought by direct observation of the size of the various cardiac chambers, by palpation of the thrill invariably present, and by measurement of the pressures within the pulmonary artery and the right and left ventricles. A search is also made for any anomaly in the venous return of the heart, particularly for a left superior vena cava, which if present is temporarily occluded. A most thorough search is made for a patent ductus arteriosus, which must be ligated.

Preparations for Cardio-pulmonary Bypass

Half-inch lengths of Paul's tubing are placed around the venae cavae close to their points of entry into the right atrium and are threaded through a rubber tube to form a snare. The ascending aorta is mobilized at a point approximately 2.5 cm. above its origin so that it will later be possible to occlude it by a clamp put across it at this site. Just proximally a purse-string suture of 5/0 silk is placed through the adventitia of the aorta on its anterior aspect. At this stage heparin (3 mg./kg. body weight) is given. A stainless-steel cannula is inserted into the previously prepared site in the common femoral artery, and this is then connected to the arterial line of the pump oxygenator. Each vena cava is cannulated via separate incisions in the wall of the right atrium in the region of the appendage. The tips of the plastic catheters used are positioned to lie approximately 3 cm. beyond the snares, and they are then joined by a Y connexion to a single tube of 1.25 cm. bore which leads to the oxygenator. The caval catheters are of such a size that flow of blood around them to the heart is not obstructed, but they are known to be more than adequate to carry the flow required during bypass. Care is taken to remove all air from arterial and venous pipelines. Elective cardiac arrest (Melrose *et al.*, 1955; Gerbode and Melrose, 1958) is induced in all cases, and the arresting solution (potassium citrate 1 g. in 50 ml. of blood) is made ready at this stage.

Cardiac Bypass and the Intracardiac Procedure

Partial bypass of the heart and lungs is now begun; the clamps previously applied to the arterial and venous pipelines are removed and venous blood flows by gravity into the oxygenator, arterialized blood being returned by the pump into the femoral artery. Stay sutures are inserted into the right ventricle. A few minutes later a partial bypass is made total by tightening and anchoring the snares around the venae cavae; all blood returning to the heart is thus diverted

by the oxygenator, and the heart is seen at once to become much smaller. A small incision is made in the right ventricle between the stay sutures and a low pressure sucker inserted into its cavity; the blood that is aspirated consists of the coronary venous return to the right atrium and the blood returning to the heart from the lungs. Blood sucked in this way is eventually returned to the oxygenator. A needle (18 s.w.g., 8 mm. in length) is next inserted into the lumen of the ascending aorta in the centre of the purse-string stitch, the aorta is then cross-clamped just distally, and the arresting solution injected as rapidly as possible. Within a few seconds cardiac arrest occurs, the needle is withdrawn and the purse-string suture tied to avoid later troublesome bleeding from the puncture site. The ventricular incision is now extended upwards and downwards and the interior of the right ventricle is inspected. The low-pressure sucker is placed in the pulmonary artery after securing a dry field.

The common type of septal defect which lies immediately below the crista supraventricularis can usually be readily identified and adequately displayed for precise closure if traction sutures are inserted at each end of it. The flaccid condition of the arrested heart greatly facilitates the exposure. The defect is closed in two layers by interrupted sutures of silk; care is taken to avoid damage to the leaflets of the aortic valve. When considered necessary for security the second layer of sutures are tied over a small piece of polyvinylformol ("ivalon") sponge. (A very large defect may require insertion of a patch of the same material, as in Case 6.) The rest of the septum is examined for the presence of a second defect, particularly inferiorly in its muscular part. If infundibular narrowing is present sufficient muscle is resected to ensure that there is no

FIG. 6.—Intracardiac pressures in Case 12 before (B) and after (A) closure of the ventricular septal defect. Prior to closure there is a well-marked gradient at the ventricular level. After closure of the defect and infundibular resection the gradient is much reduced. Note also satisfactory fall in pulmonary artery pressure.

obstruction to the outflow tract of the right ventricle (Fig. 6). Distension of the left atrium or left ventricle must be prevented at all costs. If bronchial flow is at all great the infundibulum must be resected before closure of the defect. In the presence of an excessive reflux of blood into the left ventricle through an incompetent aortic valve care is taken to prevent distension of this chamber by direct drainage through the left atrial appendage and mitral valve.

The incision in the right ventricle is next sutured, leaving the closure incomplete centrally where the original stay sutures were inserted. The aortic clamp is released; a coronary blood flow thus begins again and the arresting solution is washed out of the myocardium. The blood that

Fig. 7.—Photograph of boy (Case 16) two weeks after operation, showing the median sternotomy scar. The chest deformity, so common in patients with a ventricular septal defect, is also well seen.

initially wells up through the incompletely sutured ventricular incision is discarded, as it is rich in potassium citrate, but after about 15 seconds the low-pressure sucker is reintroduced into the ventricle and the coronary return collected and passed on to the oxygenator. Within one to three minutes cardiac contractions begin, and, as soon as it is found that the beat is powerful enough to eject blood into the aorta against the pressure maintained in it by the pump, the sucker is withdrawn and suture of the ventricle completed. A short while later the caval snares are released and a partial bypass is re-established. The arterial

inflow from the pump is steadily reduced as the patient's heart resumes full activity and responsibility for the circulation. At this stage intracardiac pressures are measured again and compared with the initial figures in order to confirm correction of the defect.

Closure.—The catheters are withdrawn from the cavae and the atrial incisions repaired. The cannula is also removed from the femoral artery and the incision in its wall carefully repaired. Protamine sulphate (4.5 mg./kg. body weight) is now given in order to restore the clotting mechanism of the blood. Haemostasis is carefully secured before closure of the chest is begun and tubes are placed to drain the pericardial sac and the mediastinum, and if either pleural cavity has been opened this is also drained; all tubes are led through underwater seals and continuous suction is applied.

The Perfusion

The perfusion was without difficulty in all but one of these patients in whom a large patent ductus arteriosus which could not be ligated made perfusion impossible. A patent ductus is a direct route from the aorta to the open heart through the pulmonary vessels, and a high proportion of the blood delivered to the aorta is returned to the machine and fails to perfuse the patient.

A flow rate of 2.4 litres per square metre of body surface was maintained throughout the bypass, which flow allowed but little variation in arterial and venous pressures. The smallest patient received 1.2 litres a minute, the largest 4.3 litres a minute.

The average perfusion was of 39 minutes (30–68 minutes), during which time elective cardiac arrest was maintained for an average of 24 minutes (13–52 minutes).

Venous drainage was obtained by gravity, a difference of 25 cm. (10 in.) being established between the height of the operating table and that of the oxygenator. This differential was always in excess of that required, and on every occasion a screw clamp on the outflow tube had to be partially closed to maintain a normal venous pressure within the great veins. Great care was taken to adjust this clamp accurately, it being felt that such adjustment gives the least possible disturbance to vascular tone and ensures a smooth perfusion.

Return of oxygenated blood into the common femoral artery was always carried out at a line pressure of less than 200 mm. Hg. This pressure, reflecting as it does both the resistance of the cannula and that of the patient's vascular bed, can be used to measure the flow rate from the pump. As the mean pressure in the aorta is known, then the pressure created by the cannula can be determined. Previous calibration of each cannula enables an accurate measurement of flow rate to be obtained from this pressure measurement.

Oxygenation was always adequate, as was carbon dioxide removal. At no time was the rotational speed of the oxygenator excessive, and usually it was below 50 revolutions a minute. Heat loss from the oxygenator was prevented by radiant-heat lamps and the body temperature maintained within 1° C.

Removal of blood from the open heart was never a problem, cross-clamping the aorta producing an almost dry field. Blood contained in the heart at any time was removed by gentle suction and stored in a settling helix before return to the heart-lung machine. An additional high-vacuum suction was available, but blood recovered in this manner was rarely re-used. The pressure in the superior and inferior venae cavae as well as intra-aortic pressure was continuously displayed and recorded. Both the electrocardiogram and the electroencephalogram were similarly monitored.

Post-operative Care

At the conclusion of the operation the patient is carefully lifted from the operating table on to a weighing machine. After allowance for drainage-tubes and dressings his weight is compared with the pre-operative figure. The difference in weight forms a useful check on blood and fluid balance derived from swab-weighing and measurement during the operation. The patient is placed on his bed in the operating theatre and transferred to the recovery ward. An oxygen tent, adequately cooled and humidified, is placed around the head of the patient, and tubes are reconnected to drainage bottles and continuous suction at 3 cm. of Hg vacuum.

A clear record is kept, on which blood transfusion is shown balanced against drainage from pleural and pericardial cavities, and watery fluids infused are balanced against urinary output and gastric aspirations. It is our practice to limit fluid for the first 24 hours to avoid gastric distension. The Ryle tube is aspirated intermittently for the first 24 hours, should nausea or gastric distension warrant it.

Intravenously dextrose 5% with sodium chloride 0.3% is given, 400 ml. per square metre of surface area during the first 24 hours and 800 ml. per square metre during the second 24 hours. Thereafter normal diet is quite rapidly resumed.

During the first 24 hours pulse and blood pressure are charted at 15-minute intervals and the patient is turned and encouraged to cough and breathe deeply. It is found useful to introduce the younger child to an oxygen tent pre-operatively so that his post-operative surroundings are not too unfamiliar. Parents are invited to visit the children as soon as they are in the recovery ward and every few hours thereafter.

Post-operative Drugs. If the patient has been already digitalized pre-operatively this is continued. Otherwise

digitalis is withheld unless the pulse rate is unduly rapid or the jugular venous pressure high. If heart block is present isoprenaline is administered as a suppository (2.5 mg.) should the heart rate fall below a figure at which a satisfactory blood pressure can be maintained. The precise figure cannot be stated, as the age and condition of the patient is the determining factor. In the two patients in this series who required this drug its use was continued at lengthening intervals from five-hourly for the first 48 hours. Antibiotics, consisting of penicillin, streptomycin, and chloramphenicol, are used prophylactically for the first four days. Some patients received erythromycin and novobiocin, but these drugs were not well tolerated.

Convalescence.—The patients were allowed up at the end of a week and were usually discharged from hospital at the end of three weeks. A number of patients had a rise in jugular venous pressure during the first week post-operatively, but this fell gradually during the last ten days in hospital. These children tend to be extremely active during the last week and can make a marked contrast with the pre-operative picture.

Post-operative Complications

Chest haemorrhage was a problem in only two patients. In all cases the clotting mechanism has been rapidly restored to normal; the platelets have been reduced at the end of the perfusion to an average of 60,000 c.mm., but the figure rises to normal early in the post-operative period. The usual blood loss has been less than 500 ml. In two patients the loss was over 1 litre and probably contributed to their death. Both were patients in whom a fall in pulmonary artery pressure had not been obtained, so that pressures on the right side of the heart were unusually high. It is possible that bleeding may have occurred from manometric puncture sites or the cardiac wounds.

Pulmonary Complications.—Coughing and deep breathing is not easy during the first few post-operative days, though we believe it is less difficult if the midline sternum splitting incision is used. In several of our cases expectoration of sputum has been a problem, but in only one instance was a tracheostomy required. The left lower lobe requires an especially careful watch as it is somewhat displaced by the enlarged heart, and the left main bronchus is often narrowed by the large pulmonary artery. Pulmonary oedema has not been encountered.

Infection.—Localized wound infection occurred in two patients, but in no instance was there any suggestion of infection of the blood stream.

Heart-block.—Transient heart-block has occurred in several patients during the period immediately following re-establishment of the heart-beat. Complete heart-block persisted in two patients, in one of whom the idioventricular rate was too low to support an adequate blood pressure even after intravenous isoprenaline in repeated doses of 0.1 mg. The artificial pacemaker connected directly to the ventricle maintained a satisfactory rate and blood pressure until the child's sudden death 10 hours post-operatively (Case 9). In the other patient the use of isoprenaline was satisfactory.

Surgical Pathology

Septal Defect.—In all patients the right ventricle was grossly enlarged, with a well-marked thrill best felt over the outflow tract and the base of the pulmonary artery. The right atrium was normal in size in all cases except one; in this latter instance the jet of blood passing through the defect was blowing the septal cusp of the tricuspid valve back into the atrium, producing tricuspid incompetence (Case 13). In all our patients the defect was located high up on the septum but inferior to the crista supraventricularis: the upper margin of this defect was formed by the annulus of the aortic valve, with the right and posterior aortic leaflet visible immediately beyond the rim. The lower margin of the defect was formed by the muscular interventricular septum, but often had a well-developed fibrous rim. One

patient (Case 9) had in addition a second defect in the muscular septum, and in Case 6 there was a single ventricular chamber. Excluding this last case, the size of the defect varied from 1 to 3.5 cm. in diameter.

Coexistent Patent Ductus Arteriosus.—In our first patient a patent ductus was not suspected until perfusion was started and a shunt from the systemic circulation into the pulmonary artery was encountered. Perfusion proceeded normally after ligating the duct. In all subsequent patients the left pulmonary artery was deliberately explored from inside the pericardium in order to exclude the presence of a ductus, and in this way two further undiagnosed ducts were discovered. One of these was successfully ligated, but the other, a thin-walled friable ductus 2.5 cm. in diameter, tore during mobilization and led to death (Case 15). The ductus diagnosed by aortography (Case 20) was ligated without difficulty.

Infundibular Obstruction.—This was present to some degree in nine of the cases. In all cases the obstruction was due to an irregular but generalized hypertrophy of the muscle of the outflow tract and the crista supraventricularis which appeared to be part of the generalized right ventricular hypertrophy. As much infundibular muscle was removed as was necessary to relieve the obstruction, and post-operative manometry rarely revealed a gradient or more than 10 mm. Hg.

Results

Mortality

Of the 15 patients with a ventricular defect as the sole lesion only one died. Among the four patients with an additional patent ductus, two died. A patient with two defects also died, but one with a single ventricle survived.

As previously mentioned, one of the deaths occurred on the table when it was found impossible to ligate a large ductus. The other three occurred between 5 and 36 hours after operation, and were of a similar pattern with sudden cessation of respiration after a period of restlessness and low blood pressure. None of these patients had more than a slight fall in pulmonary artery pressure after closure of the defect, and it seems possible that death was due to abrupt right ventricular failure. Two of these three had a moderate-to-large haemothorax, one of which was treated by open operation.

Reduction in Right Heart Pressures with Closure

We consider that a substantial fall in right ventricular and pulmonary artery pressure after closure of the defect is an important sign, since it indicates that much of the pulmonary hypertension was due to flow rather than to changes in the pulmonary vessels and therefore that the long-term results from closure of the defect are likely to be good. It also indicates that the defect is substantially closed and that no other lesion causing a further left-to-right shunt—such as a second V.S.D.—is present. In order to take account of changes in systemic pressure after closure we have expressed the right ventricular systolic pressure as a percentage of the left (R.V.P./L.V.P.%), and these pressures have been measured at operation in all cases. Prior to closure, R.V.P./L.V.P. ranged from 37 to 100%, with an average of 67%.

After closure of the defect the right ventricular pressure fell in 16 patients and was unchanged in 4. The extent of the fall has been expressed as R.V.P./L.V.P.% before closure minus R.V.P./L.V.P.% after closure—for example, before 100%, after 63%, fall=37%. The fall in pressure averaged 33%, with a range of 8 to 58%. Details are available in Tables I and II. A small fall in pressure does not imply a poor result if the initial pressure, as in Cases 2 and 4, is low, but otherwise it presumably indicates that considerable pulmonary vascular disease is present.

In the whole group of 20 patients whose defects were closed the R.V.P./L.V.P.% after closure was close to normal in five, slightly elevated in eight, moderately raised in three, and high in four.

TABLE II.—Operative Findings, Anatomical and Haemodynamic

Case No.	Size of Defect (cm.)	Infundibular Hypertrophy	Infundibular Gradient, mm.Hg		R.V.P. %* L.V.P.

Post-operative Assessment

On discharge from hospital three to six weeks after operation all the patients were active and well. The exercise tolerance was improved in most patients. This was particularly obvious in a boy of 2½ years with a huge left-to-right shunt (Case 2), who from being unable to walk more than 20 yards was able to run vigorously without distress. In one patient (Case 7) who had a very small shunt with a high resistance, and no fall in right heart pressures after closure, there was but little improvement.

The jugular venous pressure and pulse were normal in all except the patient with a single ventricle in whom a high venous pressure persisted for several weeks. The arterial pulse sometimes retained its waterhammer quality and one patient still had complete heart-block, with a rate of 90. The cardiac impulses were usually less marked after operation, but the diminution in right ventricular heave depended on the fall in right ventricular pressure obtained.

The most striking change in physical signs was, however, found on auscultation. The thrill and murmur of the ventricular defect disappeared in all patients (Fig. 1B), and in only two instances did a mitral diastolic murmur persist. In these two patients the defect appeared on other grounds to be closed, and the murmur is attributed to mild congenital mitral stenosis; one of these was the patient with a single ventricle who also had a loud apical systolic murmur possibly due to mitral incompetence. Soft or moderate ejection systolic murmurs at the left sternal edge were quite common post-operatively and probably originated in the infundibulum or pulmonary artery; they were sometimes best heard near the apex. A basal diastolic murmur persisted in four. The second heart sound remained loud and closely split in Case 7, who still had substantial pulmonary hypertension after closure, but otherwise was usually softer and was sometimes widely split from right bundle-branch block.

The electrocardiogram in most cases showed a constant and unusual pattern. There was complete right bundle-branch block with the secondary R wave persisting as far as V5-V6 together with striking T-wave inversion in all chest leads. These appearances were presumably due to the intracardiac manoeuvre and the ventriculotomy (Fig. 5).

Radiological assessment is probably not very profitable so soon after surgery, but in one case there was considerable diminution in heart size, and others have shown a definite reduction in pulmonary plethora.

Indicator dye-dilution curves performed on two patients post-operatively (Cases 5 and 6) have demonstrated the absence of a left-to-right shunt. Cardiac catheterization is being deferred until a year or more after closure of the defect.

Conclusions

Our results harmonize with those of other workers in showing that closure of ventricular septal defects can be carried out in special centres as a routine surgical procedure with an acceptably low mortality in suitable cases. The indications and contraindications to operations have been outlined, but in assessing cases for operation we have experienced two main problems: first, the detection of additional lesions; and, second, in predicting whether a good haemodynamic response will result from closure.

The most important additional defect is a patent ductus, for it renders perfusion impossible. As already mentioned, this lesion was definitely diagnosed (by aortography) in only one of our four patients with it, though it was queried in one other. We suspect the diagnostic difficulty may lie in the fact that in patients with a V.S.D. the duct is virtually functionless and therefore gives rise to practically no direct signs. Support for this hypothesis is given by the absence of a thrill over the ductus at operation in three of the four patients and by the findings in Case 20. In this last patient, prior to aortography, 2 ml. of indicator dye was injected into the aorta via a retrograde arterial catheter, and no recirculation due to dye entering the pulmonary artery (Swan and Wood, 1957) was found. Further, at operation, no change in right heart or systemic pressure was noted when the duct was ligated. One patient (Case 21) was found at operation to have severe aortic incompetence, and clinically this was not diagnosed with certainty.

The other problem is that of predicting which patients will achieve a substantial fall in pulmonary artery pressure after closure. In this respect, other workers (Zimmerman *et al.*, 1957) have emphasized the importance of the actual level of the pulmonary artery pressure, but in our series this has not been helpful. We believe that the pressure must be considered in relation to pulmonary flow and that it is useful to calculate the pulmonary arteriolar resistance. However, the difficulty in young children of measuring the oxygen consumption, and also other factors, make the calculated resistance in many cases at best an approximation. It may turn out to be just as helpful to consider simply the oxygen saturation in the pulmonary artery, which has been over 80% in all our patients whose pulmonary pressure fell after closure. As mentioned earlier, it is necessary to consider all aspects in deciding for or against operation in the borderline cases with a high pulmonary resistance. No patient should be categorically denied operation if there is evidence of an appreciable left-to-right shunt, but when the pulmonary resistance is high and the unfavourable features already mentioned are present, a much higher operative mortality must be faced. It is clear from our results, however, that a number of patients who might in other centres be considered inoperable have had their defects successfully closed.

It must be emphasized that, in such a rapidly expanding field, views necessarily change fast as a result of new experience. Firm rules should not therefore be formulated until opinion has crystallized in the light of further knowledge of the problems involved.

Summary

Twenty-one patients with ventricular septal defect have been treated by open surgery using extracorporeal circulation.

The clinical features, indications for operation, surgical technique, and post-operative care are presented.

The results of surgical treatment are given and the implications of these are discussed.

We are indebted to Dr. R. E. Bonham-Carter, not only for referring many of these patients, but also for his continued encouragement and support; to Dr. J. D. James and Dr. P. B. Booth and the staff of the North London Blood Transfusion Service for their unfailing co-operation; to Professor J. V. Dacie and his colleagues in the department of haematology in the Postgraduate Medical School of London; and to the matron and nursing staff of Hammersmith Hospital. To Mr. J. R. Robson, Mr. E. Gains, Miss M. Murphy, and Mrs. E. Victor, the technical staff of the department of surgery, and to Mr. C. Lordon and the staff of the workshops of the Postgraduate Medical School we owe a special debt of gratitude.

Mr. Z. F. Kellerman and the staff of Messrs. New Electronic Products Ltd. have since 1950 given generously of their services and have unhesitatingly met the technical challenge.

To the Nuffield Foundation we are particularly indebted; they, by financial assistance, not only ensured the development of the apparatus but also its clinical success by their support to the project as a whole.

Natural Causes, a new play on a challenging theme by Mrs. Vera Colebrook, was given a number of performances in London last month at the Hovenden Theatre Club. The action of the play takes place in the country house of an old lady who has just suffered a cerebral haemorrhage, complicated by the onset of pneumonia. Her family doctor had previously given her a solemn promise that should she fall seriously ill he will not administer any antibiotic or other drug that may prolong her life—or, rather, “prolong her death.” On the insistence of her daughter-in-law, a well-known London consultant is called in: he advises injections of penicillin. The family doctor refuses to give these, telling the consultant of his promise and insisting that there is all the difference in the world between administering a lethal dose and withholding a life-saving drug. The old lady's two children want their mother to die as she had lived, with dignity and without fear of mental deterioration. But her shrewish daughter-in-law desires only that her mother-in-law's life might be prolonged for the sake of the benefits her annuity brings to the family. The Hovenden Players, directed by Miss Valery Hovenden, were completely successful in bringing out the realism of this situation. A philosophical nurse—who assumes a more pronounced Irish brogue with private cases, because “it goes down so lovely with the patients”—adds a touch of humour to the play, which is not concerned with “mercy killing” but rather with the truth or otherwise of Clough's “Thou shalt not kill, but needst not strive officiously to keep alive.” The whole vexed problem, while remaining unsolved, is given an unexpected twist by the London consultant at the end of the play.

STAPHYLOCOCCAL INFECTION RESISTANT TO CHLORAMPHENICOL, ERYTHROMYCIN, AND NOVOBIOCIN EFFECT OF ANTIBIOTIC COMBINATIONS ON THE EMERGENCE OF RESISTANT STRAINS

BY

MARY BARBER, M.D.

A. J. MEDWAY, A.I.M.L.T.

Senior Technician

From the Department of Bacteriology, Postgraduate Medical School of London, Hammersmith

Control of the use of antibiotics in hospital communities is imperative if we are to combat the adaptability of the staphylococcus to these agents. Until recently most hospitals in Great Britain have tried to keep erythromycin and novobiocin in reserve, to be used only for the treatment of staphylococcal infection resistant to all other antibiotics. By 1957, however, about 50% of all staphylococcal infection occurring in many hospitals was found to be resistant to penicillin, streptomycin, and tetracycline, so that erythromycin and novobiocin inevitably had to be used more extensively.

The danger of the increased use of these two drugs is obvious, since it is well recognized that staphylococci develop resistance to erythromycin and novobiocin more readily than to any other antibiotic except streptomycin (cf. Hobson, 1954; Garrod and Waterworth, 1956; Lin and Coriell, 1957). Moreover, this change occurs quite often during the treatment of staphylococcal infections with erythromycin (Thomson *et al.*, 1956) and novobiocin (Nichols and Finland, 1956), and the spread of erythromycin-resistant strains in a hospital where the use of this antibiotic is extensive may be very rapid (Lepper *et al.*, 1954).

In an attempt to combat this situation a policy for the control of antibiotics was introduced into this hospital at the beginning of April, 1958. The essential items of the policy were: firstly, abandonment of penicillin except in certain wards of the hospital, and, secondly, the use of two antibiotics in combination wherever possible and always when erythromycin or novobiocin was used.

About six months previously a cross-infection committee was appointed to investigate staphylococcal infection in the hospital and to introduce measures for its control. The effect of these measures and that of the antibiotic policy are inextricably confused. Nevertheless analysis of the antibiotic sensitivity pattern of all staphylococcal infections in the hospital throughout the year has brought to light certain facts about the emergence of erythromycin- and chloramphenicol-resistant strains which are considered worth reporting.

*In receipt of a grant from the Medical Research Council.

Bacteriological Methods

All staphylococcal infections in the wards of the hospital between October 1, 1957, and September 30, 1958, were studied bacteriologically. The period covered thus included six months before the introduction of the antibiotic policy and the first six months of its operation. The strains of *Staph. pyogenes* isolated were tested for sensitivity to penicillin, streptomycin, tetracycline, chloramphenicol, erythromycin, and novobiocin by the ditch-plate method. The concentration of antibiotics used in the ditch was: penicillin, 10 units per ml.; streptomycin, 50 or 200 g. per ml.; chloramphenicol, 50 g. per ml.; and tetracycline, erythromycin, and novobiocin 25 g. per ml. The Oxford staphylococcus was streaked across the centre of each plate as a control.

Strains were recorded as sensitive if they showed a degree of sensitivity similar to that of the Oxford staphylococcus, resistant if they grew up to or across the ditch, and partially resistant if there was an intermediate degree of inhibition. Representative strains were also tested by a serial dilution method in broth. The latter tests showed that strains recorded as partially resistant were often only two to four times less sensitive than the standard organism, but strains recorded as resistant always showed a more than eightfold difference.

Most of the strains on first isolation and those showing a change in sensitivity pattern were phage-typed by the method of Williams and Rippon (1952) using 21 phages.

Antibiotic Administration

After the introduction of the antibiotic policy in April, 1958, the use of drug combinations caused an increase in the consumption of most of the antistaphylococcal antibiotics except penicillin. The approximate changes were as follows: Penicillin, $\div 3.2$; tetracycline, $\times 1.4$; chloramphenicol, $\times 1.6$; erythromycin, $\times 2$; novobiocin, $\times >5$.

In the six months following the introduction of the antibiotic policy 284 patients were treated with chloramphenicol, 275 with erythromycin, and 170 with novobiocin. The most frequently used combinations were erythromycin and novobiocin (108 patients) and erythromycin and chloramphenicol (69 patients). Further details of the use of these three antibiotics are given in Table I. Similar figures are not available for the period before the antibiotic policy.

TABLE I.—Number of Patients Treated with Chloramphenicol, Erythromycin, and Novobiocin, April 1–September 30, 1958

	Total	In Combination with				Alone*
		Chlor.	Eyth.	Novo.	Other Antibs.	
Chloramphenicol	284	—	69	8	70	137
Erythromycin	275	69	—	108	45	53
Novobiocin	170	8	108	—	25	29

* Or in combination with a sulphonamide preparation.

Analysis of Sensitivity Patterns

A total of 982 staphylococcal infections were present in the hospital during the year. Antibiotic sensitivity has been analysed separately for each quarter, and the results are presented in the Chart. The total numbers of staphylococcal infections in each quarter were respectively 247, 245, 270, and 220.

It will be seen that the incidence of infection resistant to penicillin fell from 80% at the beginning of the year to 60% at the end. This is associated with a corresponding fall in the incidence of tetracycline-resistant infections (from 55% to 27%), practically all of which were also resistant to penicillin and which were in most instances the result of cross-infection in the hospital. The percentage of infections resistant to penicillin and sensitive to tetracycline rose slightly in the second quarter and thereafter remained steady.

In the first quarter of the year the incidence of staphylococcal infection resistant to penicillin and tetracycline was 46 per 1,000 admissions to the hospital. The cross-infection committee appointed at the beginning of the investigation recommended a number of measures for the control of cross-infection which were put into operation throughout the year. Probably as a result of these, although seasonal influences cannot be excluded, the corresponding figures for the remaining three quarters of the year were respectively 33, 32.7, and 20. The fall in the percentage of staphylococcal infections in the hospital that were resistant to penicillin and tetracycline is almost certainly a reflection of this. It is probably too early for the antibiotic policy introduced in the middle of the investigation to have had much effect on the incidence of penicillin-resistant infection.

The percentage of infections resistant to chloramphenicol, erythromycin, and novobiocin remained low throughout the year. Since, however, nearly all these infections were also resistant to penicillin, streptomycin, and tetracycline, their importance cannot be exaggerated. The figures for erythromycin in each quarter were respectively 4.8, 2.8, 4.0, and 6.4, and the significance of the slight rise in the last quarter is increased by the accompanying fall in the incidence of multiple resistant infection as a whole.

Chloramphenicol-resistant Infection

The incidence and source of chloramphenicol-resistant infection are summarized in Table II. In the whole year there were 30 infections resistant to this antibiotic, and on

TABLE II.—Chloramphenicol-resistant Infections

	Total No. of Infections	No. of Strains of <i>Staph. pyogenes</i>	No. of Strains also Resistant to Erythromycin

Other strains	8	1
	23	8

All strains were resistant to penicillin, streptomycin, and tetracycline except those isolated on admission. All strains were sensitive to novobiocin and vancomycin.

the basis of bacteriophage typing it was shown that the 30 infections were probably caused by 23 strains of *Staph. pyogenes*. Three of the strains showed partial resistance and 20 were recorded as resistant. It will be seen that there is no significant difference in the figures before and after introduction of the new antibiotic policy.

Of the 23 strains involved, three were isolated from patients on admission. The remaining 20 were all resistant to penicillin, streptomycin, and tetracycline, as well as to chloramphenicol, and seven, together with one strain isolated on admission, were also resistant to erythromycin. In six instances strains of the same phage-type were isolated on two occasions from the same patient, the first being chloramphenicol-sensitive and the second chloramphenicol-resistant, and three of these strains developed resistance to erythromycin at the same time. Five of the six patients from whom these strains were isolated had been treated with chloramphenicol and erythromycin, and one with erythromycin but not chloramphenicol.

In 14 cases the only staphylococcus isolated was chloramphenicol-resistant. Five of the patients from whom these strains were isolated had previously had chloramphenicol and one erythromycin. The remaining eight strains were isolated from patients who gave no history of recent antibiotic treatment.

Erythromycin-resistant Infection

Table III summarizes the information in relation to erythromycin-resistant infection. In the whole year 23 strains of *Staph. pyogenes* resistant to this antibiotic were responsible for 44 infections. In the first half of the year eight strains caused 19 infections, whereas in the first six

All strains were resistant to penicillin, streptomycin, and tetracycline except those isolated on admission. All strains were sensitive to novobiocin and vancomycin.

months of the antibiotic policy 15 strains caused 25 infections. Two of the 23 erythromycin-resistant strains were recorded as partially resistant and 21 as resistant. It was noted, however, that many strains which were resistant on primary isolation became less resistant after subculture in the laboratory. Thirteen of the strains were tested against spiramycin: three were as sensitive as the Oxford staphylococcus, four showed a twofold, and six a fourfold increase in resistance to this antibiotic.

Three of the strains were present in patients on admission. The remaining 20 were all resistant to penicillin, streptomycin, and tetracycline, as well as to erythromycin, and eight were also resistant to chloramphenicol. In seven cases erythromycin-sensitive and erythromycin-resistant strains of the same phage-type were isolated consecutively from the same patient, and three of the strains showed a corresponding increase in resistance to chloramphenicol.

All seven patients had been treated with erythromycin—four in combination with chloramphenicol and three alone or in combination with tetracycline, to which the initial strain was not sensitive.

In 13 instances the only strain of *Staph. pyogenes* isolated was erythromycin-resistant. Ten of the patients concerned had previously had antibiotic treatment: three with erythromycin alone or plus tetracycline; four with erythromycin and chloramphenicol; and three with chloramphenicol but not erythromycin. The remaining three strains were isolated from patients who had not had recent treatment with antibiotics.

TABLE IV.—Novobiocin-resistant Infections

Source of Novobiocin-resistant Strains

Novobiocin-sensitive strain developed resistance to novobiocin during treatment with:		
Novobiocin alone	1	1
Novobiocin plus erythromycin	2	1
Other strains	1	1
	4	4

Three strains were resistant to penicillin, streptomycin, and tetracycline; and sensitive to chloramphenicol, erythromycin, and vancomycin. One strain was sensitive to penicillin, streptomycin, tetracycline, chloramphenicol, erythromycin, and vancomycin.

Novobiocin-resistant Infection

Throughout the year only four strains of *Staph. pyogenes* resistant to novobiocin were isolated (see Table IV), two in each half. Three of the strains were each isolated from only one infection. The fourth strain was responsible for infections in four children and two nurses in the same ward.

Three of the strains were also resistant to penicillin, streptomycin, and tetracycline, and sensitive to chloramphenicol, erythromycin, and vancomycin. One strain which developed resistance during novobiocin treatment was sensitive to all other antibiotics tested. The source of the strain which caused six infections is completely unknown. The remaining three strains all developed resistance during treatment with novobiocin, in two cases given in combination with erythromycin and in one case given alone.

Association of Chloramphenicol and Erythromycin Resistance

A number of observations in this study indicate an association between chloramphenicol and erythromycin resistance. Thus eight of the erythromycin-resistant strains were isolated from patients who had previously had erythromycin and chloramphenicol. In no instance, on the other hand, was an erythromycin-resistant staphylococcus isolated from a patient treated with erythromycin and novobiocin, in spite of the fact that after the introduction of the antibiotic policy 108 patients were treated with the latter combination and only 69 with erythromycin and chloramphenicol.

No fewer than 8 of the 23 erythromycin-resistant strains also showed resistance to chloramphenicol. In three cases strains of the same phage-type were isolated on two occasions from the same patient, the first being sensitive to both these antibiotics, and the second resistant. Two of the patients concerned had been treated with chloramphenicol and erythromycin, and one with erythromycin only. Three other strains showing this double resistance came from patients who had recently had antibiotic treatment, one with both the antibiotics concerned, one with erythromycin, and one with chloramphenicol.

With two strains, both of which were responsible for small outbreaks of infection (reported elsewhere; cf. Barber and Dutton, 1958), the resistance to chloramphenicol was inconstant. Thus strains resistant to penicillin, tetracycline, and erythromycin of a single phage-type infected several patients in one ward, and some of the cultures isolated were grossly resistant to chloramphenicol, whereas others were as sensitive as the Oxford staphylococcus. In one case the initial patient had been treated with erythromycin only, and in the other the patient had had a number of antibiotics, including chloramphenicol, but had never had erythromycin.

It seems probable from these observations that there is some cross-resistance between erythromycin and chloramphenicol, and preliminary studies *in vitro* have shown this to be the case. The investigation will be published in full elsewhere (Csillag and Barber), but it has already been found that strains of *Staph. pyogenes* rendered resistant to erythromycin by passage in this antibiotic develop a moderate and sometimes transitory increase in resistance to chloramphenicol.

Discussion

This investigation emphasizes the danger of erythromycin-resistant infection becoming a hospital problem if the unrestricted use of erythromycin is permitted. Since there is evidence of cross-resistance between erythromycin and chloramphenicol, combined treatment with these two antibiotics offers no solution. Monnier and Schoenbach (1951) and Fusillo, Romansky, and Kuhns (1953) demonstrated a similar increase in resistance to chloramphenicol when staphylococci were passaged in the presence of tetracycline compounds. A study of cross-resistance with chloramphenicol and other antibiotics is now in progress.

Combined treatment with erythromycin and novobiocin seems more promising. Lowbury (1957) showed that the combination of these two antibiotics delayed the emergence of erythromycin-resistant staphylococci *in vitro* and *in vivo*. In the investigation here recorded no erythromycin-resistant staphylococci were isolated from 108 patients treated in this way. This number is, of course, small, and it is too early to say whether this combination will do more than postpone the evil day; but even this is of value, since it might tide us over until new antibiotics were available.

Scott and Waterworth (1958) treated 110 patients suffering from boils with a seven-day course of erythromycin (55 patients) or E 129 (55 patients) and found no instance of increased bacterial resistance to either antibiotic. Coagulase-positive staphylococci were, however, isolated from only 15 of the original boils after treatment, although a further 23 strains, which were isolated from fresh lesions developing during or after treatment, were also found to be erythromycin-sensitive.

The *British Medical Journal* (1958) asked whether the determining factor in the development of resistance to erythromycin was "the nature of the lesion, dosage, or duration of treatment, or a property of the staphylococcus itself." In the present series length of treatment was not necessarily prolonged, and some of the patients had been treated with erythromycin for only a few days before the appearance of erythromycin-resistant staphylococci. With regard to the lesions, however, although one strain came from a boil treated with erythromycin alone, most of the strains came from more severe infections such as pneumonia, lung abscess, peritonitis, or post-operative sepsis.

The type of staphylococcus concerned is probably of considerable importance. In the present series nearly all the strains showed multiple resistance to antibiotics, and it has been suggested that such strains may be highly mutagenic (Treffers *et al.*, 1954; Barber and Dutton, 1958). All the erythromycin-resistant strains were also shown to belong to phage groups III except for a few strains of type 80. It has been shown that group III staphylococci yield antibiotic-resistant variants more readily than do other strains (Barber and Whitehead, 1949; Rountree and

Thomson, 1949; Barbour and Edwards, 1953), and the same may well be true of phage-type 80 staphylococci, which have recently become a hospital menace (Rountree and Freeman, 1955; Anderson and Williams, 1956; Gillespie and Alder, 1957; Duthie, 1957).

While staphylococci of such virulence and adaptability continue to circulate in hospital communities it is important that the use of erythromycin should remain under strict control. Although novobiocin, vancomycin, ristocetin, and kanamycin have been added to our antistaphylococcal armory, the last three have serious toxic effects, particularly on the eighth nerve. Since novobiocin, like erythromycin, has the defect that staphylococci readily become resistant to it, both should be used sparingly, and neither except in combination with each other or another chemotherapeutic agent.

Summary

A policy whereby antistaphylococcal antibiotics were used only in combination was introduced into a large general hospital.

The antibiotic sensitivity of all strains of *Staph. pyogenes* isolated from infections in the hospital was studied during a period lasting six months before the introduction of this policy and six months afterwards.

Analysis of erythromycin- and chloramphenicol-resistant infection has shown evidence of cross-resistance between these two antibiotics. Of 23 erythromycin-resistant strains, 11 came from patients who had been treated with chloramphenicol (in eight cases in combination with erythromycin and in three cases without). Moreover, eight of the erythromycin-resistant strains also showed resistance to chloramphenicol, although in two cases the patient had been treated with erythromycin but not chloramphenicol.

No such cross-resistance was noted between erythromycin and novobiocin, and of 108 patients treated with this combination none yielded a staphylococcus resistant to erythromycin, although in two instances strains resistant to novobiocin were isolated.

It is a pleasure to thank the many clinical colleagues who co-operated in this investigation and, in particular, Dr. Peter Elmes, without whose energy and enthusiasm the work would not have been possible. Our thanks are also due to Eli Lilly and Company for free supplies of erythromycin ("ilotycin").

NEPHRITIS IN NORTH YORKSHIRE

BY

J. T. A. GEORGE, M.D., D.P.H.

Deputy County Medical Officer, North Riding of Yorkshire

J. C. McDONALD, M.D., D.P.H., D.I.H.

Epidemiological Research Laboratory, Colindale

D. J. H. PAYNE, M.B., B.S., Dip.Bact.

Public Health Laboratory, Northallerton

AND

D. A. SLADE, M.R.C.S., L.R.C.P.

Pathologist, York County Hospital

Outbreaks of acute glomerulonephritis have been reported, associated in recent years with *Streptococcus pyogenes* type 12 and sometimes with other types (Rammelkamp, 1954). As the potentially epidemic nature of nephritis may still not be generally recognized, some events in northern Yorkshire during the past 18 months are recorded.

Present Investigation

On March 25, 1957, it was learnt that during the last fortnight in January there had been 24 cases of acute pharyngitis among 56 boys in a residential school for the educationally subnormal, followed 10-19 days later by acute nephritis in four of them and suspected rheumatic fever in a fifth. On February 15 all the children were given oral penicillin, and this was continued for three days. The school, which was situated in a small and rather isolated village, was visited on March 26, and nose and throat swabs and urine specimens were obtained from the 24 children who had been ill. *Str. pyogenes* type 12 was isolated from seven; the urine of three of the four who had had nephritis still contained blood cells in moderate numbers, and that of the fourth was clear; red cells were also present in the urine of five other children, two of these specimens also showing casts.

In order to ascertain the extent and effect in the community of the type 12 infection, the small local primary school (school A), a quarter of a mile (400 m.) away, was visited on March 31 and specimens were obtained from the pupils. It was clear from the results (see Table), and from the fact that a clinical case of nephritis was found, that the outbreak was not limited to the residential school. Six primary schools in villages within a 5-mile (8-km.) radius were therefore visited during the next few days, and evidence of type 12 infection was found in three of them (B, C, and D). The Table shows that 11 streptococcal strains isolated from school C were of a degraded type. Dr. R. E. O. Williams, of the Streptococcal Reference Laboratory, who was responsible for the typing of all the strains

Incidence of *Str. pyogenes* Type 12, Acute Nephritis, and Symptomless Urine Abnormalities in Pupils Attending Certain Schools in March-April, 1957

School	Exam-ined	No. of Pupils			Showing Symptomless Urine Abnormalities

A*	26	14 (54%)	1		11	4
B	34	16 (47%)	0		6	0
C	48	11 (23%)	0		13	2
D		(degraded)				
E	38	3 (8%)	0		0	0
F	18	0 (—)	0		0	0
Secondary	570	32 (6%)	0		Not tested	
Form 1B	32	9 (28%)	0		3	0

* In the same village as the residential school.

mentioned in this report, found that these strains belonged to a type related to 12, but he could not be certain whether they were derived from type 12 strains. The strains isolated from the other schools were typed without difficulty. Urine was obtained from the children in the four positive schools (A, B, C, and D), and in one negative school (E). Red blood cells were seen in 31 of the 146 specimens from the positive schools but not in 18 specimens from the negative school. Only one of these children had symptoms of nephritis—the case in school A already mentioned.

Children over the age of 11 years from the affected villages attended a large bilateral secondary school 7 miles (11 km.) away from the centre of the original outbreak. In order to assess the extent to which infection had been carried into an unaffected locality by the older children, it was decided to investigate children at this school. Throat and nose swabs were taken from the whole school early in April and urine specimens were examined from children in the form (1B) showing the highest proportion of type 12 strains. The number of red cells found in the urinary deposits of children from the different schools ranged from 1 to 50 per high-power field; as there was no standard of normality with which to compare these findings, urine samples were obtained from 287 children of similar age in two schools 20 miles (32 km.) away from the affected area. No red cells or casts were found in any of them.

No further cases of nephritis came to our notice until December, 1957, when three occurred in the Northallerton District, some 25 miles (40 km.) north of the original outbreak. Further cases occurred in the York City and Northallerton areas during January and February, 1958, so at the beginning of March circular letters from the county medical officer and from the pathologist in York were sent to all doctors in York and the North Riding warning them of the situation and asking for information on cases of nephritis. During the first six months of 1958, 27 cases were unofficially notified in and around York City, and a further 18 in or near Northallerton. In York, 25 of the 27 cases were admitted to hospital and two were treated at home. Four of the hospital cases were admitted to surgical wards—three adults for investigation of haematuria and one child as an abdominal emergency. All 27 patients were examined bacteriologically, but mostly some time after onset and many had already received antibiotic treatment; *Str. pyogenes* type 12 was isolated from nine cases and type 22 from another. In Northallerton, 15 of the 21 cases were admitted to hospital and six treated at home. Throat swabs were taken from 14 cases; eight yielded *Str. pyogenes* type 12 and one a group B streptococcus. One patient, although having a negative swab, had antibodies to *Str. pyogenes* type 12 in her blood, and another, also with a negative swab, had a sibling from whom a type 12 strain was isolated.

We are thus aware of 53 cases of frank acute nephritis in York or the North Riding during the past two winters—5 in the first winter and 48 in the second. *Str. pyogenes* type 12 was isolated from 19 of them, and many of the remainder were either not swabbed or not swabbed at a suitable time. In addition, 38 children in schools were found to have red cells in the urine but no symptoms of nephritis; *Str. pyogenes* type 12, or a related type, was isolated from 19 of these. All but four of the cases of nephritis had a history of sore throat or otitis media, and so did most of those with haematuria but no clinical illness. In some cases, however, the initial infection was not severe enough for the patient to seek medical advice. No cases followed scarlet fever.

There was no evidence that the infection was transmitted except by direct contact. The sexes were equally affected, and the commonest age group was 5-15 years, which was the group most fully investigated. Nevertheless adult cases of nephritis occurred in both sexes, the oldest being a woman of 37 and a man of 44. The average period between infection and the onset of nephritis in those giving a reliable history was 14 days; the time ranged from 7 to 24 days, but in only two cases did it exceed 18 days.

Summary

An epidemic of nephritis associated with *Streptococcus pyogenes* type 12 occurred in York and in predominantly rural areas of the North Riding during the winter months of 1957 and 1958. In several schools in which there was evidence of type 12 infection in 1957 some children were also found with symptomless haematuria. Spread of infection took place in schools and at home. Symptoms of the initial streptococcal infection were usually present but often slight, and were followed by the onset of nephritis 7 to 24 days later.

We are indebted to Dr. R. E. O. Williams for typing the strains; to Dr. H. Gray, M.O.H. Easingwold R.D., Dr. J. L. Cotton, M.O.H. Northallerton U. and R.D., and Dr. A. K. Thomas, of Tollerton, for their co-operation and help in the investigation; to Dr. J. A. Fraser, C.M.O.H. North Riding of Yorkshire, for his advice on many points; and to all those practitioners who went to the trouble of reporting cases and contacts.

AN OUTBREAK OF NEPHRITIS IN NORTHAMPTONSHIRE

BY

M. J. PLEYDELL, M.C., M.D., D.P.H.

Deputy County Medical Officer of Health, Northants

AND

W. J. A. HALL-TURNER, M.R.C.S., L.R.C.P.

Paediatric Registrar, Northampton General Hospital

In April, 1957, the head teacher of a village school telephoned the county health department to say that three children in the upper junior class at his school had fallen ill with nephritis within a period of a month. A fourth child, in the lower junior class, had been taken by his parents to Portsmouth, where he had become ill; the doctor had diagnosed pyelitis and sent the family home. Another child in the village attending a different school was under observation by the family practitioner with a sore throat and puffiness under the eyes. As a result of this outbreak there was considerable anxiety amongst the parents in the village; some of the children were being kept away from school unnecessarily, others were returning to school in an unfit condition. Although there had been a considerable amount of upper respiratory infection in the infant and lower junior classes in the early months of the year, it was not until April that the upper junior class had been affected, and it was in this month that nephritis had suddenly arisen as a complication.

Investigation

The school, which was visited on the same day, was soundly constructed and the rooms were well ventilated and

FIG. 1.—Nephritis in Northamptonshire. Incidence of 89 cases by month of onset, May, 1955, to May, 1958.

not overcrowded. All the children and staff were examined, and swabs were taken from any lesions suggestive of streptococcal infection. Group A type 12 haemolytic streptococci were obtained from lesions in two children in the upper junior class in which the cases of nephritis had occurred. One of the two children had a sore throat, the other a sore place in the nostril. The desks occupied by these two children and the children with nephritis were not grouped, but were dispersed among other desks in the classroom.

Apart from reassurance and advice to the head teacher it seemed desirable to assess the size of the outbreak. From discussions with practitioners it was evident that other cases had occurred in near-by villages, and from the paediatric department it was learned that about 25 children from the county had been admitted to hospital with nephritis since the previous October. In order to obtain further information Dr. C. M. Smith, the County Medical Officer of Health, wrote to all doctors practising in the county giving them particulars of the outbreak and asking to be notified of any cases under their care. From the replies received it is possible to present the following information.

Epidemiological Distribution

Only four cases were ascertained in 1955 (Fig. 1). Then in the first quarter of 1956 five children living in Kettering were taken ill; three of them lived in the same neighbourhood—two in houses almost opposite each other. Two months later cases were reported from Wellingborough, where the infection continued until June of the following year. By March and April, 1957, the infection had spread south-west to Northampton County Borough and had reached considerable proportions, the incidence in the county town being reflected in several small outbreaks in the outlying village communities, such as that already described. The infection then appeared to continue south-west, and by the late autumn it looked as though it was dying out. Over the winter months, however, another, and smaller, outbreak occurred, which was centred round Northampton, and again cases occurred in outlying villages and towns which had not been affected in the first outbreak.

It would be unwise to draw conclusions from data which are probably incomplete. Nevertheless, from the cases ascertained it can be said that there was no similarity between the distribution of cases of scarlet fever and nephritis during the period under review. Many of the scarlet-fever notifications were sporadic "dropping" cases, so that inevitably there were occasions when both conditions occurred in the same area at the same time. Beyond this, however, there was no evidence of association in the spread of the two infections.

Age and Sex Incidence.—In all, 89 cases were ascertained. Seventy-three occurred in children, 52% of whom were boys. One child under 3 was affected; 12 cases occurred in children aged 3 and 4 years; 45 cases in children aged 5 to 9 years; 15 cases in children aged 10 to 15 years (Fig. 2); and 16 cases in persons over 15 years.

FIG. 2.—Nephritis in Northamptonshire. Age distribution of 73 cases in children.

Clinical Picture

Most of the patients were children and were admitted initially to hospital. Parents gave a history of febrile illness two weeks previously, invariably with a sore throat or other obvious upper respiratory infection. Frequently oral penicillin had been given by the general practitioner. There then followed a period of apparent recovery until perhaps the day before admission, when the child again became unwell, with loss of appetite, lassitude, pallor and puffiness of the face, and, on occasion, headache. In some cases the parents had observed the passing of dark urine. On examination the urine was found to be loaded with albumin and gave a positive chemical test for blood, which was confirmed by microscopy.

Two weeks after the initial infection positive nose or throat swabs were obtained in a high percentage of children; in all others the anti-streptolysin titre was raised. The organism found was invariably the haemolytic streptococcus (Lancefield group A type 12). Approximately 60% had raised blood pressures, and in two cases this was high enough to produce hypertensive encephalopathy. One of these patients presented in the casualty department as a case of sudden blindness.

On admission to hospital the lingering presence of the streptococcus was always assumed and every patient received a 14-day course of intramuscular penicillin. Cases of hypertension were sedated and every patient was confined strictly to bed until the Addis count (a measure of microscopic haematuria) approached normal. When the number of red blood cells in an overnight 12-hour specimen of urine was down to 1,000,000, gradual mobilization of the patient began. He was allowed home when the red cells were less than 500,000. The average length of bed rest required was 15 weeks, though some cases took as long as 20 weeks to produce a normal Addis count. Hypertension rapidly disappeared, usually within 10 days. Several cases had grossly enlarged, pitted, and unhealthy tonsils, and one child had an infected aural polyp. These cases showed slow response to medical treatment, but when surgery was carried out the subsequent improvement was impressive.

After discharge from hospital all cases were followed up. Earlier cases showed an increase in the Addis count associated with comparatively mild upper respiratory infections. Many showed increased counts even without obvious infection. Later patients were sent home on small prophylactic doses of phenoxymethylpenicillin daily, and these have so far shown a remarkable improvement in the follow-up condition. It is too early yet to assess the long-term effects of the disease and the treatment, but from preliminary observations it would seem that there is unlikely to be any gross permanent renal damage.

Discussion

In the present outbreak the exchange of information between the health department and medical practitioners was probably of value. The experience obtained suggests that in future outbreaks of serious infections which are not notifiable it would be a useful measure to alert all practitioners as soon as possible, since early treatment may help in modifying the severity of the attack or preventing complications.

In view of the complications likely to arise from streptococcal reinfection, it is worth while considering whether schoolchildren should not receive special supervision after an attack of nephritis. Teachers could be advised that they should report at once to the principal school medical officer in the event of upper respiratory or cutaneous infections in the class or school. Any child at special risk of nephritis reinfection could then be temporarily excluded. It would seem advisable also that parents should be cautioned of the liability of reinfection, so that crowded gatherings were avoided until the child's resistance was considered satisfactory.

Summary

A description is given of an outbreak of nephritis in Northamptonshire due to group A type 12 haemolytic streptococci. In all, 89 cases were ascertained; 73 occurred in children under 16 years of age, 52% of whom were boys.

Many of the cases were notified by practitioners in response to a circular letter which notified them of the outbreak and asked for particulars regarding cases in their practice. Early exchange of such information would appear to be a useful measure in serious infections that are not notifiable.

No association was noted between the distribution of nephritis and scarlet-fever cases during the period under review.

The cases showed the familiar pattern of acute nephritis, though the severity varied greatly from patient to patient. Albuminuria and transient "frank haematuria" were constant features. Following initial penicillin (intramuscular), prolonged bed rest was the most important part of the treatment, its duration being dictated by weekly microscopy of the urine and E.S.R. estimation.

The importance of keeping post-nephritics free of further streptococcal infection is emphasized. In this respect the oral administration of phenoxymethylpenicillin is a safe and efficient method of prophylaxis. In addition it may be considered desirable to advise parents regarding the risk of reinfection, and for the children to receive special supervision at school.

We thank Dr. C. M. Smith, County Medical Officer of Health for Northamptonshire, for his advice; Dr. I. H. Gosset, consultant paediatrician, for permission to refer to cases under his care; and all medical practitioners in the county, without whose co-operation the outbreak could not have been investigated.

POSSIBLE DISADVANTAGES OF A CHEST RADIOGRAPHY SERVICE FOR GENERAL PRACTITIONERS

BY

PETER STRADLING, M.D., M.R.C.P.

Chest Physician and Lecturer

AND

W. M. DIXON, M.B., M.R.C.P.

Formerly Assistant Chest Physician

From the Hammersmith Chest Clinic and Postgraduate Medical School of London

It is common practice in many chest clinics to provide, in addition to normal consultations, special sessions to which practitioners may refer their patients for chest radiography only. These patients form a selected group in that they are usually referred because of symptoms which could arise from respiratory disease. If a chest radiograph shows an abnormality it is mutually understood by practitioner and physician that the patient may be recalled to the clinic for further investigation.

The diagnostic value of this service is demonstrated by the regularly high yield of abnormalities; its possible disadvantages are seldom even discussed. Disease not obvious on the chest film might be found by clinical examination. Moreover, a normal x-ray report from the clinic might allay practitioners' fears and, by false reassurance, delay diagnosis.

The following experiment was designed to determine, in those patients whose chest radiographs were reported as normal, (a) the amount of clinically discoverable disease present on attendance, (b) the incidence of early disease missed on radiography as represented by its appearance within the next few months, and (c) the extent to which normal x-ray reports influenced practitioners in their appreciation of any subsequent development.

Method

The routine "x-ray only" service in this clinic has always been conducted on 70-mm. roll film. Both postero-anterior and antero-posterior lordotic films are taken, and subsequently read by two observers independently to minimize error due to observer variation (Stradling and Johnston, 1955). In addition, during the period October, 1956, to May, 1957, inclusive, with the full co-operation of the practitioners concerned, certain of the referred patients underwent clinical examination at the time of routine radiography. To avoid bias and to obtain a group of suitable size for analysis, a systematic sampling method was employed; all patients born in the month of May were invited to co-operate, and none refused to be examined.

At the clinical interview the physician took a careful history, conducted a full physical examination, including urinalysis, and viewed a full-sized chest radiograph. When necessary, patients were referred to other hospital departments for investigation. When the 70-mm. films were read on the following day the patients' names on these films were obscured to avoid possible recognition before the observers had given their reports. If an abnormality was found during this routine film reading the patient was excluded from further study in the systematic sample even if already examined clinically. Thus further consideration is of a representative group of patients whose miniature radiographs were all considered normal.

During the same months a second systematic sample of patients (all those born in November) was collected for later analysis. These patients were not examined in the clinic, but those who were reported to have normal miniature radiographs were followed up four to eight months later by means of a questionnaire addressed to their practitioners. Inquiries were made to determine subsequent clinical developments within the follow-up period, any further action practitioners may have taken following the report of a normal chest radiograph, and in particular whether this report had led to diagnostic delay through the false reassurance of doctor or patient. It was specifically asked whether the report had been (a) of assistance, (b) of no help, or (c) actually misleading in this respect.

Results

Of 673 patients radiographed during the period under review, 155 (23%) were recalled for further investigation by the routine procedure when the miniature films were read. This again confirms the positive value of such a service and also establishes that the yield of abnormalities was in no way unusual during this period, for in 1955 and 1956 respectively 25% and 18% of the films proved to be abnormal. That the service itself provides representative material for analysis is shown by the figure of 4,000-5,000 miniature radiographs taken annually and the large number of practitioners referring patients.

The 74 patients forming the first systematic sample also proved representative in this respect, for 18 (24%) would have been recalled on viewing the 70-mm. films also. As members of the sample, however, they had already been examined and appropriate action taken. On no occasion was an abnormality discovered by the routine reading of miniature films in a patient already considered normal at the full examination undertaken as part of the experiment. Furthermore, no abnormality was discovered on the large radiographs that was not seen on the miniatures.

There remain in the first sample 56 patients whose miniature films were reported as normal. On physical examination 4 (5.4% of the sample) additional thoracic abnormalities were found in these patients. Two of these conditions (2.7%) proved significant and required treatment: one elderly man suffered from chronic bronchitis aggravated by excessive smoking, which he was advised to stop; another had an acute exacerbation of his chronic bronchitis, which was successfully treated with tetracycline. Relatively insignificant abnormalities not requiring treatment were found in the other two patients: one had mild costochondritis and the other a slight degree of pectus excavatum.

Significant extrathoracic disease was discovered in five patients (6.7%). One young woman had chronic paranasal sinusitis not previously diagnosed, two had iron-deficiency anaemia, and one had severe hypertension requiring hypotensive therapy. The fifth patient had cardiac neurosis: reassurance following full physical examination and investigation with normal findings led to relief of her symptoms. In two other patients (2.7%) insignificant abnormalities were discovered: mild systemic hypertension at the age of 77 and splenomegaly due to chronic malaria, already known to the practitioner.

By chance the second systematic sample also consisted of 74 patients. The number of abnormal reports on the miniature radiographs was 11 (13.5%), and these are not considered further. Questionnaires were circulated in respect of the remaining 63 patients, whose miniature films were reported normal, and every one of the 32 practitioners involved responded to the inquiry. Only two patients are untraced: they failed to revisit their doctors and had apparently left the district.

There remain for analysis 61 replies relating to patients with normal radiographs. All these patients were seen by their doctors soon after the initial radiography, and of the 61 replies, 60 stated that the report had been of assistance in making a diagnosis; usually by narrowing the field of possibilities or practically excluding a more serious pulmonary disease such as carcinoma or tuberculosis. Of these 60 patients, their practitioners had considered 48 normal or to have recovered from the illness which prompted reference for chest radiography. In the other 12 (16.2% of the sample) definite diagnoses were made by the practitioners: bronchitis with or without asthma was present in eight patients (10.8% of the sample) and non-thoracic disease in four others (5.4%). The diagnoses were hepatitis, hypochromic anaemia, alcoholic dyspepsia, and gout.

The subsequent clinical status of all 61 patients was either known or checked on receipt of the replies. None had developed any further disease during the follow-up period. In one, however, carcinoma of the bronchus was diagnosed soon after follow-up was complete. This case is discussed below.

On only one occasion did a practitioner feel that the radiograph had not helped towards a diagnosis. This patient, with pain in the chest and chronic bronchitis, was considered to have two fractured ribs on subsequent clinical examination at another hospital. The fractures, notoriously difficult to diagnose radiologically, were not visible on rescrutiny of our films.

Discussion and Conclusions

Chest radiography services, similar to that described, are now provided for practitioners by a large proportion of chest clinics. The widespread acceptance of such a facility is largely based upon the undoubted convenience to both patient and practitioner and an appreciation by the majority of the profession of its intrinsic value as a diagnostic aid. Moreover, the public health value of these services is very real in the case of tuberculosis: it is usual to obtain a yield of cases approximately 10 times that from mass radiography surveys of presumably healthy populations

(Toussaint and Pritchard, 1944; Sutherland, 1952; Trenchard and Grenville-Mathers, 1952). Early diagnosis, so often achieved when radiology is applied promptly to patients with minor symptoms, helps to prevent further spread of his disease both in the patient and in the community. It is the general practitioner who is most often presented with the diagnostic opportunity. He must act, but can do so only if he has ready access to diagnostic radiology (Stradling, 1948).

Nevertheless, there has always been an uneasy feeling in the minds of some physicians that perhaps such services were misconceived. It is thought by them that the ready availability of chest radiography might encourage slipshod physical examinations; that the x-ray examination might be used as an unwise short-cut to diagnosis or as a method of passing to a colleague responsibility for further action. From this it is argued that diagnostic errors can be avoided only by full physical examination at hospital or clinic whenever patients attend for chest radiography. But this would defeat one of the main aims of routine radiography services—the ability to deal rapidly with as many patients as practitioners choose to refer. Certainly it is only by the use of radiography that patients with minimal or no symptoms will have their pulmonary disease discovered in an early and treatable stage. The fact that the examination is over quickly is one of the main attractions to the patient; many of these relatively fit people would not attend if they thought that a long interview and an examination were involved.

The advantages of such radiography services have long been accepted by most chest physicians as outweighing possible disadvantages. Indirect evidence that this is justified, based on a retrospective survey of radiographs taken at routine consultations in a chest clinic, has been provided by Bradbury *et al.* (1951). In a group of 200 consecutive new patients every one of the 21 shown to have abnormalities on full clinical examination was picked out for recall on resurvey of the radiographs alone.

Our direct assessment of the situation has confirmed our confidence in the radiography service provided. Only 2.7% of the first sample of patients investigated proved to have thoracic disease needing treatment at the time their miniature films were reported normal. The corresponding figure for non-thoracic disease was 6.7%. These abnormalities were all either known to the practitioners concerned or discoverable by clinical examination in the surgery.

Furthermore, it is significant that the figures for non-thoracic disease discovered by physical examination, either under conditions of controlled trial at hospital or in the practitioners' surgeries, proved similar (6.7% and 5.4%). This very similarity indicates to us that practitioners are not apparently being distracted from diagnosing extra-thoracic disease by the report of a "normal" chest radiograph. Far from suggesting that such a report delayed diagnosis, our findings have revealed it as a positive, welcome, and correctly used diagnostic aid. Of the 32 doctors circulated with the questionnaire, 16 added unsolicited footnotes indicating the great importance they attached to a freely available chest radiography service. None of the 61 patients with normal reports on their initial radiographs developed any significant illness during the follow-up period of four to eight months. It is felt that this period is long enough to have revealed any such illness that might have been present at a detectable stage when radiography took place. The bronchial carcinoma diagnosed in one patient soon after follow-up was completed is considered to be an unrelated finding. This patient was admitted urgently with superior vena caval obstruction ten months after the symptoms leading to radiography had subsided. It is unlikely that an earlier diagnosis would have been made had the original radiographs never been taken: the terminal symptoms had been present for only a few weeks.

The success of a freely available chest radiography service depends upon the mutual co-operation of general practitioner and chest physician. Each has his full part to play: the practitioner in referring any patient with even minor

pulmonary symptoms; the physician in detecting the abnormal films and taking appropriate action on these. The practitioner also retains responsibility for those patients reported to have normal films: symptoms must be accounted for and further investigations arranged if this proves difficult. Radiography must be recognized for what it is—a diagnostic aid that must take its place with all others necessary for building up the full clinical picture. Repeat radiography at a suitable interval is essential if suspicious symptoms persist.

In our experience the necessary co-operation is fully obtainable. The high yield of initial abnormalities, the low yield of disease on additional physical examination, and the absence of serious developments during a period of follow-up, all indicate that such services are being used to the best advantage and that they are of the highest clinical and public health value. Disadvantages are more hypothetical than real, and are far outweighed by the advantages to practitioner, physician, and community alike.

Summary

Many chest clinics provide a chest radiography service for general practitioners in addition to the usual consulting sessions. The positive value of such a service is acknowledged, but its possible disadvantages have not previously been investigated.

Clinical examinations were made of 74 patients, chosen by a systematic sampling method from a group referred for "x-ray only." The thoracic abnormalities so discovered in those with normal chest radiographs represented 5.4% of the sample. Another 6.7% had non-thoracic diseases detected by clinical but not by radiological examination.

A second systematic sample was followed up some months later by a questionnaire addressed to the patients' practitioners. This showed that a similar incidence of thoracic and non-thoracic disease had been found by them. It is concluded that practitioners are not distracted from diagnosis by a report of a normal radiograph: such a report often proved of great value in excluding serious disease. The possible disadvantages of a chest radiography service for general practitioners are largely theoretical and are not borne out by practical experience.

We gratefully acknowledge constructive criticism from Drs. J. G. Scadding and Ian Sutherland. Our sincere thanks are also due to the many general practitioners who co-operated so fully and made the survey possible.

GOLDBERG-MAXWELL SYNDROME

REPORT OF THE ANOMALY IN THREE SISTERS

BY

RAMA VAISH, M.B., M.S., M.R.C.O.G.

Lecturer in Obstetrics and Gynaecology, G.S.V.M. Medical College, Kanpur; Obstetric Surgeon, A.H.M. and Dufferin Hospital, Kanpur, Uttar Pradesh, India

In 1948 Goldberg and Maxwell described a case of feminine type of male pseudohermaphroditism and collected seven other cases from the literature which they believed belonged to the same group. Up till 1954, altogether 22 examples of Goldberg-Maxwell syndrome have been reported in the literature. Below is the report of this condition occurring in three sisters.

Case Report

A female Hindu, 21 years of age, married, was admitted at the A.H.M. and Dufferin Hospital, Kanpur, for the investigation and treatment of primary amenorrhoea. She looked perfectly feminine. Her height was 5 ft. 5 in. (1.65 m.), chest 35 in. (0.89 m.), and waist 28 in. (0.71 m.). Her breasts were well developed and the areolae and nipples normal. Axillary and pubic hair were absent. On vaginal examination the external genitalia were found to be normal. The labia were shaped normally, the urethra was situated correctly, and the clitoris was of usual size. The vagina was of ordinary dimensions, being 3½ in. (8.9 cm.) in length and quite capacious. The vagina ended in a blind pouch and no cervix was felt or seen, the vaginal vault being a smooth dome with no elevation or depression. Nothing could be felt at the site of the uterus.

The patient had been married two years and was perfectly happy as the female partner. Her sexual inclinations were female and her libido was normal. Her family history was most interesting, as two of her sisters also showed the same abnormality. Her eldest sister, 25 years old, had been married for seven years, but had no children and had never menstruated. Unfortunately a physical examination could not be carried out on her as she was in Calcutta; but from the description given by her sister it was quite obvious that she also suffered from the same anomaly. The second sister was 23 years old, and had been a widow for five years. She had never menstruated and had no issue. Her appearance was feminine and she had well-developed breasts, but axillary and pubic hair was absent. The external genitalia and vagina were normal; the latter ended in a cul-de-sac, and the uterus and cervix were absent. The third, and youngest, sister was 12 years old, unmarried, and had small, adolescent breasts. The axillary and pubic hair had just started to appear and she had menstruated twice. External genitalia were normal. Rectal and vaginal examination could not be done. Skin specimens were taken for biopsy from the second and third sisters, but report on the nuclear sex could not be given as the preservation of tissue was not satisfactory.

Tests for the estimation of hormone levels in blood and urine could not be carried out owing to lack of facilities for hormone assay. Laparotomy was performed on July 25, 1957. The findings were as follows. The uterus was absent, and in its place there was a tiny nodule of fibro-fatty tissue. The tube, gonad, broad ligament, and round ligament were absent on the right side. On the left side the tube was absent; the broad ligament was very rudimentary, ending outwards in a thin crescentic fold. The left gonad was situated in the region of the left iliac fossa, attached by a fold of peritoneum to the posterior abdominal wall. It was about 3 in. (7.6 cm.) long and 1½ in. (3.8 cm.) wide, and consisted of cysts 2 mm. to 1 cm. in diameter. A large piece was taken from the left gonad as a biopsy specimen, and the abdomen was closed.

The histological report on the specimen was: "Section shows number of tubular structures separated by a variable amount of fibro-collagenous stroma. These tubules are lined by one or two layers of rounded cubical cells. The cytoplasm of some of these cells is vacuolated or clear in appearance. The stroma in between these tubules contains small islands of Leydig cells. The latter are rounded or ovoid in shape, having intensely eosinophilic cytoplasm."

Discussion

Although only 22 cases of Goldberg-Maxwell syndrome have been described in the literature from 1948 to 1954, the condition is not so uncommon. In the last 10 months, while working in this hospital, besides the above-mentioned cases of three sisters, I have found this condition also in another patient, who complained of primary amenorrhoea and sterility. A skin biopsy specimen was taken for nuclear sexing, but she did not report back. I think many of these cases are sent away by general practitioners as hopeless cases for treatment from the point of view of producing menstruation or pregnancy owing to the absence of the uterus.

The Goldberg-Maxwell syndrome comprises a very distinctive group of patients in whom the bodily habitus and sexual behaviour are essentially feminine. They are brought up as females, marry, and live as female partners. They consult the gynaecologist for primary amenorrhoea and sterility. The breasts are normal in size, but pubic and axillary hair is absent. The external genitalia—that is, the labia, urethra, clitoris, and vestibule—are normal in shape and situation. The vagina is of normal length and capacity; therefore there is no difficulty in coitus, and many of these patients are able to have orgasm. The vagina ends as a blind pouch, there being no cervix and uterus; although in some cases a fibro-fatty nodule or a vestigial uterus may be present.

The gonads are found in the abdomen, usually in the position of the ovaries, but may be situated elsewhere in the abdomen and attached to the posterior abdominal wall by a small mesentery. The broad and ovarian ligaments are absent or rudimentary. These gonads resemble an infantile type of ovary in appearance, being long, bulky, and lobulated. Cysts are sometimes present in their substance. On histological examination the gonads are found to be devoid of ovarian elements, but present the structure of immature, sterile, cryptorchid testes as typically found in the case reported in this article.

According to Goldberg and Maxwell, the urinary F.S.H. output is high (at least 96 M.U. in 24 hours), indicating primary gonadal deficiency; and 17-ketosteroid output is within normal range. Vaginal smears indicate a fair degree of oestrogenic stimulation of vaginal mucosa.

It has been said that the absence of pubic and axillary hair is a genetic abnormality comparable to the various congenital abnormalities found in ovarian agenesis or Turner's syndrome. Another feature of the Goldberg-Maxwell syndrome is the very strong family incidence, as will be obvious from the above case report of three sisters and from Schneider's cases, six of which occurred in one family and were spread over three generations.

Although some authors advocate the removal of gonads for fear of occurrence of neoplasm in cryptorchid testes, this point is highly debatable. Removal of these gonads may lead to unpleasant climacteric disturbances, as the gonads are responsible for the production of oestrogens, and not the adrenal cortex as thought by some. For this reason the syndrome has also been described under the heading of "oestrogen-producing testes." Adrenocortical function has been tested in various ways in these cases, but impairment of function of adrenal glands has not been found.

The nuclear sex of these cases is male. Jost and other workers have carried out certain experiments on animals by which they explain the occurrence of male nuclear patterns in these anatomically female cases. They postulate the

female form to be the basic or neuter, and the male differentiation to occur only in the presence of functioning testes during development of the embryo. Graham, in his experimental study in cats, has pointed out that sex chromatin can be recognized in the early embryo before the gonads have appeared, and therefore the sex is genetically determined and does not depend upon the hormonal status of the individual. Hoffenberg and Jackson have explained the varieties of gonadal dysgenesis and the various forms of human intersex by postulating three closely connected genes situated on the same chromosome. These authors have postulated one gene for infantilism or intrauterine hypogonadism—called "I"; one gene for shortness of stature, "S"; and one gene-complex for various anomalies of vegetative system called "A." According to them, the infantilism in gonadal dysgenesis results from very early failure of the developing gonad (their factor I), with consequent feminization of genital tract and body form. If gonadal dysgenesis occurs at a later stage of the male embryonic development, partial development along masculine lines will already have taken place. Further development of the genital tract will be of the female type, and thus "male pseudohermaphroditism" will result. This is equivalent to their "I" factor coming into operation at a slightly later stage. They conclude thus: "I" alone (slightly later in genetic male) = male pseudohermaphroditism; "I" (slightly later in genetic male) + S + A = male pseudohermaphroditism with short stature and anomalies.

The observations of Jost and Graham have led to the adoption of the term "gonadal dysgenesis" in preference to "ovarian agenesis." It also suggests that the Goldberg-Maxwell syndrome is, in fact, a variety of gonadal dysgenesis, where genetic development has failed in its attempt to produce a normally functioning testis and therefore the basic female pattern has continued. In this syndrome the failure to develop has probably occurred at a very early stage of development of the embryo, with the emergence of a complete feminine form and none of the male features. We can therefore say that the Goldberg-Maxwell syndrome is the earliest form of male pseudohermaphroditism.

Summary

The syndrome of Goldberg and Maxwell occurring in three sisters has been described.

The various features of the syndrome have been surveyed in detail.

The genetic aspects of the syndrome have been discussed in the light of modern work, and a hypothesis is produced to account for the syndrome.

AN ERYTHROPOIETIC FACTOR PRODUCED IN THE KIDNEY

PRELIMINARY REPORT

BY

SVERRE OSNES, M.D.

From the Institute of General and Experimental Pathology, University of Oslo (Director: Professor L. Kreyberg, M.D.)

A systematic study has been made of the response in mice to x-irradiation of the kidneys. The exteriorized kidneys were exposed to a single x-ray irradiation. The doses ranged between 100 and 18,000 r. By irradiation of the kidneys in mice a condition was produced resembling the essential features of glomerulonephritis in man with increasing nitrogen accumulation in the blood, anaemia, acidosis, oedema, hypertonia with hypertrophy of the heart, atrophy and granulation of the kidneys, albuminuria, haematuria, cast formation, decreased concentration of the urine to isosthenuria, and final collapse in a uraemic condition.

Experimental Findings

After 8,000 to 12,000 r increased blood pressure was observed in 10 days, whereas after 1,000 r about 8-12 months was necessary for this development. After unilateral nephrectomy and irradiation of the remaining kidney with 500 r the blood urea level increased in the course of five months. With the same procedure, and using 8,000 r, a rise in blood urea was observed after five days.

The anaemia caused by x-ray irradiation of the kidneys in mice was hypochromic to normochromic. The bone marrow showed a hypoplastic erythropoiesis.

In experiments with irradiation of the total amount of kidney tissue, the first changes observed were an increase of the blood urea level and a decrease in the haemoglobin values. Even at a time when the rise in blood urea was only from 20 to 23-24 mg. per 100 ml., a decrease in the haemoglobin value could be traced. It is therefore unlikely that the former caused the latter.

Through variation of the experimental procedure it has been possible to demonstrate the following.

1. In mice having a very small amount of kidney tissue shielded during the irradiation, the haemoglobin is maintained at a higher level than that usually found in connexion with the increased blood urea figures observed in these animals, and higher than in the animals with all the kidney tissue irradiated.

2. If one-quarter to one-third of one kidney is shielded during the irradiation the haemoglobin values may be maintained at the normal level, in spite of the development of

Blood urea and haemoglobin values in a mouse after unilateral nephrectomy and irradiation of approximately three-quarters of the remaining kidney with 8,000 r.

a considerable uraemia. The Chart shows the blood urea and the haemoglobin values in an animal which had been subjected to unilateral nephrectomy and irradiation of approximately three-quarters of the remaining kidney with 8,000 r. After six months the blood urea had reached 153 mg. per 100 ml., whereas the haemoglobin value was in the normal range, actually 111%.

3. Irradiation of one kidney and formation of an intra-peritoneal cutlet of the ureter from the other non-irradiated kidney is associated with normal haemoglobin values.

These experiments indicate that the failure of the kidney as an excretory organ and the development of the anaemia are parallel phenomena and independent of each other. These experiments also indicate that the kidney produces a principle of importance in erythropoiesis.

Table I gives the reticulocyte counts in (a) mice with both ureters ligated, (b) mice with total nephrectomy, (c) mice with partial nephrectomy, and (d) normal mice with intact kidneys. In all the groups acute anaemia was produced through bleeding. No reticulocyte reaction was found in the nephrectomized animals, whereas a reticulocytosis developed in the animals with ligated ureters. These observations correspond well with the findings of Jacobson *et al.*

TABLE I.—Reticulocyte Count in Mice Bled ("Stimulus") in Connexion with Different Operations

Operation	Stimulus	Reticulocytes %					Hb % 6 Days after Operation
		Before Operation	After Operation				
			12 Hours	24 Hours	2 Days	6 Days	
Ligation of ureters ..	Bleeding	2.7		4.7	Dead		
Total nephrectomy	"	2.1	2.3	2.2	"		
Partial nephrectomy (half a kidney left intact) ..	"	2.0	4.2	5.9	7.0	21.3	
Controls. No operation	"	2.9	6.5	13.0	13.2	32.1	
						48 50	

Each group comprises three mice.

TABLE II.—Reticulocyte Count in Serum-injected Mice

Condition of Experimental Animals	Stimulus	Reticulocytes %					
		Before Serum Inj.	After Serum Injection				
			1 Day	4 Days	6 Days	8 Days	10 Days
(A) Uraemic mice with anaemia (irradiated kidneys)	"Activated" serum	2.7	6.3	7.8	8.4	6.2	
(B) Normal mice	"	2.4					
(C) Nephrectomized mice	Bleeding "activated" serum	2.6	4.3	4.0	4.7	3.4	1.6
(D) Uraemic mice with anaemia (irradiated kidneys)	Ultra filtrate of "activated" serum	2.4		7.5	9.3	12.7	9.7

Each group includes three to five mice.

(1957), who studied the erythropoietic titre in rats and rabbits, nephrectomized or with ligated ureters. The reticulocyte reaction seemed to be stronger in the animals with intact kidneys than in those with reduced kidney substance.

Serum from bled normal mice ("activated" serum) injected into mice with anaemia after irradiation of their total kidney mass produces reticulocytosis. As shown in Table II A, the reticulocyte response is considerable, in spite of a severe uraemia and acidosis, even after a single injection of "activated" serum (0.3 ml.). These experiments show that the bone marrow of uraemic mice responds to an erythropoietic principle present in the blood of bled animals. This erythropoietic principle is able to counteract the anaemia caused by irradiation damage in kidneys.

"Activated" serum will also produce a reticulocyte response in normal mice with normal haemoglobin values (Table II B). This observation may explain the polycythaemia sometimes seen in connexion with renal tumours, and it may indicate that the principle observed may be a factor of importance also for the normal erythropoiesis.

As mentioned above, after an acute haemorrhage no reticulocyte response is found in nephrectomized mice. If the nephrectomized animals are injected with "activated" serum a reticulocyte response develops (Table II C).

Table II D summarizes the results of experiments with injection of protein-free ultrafiltrate from "activated" serum into mice with anaemia after irradiation of the kidneys. Also this protein-free filtrate contains an active principle.

Conclusion

An attempt has been made to demonstrate morphological structures, which may be related to the functional findings recorded above. In normal mouse kidneys stained with crystal violet and light green (Wilson, 1952) the juxtaglomerular cells show definite granules. In mice with anaemia produced through daily bleeding there is in some instances a distinct reduction of the number of granules in the juxtaglomerular cells and diminution of the individual granules.

Some months after unilateral nephrectomy and x-ray irradiation of the greater part of the other kidney no granules are found in the juxtaglomerular cells in the non-irradiated part of the kidney, and none or very few and small granules in the irradiated part. In bilaterally irradiated kidneys the granules in the juxtaglomerular cells are well preserved and the cells may even appear to be increased in size, with enlargement of the individual granules.

Further studies of the possible relationship between the alteration of the granules in the juxtaglomerular cells and the erythropoiesis are in progress.

ADDENDUM.—Since erythropoietin is regarded as a protein or a protein-bound non-filterable principle, and since the ultrafiltrate of "activated" serum is effective in anaemic mice with irradiation-induced nephritis but gives no reticulocytosis in normal mice, the indication is that the substance active in nephritic mice is different from erythropoietin. It can also be demonstrated that the serum from nephritic mice with anaemia can induce reticulocytosis in normal mice (erythropoietin effect). Further investigations indicate that the erythropoietic principle which is active in nephritic mice is connected to the granules of the juxtaglomerular cells. Such a substance may be referred to by the name of "juxtaglomerulin." A detailed account will be published later.

The author is indebted to the Norwegian Cancer Society (Landsforeningen mot Krefte) for research grants.

A proposal that W.H.O. should be asked to consider organizing an International Public Health and Medical Research Year was unanimously endorsed by the U.N. General Assembly's social, humanitarian, and cultural committee in New York on November 12. The committee adopted a resolution under which the Assembly would invite W.H.O., in accordance with its agreement with the United Nations, to consider a recommendation to organize the Year and to adopt ways of intensifying international co-operation in health matters. Under the finally adopted resolution, the Assembly would state its desire to combat widely prevalent diseases such as malaria, tuberculosis, smallpox, cholera, cancer, cardiovascular ailments, leprosy, and poliomyelitis, and to solve other serious health problems. The resolution, after noting other fields of effort such as the use of atomic energy in medicine and popular health education where international co-operation might be intensified, invites W.H.O. to inform the next General Assembly session (in 1959) of its reaction to these proposals.

HAEMOGLOBIN-H DISEASE

BY

J. P. BINGLE, B.M., M.R.C.P.

Medical School

Haemoglobin-H was first described in 1955 by Rigas, Koler, and Osgood. It differs from the other abnormal haemoglobins so far described in that its inheritance cannot be followed by electrophoresis in its heterozygous and homozygous forms. Usually in the haemoglobinopathies, adult haemoglobin (HbA) and the abnormal haemoglobin are present in approximately equal quantities in the heterozygous state. In the homozygous state all or nearly all the haemoglobin present is of the abnormal type, the patient showing the features of the appropriate disease. In patients with haemoglobin-H disease the proportion of abnormal haemoglobin found varies from about 10 to 35%. It is irregularly found in relatives of these patients. In both these respects it resembles the appearance of haemoglobin-F in thalassaemia. Clinically, haemoglobin-H disease is very similar to thalassaemia minor. Two cases of this rare disease are reported in which red-cell survival and marrow iron turnover have been studied.

Methods

1. *Electrophoresis* of haemoglobins was carried out on Whatman No. 1 and No. 31 extra thick chromatography papers, using a horizontal technique in barbiturate buffer pH 8.6, M=0.05. By this technique HbA₂ can be separated from HbA.
 2. *Red-cell survival time* was estimated using the patient's own cells labelled with radioactive chromium (⁵¹Cr) as described by Joske, McAlister, and Prankerd (1956).
 3. *The radioactive iron* (⁵⁹Fe) turnover was studied by the technique described by Harris, McAlister, Prankerd, and Singh (1957).
 4. *The foetal haemoglobin (HbF) percentage* was estimated by the method of Singer, Chernoff, and Singer (1951).
- Identification of Haemoglobin-H.*—The abnormal haemoglobin found in the cases described was identified by comparison with a sample kindly supplied by Dr. J. C. White and by moving boundary electrophoresis carried out by Dr. E. M. Shooter and Mr. R. E. Skinner.

Case Reports

Case 1.—A Greek Cypriot, aged 23 years, living in London, attended hospital complaining of occasional nocturnal epileptic fits. He had always been pale and had had a few attacks of jaundice. When he was 7 years old he was treated in a sanatorium for tuberculosis. On examination the only abnormal physical signs were pallor, slightly icteric conjunctivae, and a just palpable spleen. When he was first seen his reticulocyte count was 7.5%. This gradually fell to normal at the time of the radioactive studies.

Case 2.—A Greek Cypriot woman, aged 22 years, living in London, attended hospital complaining of feeling unduly tired and weak during the past two years. On examination there were no abnormal physical signs apart from slight pallor. Her spleen was not palpable.

The investigations in both cases are set out in the table below.

Analysis of the Cases

	Case 1	Case 2
Haemoglobin	11 g./100 ml.	10 g./100 ml.
Red cell count	5.9 m./c.mm.	4.9 m./c.mm.
Packed cell volume	39%	37%
Mean cell diameter	7.7 μ	7.4 μ
Mean cell volume	28 g./100 ml.	25 g./100 ml.
Mean cell volume	66 cubic microns	75 cubic microns
average thickness	1.4 μ	1.7 μ
Reticulocytes	7.5%–2%	3.5%
Red film	Marked variation in size and shape. No target cells.	Marked variation in size and shape. No target cells.
Red cell osmotic fragility (Normal range, 0.48–0.30% saline)	0.42–0.21% saline	0.45–0.24% saline
Foetal haemoglobin	3.3%	3.2%
Schumm's test	Positive	Positive
Direct van den Bergh	Negative	Negative
Total plasma bilirubin	1.3 mg./100 ml.	0.5 mg./100 ml.
Urinary urobilinogen (Schlesinger's test)	Slight excess	No excess
Radiographs	Skull: normal Skeleton: normal	Skull: normal Humerus: normal

Results of Radioactive Iron and Chromium Studies

Figs. 1 and 2 show the results of these analyses. The uptake of ⁵⁹Fe was reduced over the marrow sites in the fourth and fifth lumbar vertebrae, but was increased in the shafts of the long bones.

These results are interpreted as showing a reduction in marrow activity per unit volume of marrow, but an increase in total marrow volume due to peripheral spread in the skeleton. The reduction in marrow activity was more pronounced in Case 1. In both cases the ⁵⁹Fe uptake over the spleen and liver showed no evidence of extramedullary red cell production. The rate of ⁵⁹Fe appearance in the red cells was slightly increased—T_{1/2}* Case 1=3.0 days, Case 2=2.7 days (normal=3.1 ± 0.2 days)—indicating a slightly increased out-pur of red cells.

The ⁵¹Cr survival time of red cells was slightly reduced in Case 2—T_{1/2}†=13 days (normal 22–24 days)—and the mean cell life may be calculated to be about 70 days. There was no evidence of any excessive red cell destruction in the spleen. In Case 1 the ⁵¹Cr survival time of the red cells was almost normal—T_{1/2}†=20 days—but earlier there had been undoubted indirect evidence of haemolysis.

FIG. 1.—Uptake of ⁵⁹Fe measured as relative activity over L. 4 and 5. Vertical axis=Relative units of radioactivity. x—x=Case 1. ●—●=Case 2. ----=Normal.

FIG. 2.—Rate of appearance of ⁵⁹Fe in red cells. Vertical axis=Fraction of injected ⁵⁹Fe in red cells. x—x=Case 1. ●—●=Case 2. ----=Normal.

The Family of Case 1

1. Aged 68. Her blood contained about 10% of haemoglobin-H and she had the clinical and haematological picture of haemoglobin-H disease. Haemoglobin 9 g./100 ml.
2. Deceased.

*Half the time taken for the radioactive iron in the red cells to reach equilibrium.

†Half the time taken for the disappearance of radioactive chromium from the peripheral blood.

3. No abnormality found on clinical and haematological examination. Osmotic fragility of red cells within normal limits. Foetal haemoglobin 2% of total.

4. No abnormality on clinical and haematological examination. Osmotic fragility of red cells was within normal limits. Foetal haemoglobin less than 2% of total.

5. Case 1, described.

6 and 7. No haemoglobin-H found on paper electrophoresis. Foetal haemoglobin less than 2% of total.

Paper electrophoresis did not show any increase of HbA₂ in any of the relatives of Case 1.

The Family of Case 2

1. Paper electrophoresis showed no haemoglobin-H. Haemoglobin 8.9 g./100 ml. This anaemia responded to the administration of iron, her haemoglobin rising to 12 g./100 ml. Foetal haemoglobin 2% of total.

2. Not examined.

3. Electrophoresis showed haemoglobins A and H. She was suffering from a mild anaemia, similar to Case 2; haemoglobin 10.4 g./100 ml. Occasional target cells seen in blood film. Foetal haemoglobin less than 2% of total.

4. Case 2, described.

5. Not examined.

6. Paper electrophoresis showed no haemoglobin-H. Foetal haemoglobin less than 2% of total.

7. Paper electrophoresis showed no haemoglobin-H. Foetal haemoglobin 5% of total. (Child aged 1½ years; haemoglobin 13 g./100 ml.; normal red cell fragility.)

Paper electrophoresis did not show any increase of HbA₂ in any of the relatives of Case 2.

Fig. 3.—Family tree of Case 1. Fig. 4.—Family tree of Case 2.

Discussion

The results described show that haemoglobin-H disease is characterized by a slight reduction in the life span of red cells which is not associated with splenic destruction. There is a decrease in marrow activity, which is compensated for by marrow extension, and this results in a slight increase in total red cell output. Output, however, does not compensate completely for haemolysis. The life span of red cells appears to be variable, as a patient who at one time showed clear evidence of haemolysis later had an almost normal cell survival. These findings are similar to those in thalassaemia (Bailey and Prankerd, 1958), which the disease closely resembles in clinical features and haematological findings. However, it differs from thalassaemia minor in that HbA₂ is not increased in the patients or their relatives (Vella, Wells, Ager, and Lehmann, 1958). The cases so far reported have been from races in which thalassaemia occurs (Vella *et al.*, 1958); and Motulsky (1956) states that haemoglobin-H disease is the result of the interaction of the thalassaemia and "H" genes. Our two families show no evidence to support this theory, as none of the relatives have thalassaemia.

Summary

Four cases of haemoglobin-H disease are reported from two Greek Cypriot families living in London. One case from each family has been studied in detail, and results of red cell survival time and marrow iron turnover are presented. The familial nature of the disease is demonstrated.

We are grateful to Dr. E. A. Blake Pritchard for permission to study and publish Case 1.

TOXIC PSYCHOSIS FOLLOWING ATROPINE EYE-DROPS

BY

J. P. BAKER, M.B., M.R.C.S.

AND

J. D. FARLEY, M.B., B.S.

From the Three Counties Hospital, Arlesey, Beds

It is well known that atropine may produce a delirium in addition to its more characteristic autonomic effects, and that in certain sensitive subjects these effects will arise with normal pharmacological doses. It is less well known that atropine can produce delirious states with minor or absent peripheral signs of intoxication and that severe mental reactions can follow routine instillation of atropine eye-drops.

The case described is one of acute toxic psychosis caused by routine atropinization of the right eye over a period of three and a half weeks in the course of treatment of retinal detachment.

The condition is rare in adults and few cases have been reported in the literature (Hopkins and Robyns-Jones, 1937; Listwan and Whealy, 1953; Schinko, 1954), but it is suggested that milder degrees of mental disturbance often seen after eye surgery and attributed to emotional stress of the post-operative regime may be due in part to atropine intoxication.

Case Report

The patient was a married woman of 33, without children, intelligent, and described by her family as somewhat highly strung, emotional, and imaginative. After the death of her father two years ago she had spent three days in a neurosis unit, the diagnosis being reactive depression with hysterical features. There was a similar episode 11 years ago after the death of her first husband, but without admission to hospital.

The medical history included rheumatic fever at the age of 12, followed by a slight persistent tachycardia, and myopia requiring 10 dioptries correction. She had recently worn contact lenses. There was no significant family history.

On June 29, 1957, she was admitted to Moorfields Annexe, Highgate, with a right temporal retinal detachment. Treatment with bed rest, double eye pads, and daily instillations of 1% atropine sulphate drops was instituted. On July 4 she was transferred to Moorfields Hospital, where the atropine drops were instilled twice daily. At this time she was judged to be "unstable in temperament," and phenobarbitone, ½ gr. (32 mg.) t.d.s., was added to her treatment.

Diathermy and subretinal aspiration was performed on July 8 under thiopentone, gallamine triethiodide, gas and oxygen, with premedication by "omnupon" and scopolamine. There were no complications. Atropine drops twice daily, eye pads, and strict bed rest were continued until July 19, when masked glasses were substituted for the pads.

more liberty of movement was allowed in bed, and the phenobarbitone was replaced by chlorpromazine, 25 mg. t.d.s.

Over the next four days she became increasingly noisy, disorientated, and irrational, and required oral and intramuscular barbiturates. By July 23 she was quite unmanageable and was transferred to Three Counties Hospital on an Urgency Order.

On admission she was disorientated in time and place, was amnesic for recent events, mistook identities, and asked if she was to have an operation. She was restless and garrulous, refused to stay in bed, called out in terror, and at times wept uncontrollably. She stated that she had seen the Cross and "boats to sail away in," and had heard the voices of near relatives. She believed people to be talking about her and plotting against her. At times she showed partial insight.

On examination she was of average physique; the right pupil was fully dilated and the left less so and reacting to light; the gait was slightly ataxic; there was a tachycardia of 150 a minute, and the blood pressure was 170/90. There were no other abnormal physical findings.

Next day her mental state had deteriorated. She was resistive and hostile, offered violence, was incontinent, and refused food. This state was not continuous, but was broken by more lucid intervals, during one of which she was sufficiently quiet for an E.C.G. tracing to be taken. This showed (first tracing in Figure) a regular sinus tachycardia,

E.C.G. Lead V₁. (1) On admission (July 24). (2) At 11 a.m. on August 13. (3) At 3.45 p.m. on August 13—atropine sulphate, 1/66 gr. (1 mg.), given at 11.10 a.m. (4) At 6.45 p.m. on August 13—neostigmine, 1 mg., given at 4 p.m.

rate 130, with diphasic T wave throughout the chest leads and some elevation of the ST segment. The white-cell count was 15,000, with a polymorphonuclear leucocytosis; Hb, 102%; W.R. negative; E.S.R. 7 mm./hr.; urine, N.A.D.; chest x-ray examination N.A.D.

At this stage the diagnosis lay between an acute schizophrenic reaction and a toxic delirium, the latter being more probable because of the lucid intervals, visual hallucinations, and disorientation, together with the myocardial findings. It was tentatively suggested that the condition might be due to atropine poisoning, but this was discounted by outside medical opinion; for fear of neglecting the post-operative care of the eye the drops were continued.

By July 25, despite sedation, her mental condition had deteriorated further and tube feeding had to be instituted. Electroplexy was considered, but thought to be too dangerous in view of the toxic state of the myocardium. The pulse rate remained at approximately 150. It was decided to discontinue atropine, and within 24 hours there was some improvement in her mental state.

After 48 hours the pulse rate had fallen to 96, but mentally she was relapsing again and refusing nourishment. It was now thought that her myocardial condition had improved enough to allow electroplexy, which was indicated by her continued overactivity, resistiveness, and refusal to take nourishment. Daily E.C.T. was given until July 30, by which time she had greatly improved, was normal in behaviour and mood, and had no disturbance of cognitive function. Over the next few days, however, she again became more

labile emotionally, rather demanding and querulous, and was expressing paranoid ideas.

By August 6 she had gained in insight and was more settled, but still emotionally unstable and liable to tears. On the 8th a suture was removed from the eye by our visiting ophthalmic surgeon and a satisfactory report given on the state of the retina. An E.C.G. tracing taken on August 9 was within normal limits, rate 96.

In view of the possibility that this patient might need further treatment to her eyes in the future, it was considered important to assess the part played by atropine in the aetiology of her psychosis, so on August 9 an injection of atropine sulphate, 1/100 gr. (0.65 mg.) was given subcutaneously, with the suggestion that it was a sedative. Six hours later she developed a garrulous, emotional, paranoid, hallucinated state resembling in lesser degree her condition of the previous week. Systemic effects were negligible. Unfortunately she was too uncooperative to permit a further E.C.G. being taken. Next morning she was more settled, but still showed some pressure of ideas and a tendency to form illusions.

In order to eliminate the possibility that this was a chance relapse, and if possible to have electrocardiographic confirmation of the effects of atropine, a further trial dose of the drug, this time 1/66 gr. (1 mg.), was given subcutaneously at 11.10 a.m. on August 13, again with the suggestion that it was a sedative. An E.C.G. was taken (second tracing in Figure) 10 minutes before the injection and was normal, rate 96. By midday she showed pressure of ideas and increased lability of affect, but no significant systemic effects or alteration of the pulse rate. By 2 p.m. she complained of a burning sensation in the palms of her hands and in her brain, and said she felt she could no longer contain herself or suppress her feelings. She began to make absurd accusations against the hospital and demanded her immediate discharge on the grounds that her room was a locked cell (untrue) and that the tea was not strong enough. She asserted that patients were being given nicotine injections to make them cough, and that others were being gassed. She could smell the gas (not true) and insisted that she could hear men laughing, her sister's voice, and the click of billiard balls. Visual hallucinations were also suspected.

An E.C.G. taken at 3.45 p.m. (third tracing in Figure) showed the same slight elevation of the ST segment and diphasic T wave as in the tracing taken on admission (first tracing in Figure). There was no increase in sinus rate.

At 4 p.m. 1 mg. of neostigmine was given, and a further E.C.G. taken at 6.45 p.m. (tracing 4 in Figure) showed that the myocardial changes produced by the atropine had resolved. Her mental condition, however, did not settle markedly until next morning, and not completely until three days later.

She was discharged on August 16, and has since remained well and has returned to work.

Discussion

Listwan and Whealy (1953) described the characteristic mental symptoms of atropine intoxication as a confusional state with vivid visual hallucinations, restlessness, muscular incoordination, and later increased emotionalism with a short period of retrograde amnesia. In our case all these features were present together with aural and olfactory hallucinations. Peripheral post-ganglionic cholinergic effects were minimal apart from the tachycardia on admission. It is thought that the E.C.G. changes were due to direct action on the myocardium, as in the model psychosis there was no increase in sinus rate.

Fleury and Marx (1949) pointed out that intoxication is not due to transconjunctival absorption but to the swallowing of atropine-laden tears. In 1% atropine sulphate, each drop contains 1/110 gr. (0.6 mg.). Assuming complete absorption, three drops in the normal subject will produce parasympathetic paralysis, six drops restlessness, and 15 drops mental symptoms and ataxia. In sensitive subjects

mental or peripheral symptoms will follow much smaller doses. Children (Tyson, 1889; Kelyack, 1890; Scally, 1936; Duggan, 1937; Belz, 1949; Fleury and Marx, 1949) and the elderly (Métivier, 1935) are particularly affected.

Recommendations to reduce the risk of side-effects from atropinization of the eye have included the use of a 0.5% solution, precautions to avoid concentration of the solution by evaporation, and compression of the internal angle of the eye to obstruct the lacrimal duct during instillation (Belz, 1949; Fleury and Marx, 1949).

It would be interesting to know if any positive correlation could be found between the more minor emotional disturbances and restlessness which often accompany eye surgery, and any particular dosage or method of atropine administration.

Summary

A case is described in which an acute confusional psychosis resulted from the routine administration of 1% atropine sulphate drops in the treatment of retinal detachment. The psychosis was accompanied by myocardial changes giving rise to considerable concern. Other peripheral signs of atropine intoxication were absent. A remission of the confusional state followed discontinuation of the eye-drops and a short course of electroplexy; paranoid trends and emotional lability persisted for a further few days.

At a later date, in order to establish a diagnosis, small test doses of atropine were given by injection. Both the psychotic symptoms and the myocardial change seen when the patient was having atropine eye-drops were reproduced.

The literature concerning mental symptoms following the use of atropine eye-drops is reviewed and possible preventive measures against intoxication are described.

It is suggested that closer investigation might be made into the origin of states of minor emotional disturbance, usually attributed to psychological stress, in patients undergoing eye surgery with prolonged routine atropinization. E.C.G. changes appear to be useful in establishing a diagnosis of atropine sensitivity where other peripheral signs of intoxication are lacking.

Our thanks are due to Dr. Leslie Ford, medical superintendent of Three Counties Hospital, for permission to publish this case, to Dr. L. G. M. Page, deputy medical superintendent, for his help and advice, and to Dr. D. W. Hill for details of treatment at Moorfields Eye Hospital.

Opening a conference on cerebral palsy, held in London on November 21 by the British Council for the Welfare of Spastics, Mr. R. H. M. THOMPSON, Parliamentary Secretary to the Ministry of Health, said that the overall needs of children and young people suffering from cerebral palsy were early ascertainment, full assessment, expert treatment, education, training for future employment, and continuing aftercare in the community. At the same time the parents needed guidance in the child's home management, and help in coping with their own numerous practical and personal problems. The need was to build up a system of comprehensive care available to sufferers throughout their lives. Mr. Thompson thought the greatest need was for further understanding of the causation of the disease, for it was only in this way that we could prevent it. Research into its causation and treatment would ultimately be of benefit to children suffering from other handicaps also.

RENAL COLIC AND ANURIA FROM ACETAZOLAMIDE

BY

J. G. YATES-BELL M.B., F.R.C.S.

Urological Surgeon, King's College Hospital, London

Acetazolamide, "diamox," is a sulphonamide derivative and inactivates carbonic anhydrase. By oral administration it is rapidly absorbed, and is excreted largely unchanged by the kidney within 6-12 hours. The inhibition of carbonic anhydrase leads to increase of sodium bicarbonate in the urine and increased potassium output.

Acetazolamide is widely used for glaucoma and as a diuretic in cardiac disease, and is reputedly very free from serious complications; only three papers have appeared in America reporting complications and none at all in Great Britain, which is the reason for the publication of this case.

Case Report

The patient, a man aged 54, was quite well until 5.30 p.m. on May 1, 1958, when he passed urine normally. Shortly afterwards urgency developed and a quantity of "very thick urine" was passed with pain. Pain then developed in the right loin; it radiated to the groin and was associated with frequency, penile pain, and haematuria. He was seen by Dr. J. Williams, who diagnosed renal colic.

Next day the patient voided 15 oz. (425 ml.) of clear urine in the morning and complained only of a dull ache in the right loin. Later, severe low back pain developed with left-sided abdominal pain and vomiting.

On May 3 the severe low back pain and vomiting continued and no urine was passed for 24 hours. The patient was admitted to Leatherhead Hospital; temperature 99° F. (37.2° C.). No stones were seen by straight radiograph. Cystoscopy (lignocaine gel analgesia) showed the bladder to be empty but otherwise normal. The right ureter was inactive and a catheter could not be passed beyond 1 cm. The left ureter was obstructed at 5 cm., but a catheter with stylet was successfully forced through and bloody urine poured down the ureteric catheter under considerable pressure.

The ureteric catheter was tied in and 38 oz. (1,077 ml.) drained through it during the night. Distaquaine penicillin, 300,000 units, was given daily for six days from May 3. Sulphonamide crystalluria was diagnosed, and sodium bicarbonate, 60 gr. (4 g.) 4-hourly, was given orally and intravenous saline discontinued early, as the patient took well by mouth.

On May 4 the blood urea was 95 mg. per 100 ml.; plasma CO₂, 16.1 mEq/l.; serum chlorides, 106 mEq/l.; sodium, 139 mEq/l.; potassium, 4.6 mEq/l. Urine: bladder and left ureter, sterile; red cells ++; no crystals.

Progress was satisfactory; urine drained well from the ureteric catheter and the left renal pain was relieved at once. After about 12 hours the patient voided a few ounces of urine around the catheter; this was thought to be from the right kidney, as relief of right renal pain then occurred. The blood pressure was 150/85. The ureteric catheter was removed on May 6 after retrograde pyelography had shown a curious beaded appearance at the lower end of the ureter which might have been due to oedema or collections of crystals. The blood urea had fallen to 72 mg./100 ml.

The following day the patient was passing clear urine, but a peak of temperature followed, due to pyocyanus infection of the urine, which responded well to a five-day course of chloramphenicol.

On May 18 the patient was discharged well with a blood urea of 29 mg./100 ml.

Discussion

The diagnosis of this case lay between bilateral non-opaque ureteric calculi and crystalluria. The obstruction to the ureteric catheter very closely resembled the blockage experienced in sulphonamide crystalluria.

It was known that the patient had attended elsewhere for blurred vision (? glaucoma) in the left eye; he had improved somewhat on 2% pilocarpine, and was then given acetazolamide as follows: Two tablets on April 25, 26, 27, and 28, none on the 29th, two on the 30th, and one on May 1. The thick urine appeared during the evening of May 1 and was rapidly followed by bilateral renal colic and anuria; it seemed reasonable, therefore, to blame the tablets. Advice was sought from various medical colleagues, and it was concluded that the patient might have been taking sulphonamide tablets instead of the "harmless diuretic" acetazolamide.

Mr. C. R. Davenport, senior pharmacist at King's College Hospital, pointed out the sulphonamide nature of acetazolamide, of which I and most of my colleagues appeared to be ignorant. This seemed to clinch the diagnosis, and Messrs. Lederle, the manufacturers, were contacted, and provided helpful information.

Dr. L. H. Worth reported the following case at the Royal Society of Medicine on February 28, 1956, but the account was not published.

A man, aged 47, was given acetazolamide, 1 tablet twice daily, for two weeks from January 13, 1956, and the dose was increased to 1 tablet thrice daily on January 27. From the evening of January 31 until his death on February 5 he had complete anuria. The bladder was empty and no urine was obtained by ureteric catheterization. No crystals were found to be obstructing the moderately distended and oedematous ureters.

The story in Dr. Worth's case closely resembles the story in the present case.

Persky, Chambers, and Potts (1956) report three cases of ureteric colic following acetazolamide administration. Stones were removed by cystoscopy from the ureter in two patients, and it was suspected that some had been voided naturally in the third. The stones were not analysed. All three patients voided an acid urine, which is against phosphaturia, and it is suggested that the suppression of citrate production was the cause.

Glushien and Fisher (1956) reported post-mortem findings on a man of 55 who had had 250 mg. of acetazolamide thrice daily for four days. The kidneys closely resembled those of patients "succumbing to sulphonamide intoxication," but there was no clinical evidence of renal failure or sulphonamide intoxication during life.

Summary

A case of renal colic and anuria due to acetazolamide is reported.

The condition resembles sulphonamide crystalluria and responds to treatment for that condition.

In no case have sulphonamide crystals been detected, nor has an expected phosphaturia been confirmed.

Further investigation on the urine of patients taking acetazolamide are being carried out and will be necessary to explain the mechanism of this rare but serious complication.

I wish to thank Dr. N. E. G. Richardson for her help in the pathological investigation and Mr. C. R. Davenport and Mr. J. R. Wilson for their help.

Medical Memoranda

Value of Penthienate Methobromide in Lienteric Diarrhoea and Encopresis in Childhood

Penthienate methobromide ("monodral"), like other anticholinergic drugs, depresses the motility and secretion of the stomach and reduces the motor activity of the intestine. Its therapeutic value in the treatment of peptic ulcer and dyspepsia is accepted, but its value in the treatment of disorders of the small intestine and colon remains unproved. Nevertheless, Ingegno (1954) considers that penthienate can control diarrhoea in patients with an "irritable" or "spastic" colon. I have, however, been unable to find any reference to its use in cases of lienteric diarrhoea and faecal incontinence in childhood. For this reason I record the effect of the drug upon 28 children between 4 and 12 years of age who were suffering from one or both of these complaints.

MATERIAL AND METHOD

Of the 28 patients selected, 12 suffered from lienteric diarrhoea and 16 from faecal incontinence. The patients were seen in a hospital out-patient department, so that the diagnosis of the conditions was largely dependent upon the history and physical examination of each child. Urinalysis, radiological examination, E.S.R., and Mantoux tests were performed where they were considered necessary. Cases of incontinence due to indigestion or chronic constipation were excluded from the series. Twelve of the cases with encopresis probably also suffered from lienteric diarrhoea. To subdivide the group accurately would not be easy, nor would it serve any useful purpose.

Histories obtained from the 12 patients with lienteric diarrhoea showed that the condition had been present for periods varying from two months to three and a half years, and that nine of them had some degree of abdominal pain or discomfort from time to time. In the 16 cases of bowel incontinence the duration of symptoms varied from two months to five years, and 12 of them had diarrhoea and six had attacks of abdominal pain. Ten patients had urinary incontinence as well as faecal incontinence. In four of the 28 children, food, such as soup and fruit, could aggravate their condition. Five other patients were similarly affected by mental strain. In two cases the symptoms may have been partially due to difficulties in training, because one child was mentally retarded and the other was deaf. These factors, however, did not prevent penthienate from having some beneficial effect.

All the patients were treated in the hospital out-patient department. They were advised to take their usual diet, but the fluid intake of the 10 patients with both urinary and faecal incontinence was restricted. In each case penthienate was prescribed, a 5-mg. capsule to be taken two or three times a day after food. Treatment was continued for at least two months.

RESULTS

Of the 12 children with lienteric diarrhoea, 11 became asymptomatic. The patient who failed to respond to the specific treatment was admitted to hospital, where he immediately recovered with no medicine, presumably because of the change in his environment and mode of living. Of the 16 patients who were treated for encopresis, eight obtained relief, and eight partial relief of their complaint. Twelve of these patients also had diarrhoea, and this subsided completely in seven cases and diminished in severity in the remaining five. It is apparent that penthienate therapy benefited almost all of the 28 patients, the results being exceptionally good in those suffering from lienteric diarrhoea only and in half of those patients suffering from faecal incontinence. All but one case obtained some relief of their diarrhoea, and in some cases it was complete.

The influence of penthienate on abdominal pain, which was present in 15 out of the 28 patients, varied: in 10 out of the 15 the pain either disappeared or diminished, and in 5 the frequency and severity of the pain either continued

unaltered or became worse. The aggravation of the pain may have been due to the treatment, for two patients who had no abdominal pain or discomfort prior to penthienate therapy developed it while taking the drug.

Enuresis was noted in nine children. The response of this condition to penthienate was recorded: only one gained normal bladder control, in seven control of the bladder improved, and in one it remained unchanged. It would therefore seem that both abdominal pain and enuresis, when associated with either lenteric diarrhoea or encopresis, are likely to be alleviated by this treatment.

COMMENT

This paper does not describe a scientifically controlled investigation. Neither the methods of diagnosis of the conditions nor those of assessing the results of treatment fulfil the necessary conditions. Nevertheless, from a clinical point of view it is apparent that treatment of lenteric diarrhoea and faecal incontinence with penthienate leads to a marked improvement in most cases. The drug appears to be more effective than older methods of treatment, and when used alone or in conjunction with other remedies constitutes a definite advance in the treatment of these conditions.

ADDENDUM.—Since this memorandum was submitted for publication three further cases of encopresis and diarrhoea have been treated with penthienate methobromide. In one the encopresis was abolished and in the other two it was greatly improved. The diarrhoea subsided in each case.

Resistant Staphylococcal Puerperal Septicaemia Susceptible to Vancomycin

The resistant staphylococcus has for some time been a commonplace in the hospital nursery, and has lately invaded the general surgical wards, causing severe, sometimes fatal, damage. Its spread to the parturient mother, though not yet generally publicized, is obviously only a matter of time, and with this in mind we have thought it might be useful to record our recent experience with such a case.

CASE REPORT

The patient, a 10-para aged 40, was admitted to hospital with ruptured membranes on February 3, 1958, 11 weeks before the expected date of delivery. She continued to drain clear liquor, but as labour did not begin spontaneously antibiotic therapy was instituted after two days with "crystamycin," 1 g. twice daily. There was no change until nine days later, when the patient suddenly complained of severe malaise, and had a rigor with a temperature of 104° F. (40° C.). As the symptoms pointed to an infection of the urinary tract treatment was changed to "sulphatriad" and potassium citrate in high dosage, but, despite the persistence of pyrexia, this was discontinued when the result of urine examination proved negative. Labour began the same evening. The foetal heart sounds had disappeared four hours previously. She was delivered five hours later of a stillborn foetus of 4 lb. 15 oz. (2,210 g.) showing early maceration. The delivery was spontaneous, with a normal and complete third stage. Oxytetracycline ("terramycin"), 250 mg., was given six-hourly, together with vitamin-B complex in high dosage, and the temperature remained normal over the next two days. It then suddenly shot up again, rapidly becoming established as a high fever ranging between 103 and 106° F. (38.9 and 41.1° C.) with subnormal intermissions. The clinical picture was that of a typical septicaemia with recurrent rigors, physical deterioration, liver enlargement, and anaemia. A vaginal swab and repeated blood cultures yielded a profuse growth of *Staphylococcus aureus* resistant to penicillin but sensitive to chloramphenicol and erythromycin. Appropriate combined chemotherapy, details of which are shown in the accompanying Chart, failed to produce any improvement; the septicaemic condition continued unchecked and there

was clinical evidence of localization in the liver and on the heart valves as shown by hepatomegaly, and a harsh apical systolic murmur conducted into the axilla. The general condition of the patient rapidly deteriorated, with increasing hepatomegaly and incipient endocarditis, the E.S.R. remained high between 35 and 40 mm. (Westergren), the Hb percentage diminished from 84 to 57, and the cells showed marked toxic granulation.

At this stage it was decided to try the effect of the new antibiotic vancomycin, and, though not yet commercially available, a supply was obtained from the makers. The

result was immediate and dramatic. After the second eight-hourly intravenous injection of 500 mg., the temperature fell to normal, and, except for a small peak the following day, remained permanently subnormal. Blood cultures became sterile after three days, and the blood picture returned to normal. All the clinical signs and symptoms regressed rapidly and completely, and there was no remission when the drug was discontinued after 10 days, the patient leaving hospital very fit and well after a further 10 days.

COMMENT

Vancomycin is a new antibiotic produced from *Streptomyces orientalis*, an organism found in some Indonesian soils. Fairbrother and Williams (1956) have shown that it is lethal *in vitro* to most strains of *Staph. aureus* resistant to other antibiotics. More important, bacterial resistance to it is apparently unknown (Garrod and Waterworth, 1956). Only a small number of clinical cases have so far been treated (Kirby and Divilbiss, 1957; Griffith and Peck, 1956), but its value, though still largely undocumented, appears to be established, and it would seem the ideal counter to the increasing bugbear of the resistant staphylococcus. It unfortunately has one grave disadvantage—that it can be administered only by the intravenous route.

Vancomycin is manufactured under the trade name of "vancocin" by Eli Lilly and Co. Ltd., and we are much indebted to Mr. Cooke, of this firm, for a generous supply of the drug. We also thank Mr. A. Dickson Wright and Dr. Geoffrey Konstam for clinical advice and help.

Reviews

HARVEY TERCENTENARY CONGRESS

Circulation. Proceedings of the Harvey Tercentenary Congress. Edited by John McMichael, M.D., F.R.C.P., F.R.S. (Pp. 503+xxiii; illustrated. 50s.) Oxford: Blackwell Scientific Publications, 1958.

This book contains a summary of contributions made at the Harvey Tercentenary Congress last year. The standard of the contributions can be judged from the high international renown of all the contributors. The first part consists of eight short articles centred around Harvey himself, all of them very welcome to the medical historian. The main body of the book presents a most interesting cross-section of modern research on the circulation. It is only on seeing all the contributions to this congress collected together that one fully appreciates how successfully the celebrations were designed to bring out the protean forms of present-day research on the cardiovascular system. What is so striking is that all the contributions except three deal with the problems of blood flow, pressure, or resistance in the various circulations of the body. Harvey concerned himself directly with the question of cardiac output, and Stephen Hales, of Teddington, carried the matter further to quantitative estimation of systemic blood pressure. The largest part of the present work is devoted to the developments of just those problems of circulation which these two investigators originated. It is surprising to realize that these aspects of the circulation, which are indeed the next logical step from Harvey's own work, have had to wait for some 300 years for their further successful development.

It is a sign of our rapidly changing times that in such a book, summarizing present-day work on the heart and circulation, there is only one electrocardiogram and about a dozen radiographs. The large majority of the many illustrations concern haemodynamics and results of the application of the Fick principle. Thus, for those who wish to see where Harvey's original work leads, this book is of inestimable value. Incidentally, the quality of its production matches that of the contributions. Our gratitude to the Harveian Society, and in particular to Mr. Dickson Wright and Dr. Geraint James, for their inspired organization of these timely proceedings must be great indeed. Professor John McMichael has constructed an attractive book out of the varied historical and scientific contributions which constitutes at once a worthy and logical acknowledgment of Harvey's greatness.

K. D. KEELE.

ATOMIC ENERGY AND MENTAL HEALTH

Mental Health Aspects of the Peaceful Uses of Atomic Energy. Report of a Study Group. (Pp. 53. 3s. 6d.) Geneva: World Health Organization, 1958.

This report contains the collective views of an international group of experts "that met in Geneva under the auspices of W.H.O. for nearly a week in October, 1957. Tribute is paid to the stimulus provided by the World Federation for Mental Health, whose executive board had approved a statement and adopted a resolution dealing with the same subject at a meeting held in London earlier in the year. (These are reprinted in two annexes.) Some—but by no means all—of the topics considered in the report proper may be indicated by the main sectional headings. These are: (1) the personal challenge of atomic energy; (2) the question of brain damage from radiation; (3) the socio-economic impact of atomic energy on mental health; (4) unhealthy emotional responses immediately provoked by the advent of atomic energy; (5) mental health tasks. The third annexe is entitled "The Press and Atomic Energy."

It will be seen that the study group did not feel narrowly confined as to what could profitably be discussed and pro-

mulgated. It is conceded that no one can predict with confidence what atomic developments may take place, nor what their effect might be upon both individuals and groups. But it is argued that, whilst the material world may change with dramatic rapidity, human nature—so long as humanity survives—is likely to remain much the same. A liability to irrational fears and irresponsible actions will continue, and may be further intensified by new and startling developments. The basic principles of mental hygiene will maintain their validity. For example, children should "have an upbringing free from anxiety and hate—producing in individuals self-reliance and a sense of responsibility towards others." Again, "the creation of good human relations in the family, the place of work and the community" is of fundamental importance, as is the "education in mental health requirements" amongst "those in responsible positions in public life."

Amongst the "specific suggestions" under the section "Mental Health Tasks" it is proposed "that in local areas small but highly qualified interdisciplinary teams should be formed consisting of, perhaps, a psychiatrist, a psychologist, a sociologist, and a journalist. The plan could be carried out in the central governmental organization as well as in the local district or community." The duties of such teams would include the study of local conditions and local mental health problems; advice—"having regard to modern techniques of vocational selection"—in the selection of the more highly responsible personnel of atomic installations; the instruction of such personnel and of atomic scientists in the "basic psychological principles of human relations"; and in general the education of the public with the assistance of "specialized journalists in human relations."

The report concludes with an oracular peroration: "But in the long run the greatest hope of mental health in the future of the peaceful uses of atomic energy is the raising of a new generation which has learnt to live on terms with ignorance and uncertainty and which, in the words of Joseph Addison, the eighteenth-century English poet, 'rides in the Whirlwind, and directs the Storm.'"

DESMOND CURRAN

ENDOCRINE PATHOLOGY OF OVARY

Endocrine Pathology of the Ovary. By John McLean Morris, M.D., and Robert E. Scully, M.D. (Pp. 151; illustrated. 63s.) London: Henry Kimpton, 1958.

Although it is common knowledge that granulosa-cell tumours of the ovary may produce oestrogens and arrhenoblastomas cause virilization, pathological secretion of hormones by the ovary in other circumstances, and the consequences that may ensue from this, are much less widely appreciated. The admirable monograph by Morris and Scully, two acknowledged experts in this field, should therefore fill an important gap in medical literature. Its purpose, as set out in the preface, is "to correlate the pathological changes occurring in the ovary with the accompanying clinical endocrine findings and to evaluate both in the light of the material available for study." In this it succeeds admirably. The book is beautifully produced, well documented, and illustrated with superb photomicrographs. It begins with a very clear account of the cells of the gonads, which is followed by a summary of their embryology and the part played by hormones in sexual differentiation. The remainder of the introduction is concerned with the currently available hormone assays and with a classification of endocrine effects. There follow sections on non-neoplastic abnormalities of the ovary producing endocrine effects; granulosa-theca-cell tumours; Sertoli-Leydig cell tumours; sex-chord mesenchyme and mixed-cell tumours; lipid-cell tumours; germinomas, teratomas, and related tumours; and, finally, tumours with "functioning stroma." Everyone with an interest in ovarian pathology or in the endocrinology of the gonads can expect to read this book with enjoyment and profit.

G. I. M. SWYER.

LIPIDS AND ATHEROSCLEROSIS

Chemistry of Lipides as Related to Atherosclerosis. A Symposium. Edited by Irvine H. Page, M.D. (Pp. 342+xii; illustrated 63s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1958.

This book is a manifestation of the great increase of interest in atherosclerosis. Various aetiological theories have been proposed, and one of the factors which has been incriminated is dietary fat. The possible aetiological importance of dietary fat and the experimental and clinical evidence for an association of hypercholesterolaemia with atherosclerosis have focused attention on lipid metabolism. The lipids are of major significance in the problems of atherosclerotic heart disease whether they are of primary or secondary aetiological importance. The time is ripe, therefore, for a concise but detailed account of the chemistry of the lipids in relation to atherosclerosis. This book fills the purpose admirably. It contains the proceedings of an international symposium held last year in the United States. The contents include chapters concerning the chemistry or metabolism of cholesterol, fatty acids, triglycerides, phospholipids, and sphingolipids. Perhaps chapters of greater medical interest are those concerning dietary fats and human lipid levels, unsaturated fatty acids in coronary disease, lipoprotein lipase and the nature of the lipaemia clearing reaction, lipoproteins, and the non-esterified fatty acids in plasma.

For those not specifically interested in the problems of atherosclerosis this monograph will, as the title implies, hold limited attraction; for them it is sufficient to quote a statement of practical policy from I. H. Page's well-balanced introduction: "The evidence at present does not convey any implications for drastic dietary change, specifically in the quantity or type of fat in the diet of the general population on the premise that such changes will definitely lessen the incidence of coronary artery disease." For those actively studying atherosclerosis this book should prove most rewarding, and reference will often be made to it.

M. F. OLIVER.

HYPNOTHERAPY

Hypnosis in Health and Sickness. By Gordon Ambrose, L.M.S.S.A., and George Newbold, M.B., B.Sc., M.R.C.S., M.M.S.A., D.R.C.O.G., D.C.H. (Pp. 196. 15s.) London: Staples Press Ltd. 1957.

When the great Liston saw the inhalation of ether producing surgical anaesthesia for the first time at University College Hospital in 1841 he is said to have remarked, "This beats mesmerism hollow." And it has been one of the tragedies of mesmerism and of hypnosis since then that, although sometimes very useful treatments, they have so often turned out to be only temporary palliatives for a wide range of ailments, for some of which better and more specific treatments are always in the process of being discovered. But exponents of hypnotism have never been backward in pressing its therapeutic virtues, and this has resulted in wave after wave of enthusiasm for mesmerism or hypnosis, always followed by profound disillusionment when it has become practised on too wide and indiscriminate a scale.

This particular book seems to be written more for the lay reader than the general practitioner and medical specialist. Note its style: "The cerebellum, which lies behind and below the cerebrum, is divided into two hemispheres," etc. Special care is therefore necessary to avoid the raising of false treatment hopes in the lay mind. But when we turn to such chapters in this book as "Disorders of Women and Hypnototherapy" we find the possibilities of hypnosis discussed in such varied conditions as delayed menstruation, amenorrhoea, pseudocyesis, functional uterine bleeding, dysmenorrhoea, sterility, the menopause, psychogenic leucorrhoea, pruritus vulvae, and so on. And in the field of the neuroses claims are made that hypnosis may help certain patients with anxiety states, depressions, hysterical personalities, obsessional compulsive illnesses, psychosomatic

illnesses, and post-herpetic neuralgia. There are other special chapters on "Hypnosis in Midwifery" and "Hypnosis in Children." A final chapter on "Other Uses of Hypnosis" includes dentistry, obesity, smoking, homosexuality, alcoholism, and sport, and the uses of hypnosis in helping to pass examinations and as an aid to members of the theatrical profession. Few normal, neurotic, and especially hypochondriacal people will fail to find at least one of their complaints, and its treatment by hypnosis, discussed in this book. It is a conscientious and sincere attempt to discuss the possibilities of hypnotic treatment in a whole variety of conditions, and in terms understandable to the ordinary reader. But the general impression left in the lay mind, as it was in the reviewer's, may prove to be an exaggerated one as to the possibilities of hypnotherapy in so many of life's very varied ills.

WILLIAM SARGANT

SURGICAL MANAGEMENT

Principles of General Surgical Management. By H. A. F. Dudley, F.R.C.S.E., with the assistance of B. C. Paton, M.R.C.P.E., I. F. MacLaren, F.R.C.S.E., I. B. Tait, F.R.C.S.E., and G. F. Murnaghan, F.R.C.S., F.R.C.S.E. With a foreword by John Bruce, C.B.E., T.D., F.R.C.S.E. (Pp. 203+viii; illustrated. 27s. 6d.) Edinburgh and London: E. and S. Livingstone. 1958.

This book has been written for house-surgeons, and it contains a deal of practical information set out in a most readable manner. Like some of the better books of its type, it can be read with advantage by those who are more senior. The pre- and post-operative treatment of patients is considered in a sensible manner, with particular reference to the more common complications and their prevention. There is special consideration of abdominal operations and those on the urinary tract, post-operative thrombo-embolism, and parenteral therapy. A chapter is also devoted to investigative work. The author admits to the expression of dogmatic opinion, and in a book of this kind it may well be a virtue. This book would help the surgical dresser in appreciation of his patients, and the house-surgeon who possessed its knowledge would be useful indeed. It can be strongly recommended.

MATURITY AND BEHAVIOUR

Physical Maturing and Behaviour at Adolescence. By J. M. Tanner, M.D., D.Sc., D.P.M. (Pp. 45; illustrated. 2s. 6d.) London: National Children's Home. 1953.

This is the 1958 National Children's Home Lecture, one of a series devoted to child welfare. It is based largely on material drawn from Dr. Tanner's book *Growth at Adolescence* (Oxford, 1955). Perhaps the only point which calls for comment is a welcome emphasis on the significance of developmental age in relation to educational achievement. The fact that children who mature early appear to be intellectually a little more advanced than those who mature late has some bearing on the reliability of a classification based on an examination at fixed age, such as the 11-plus.

T. McKEOWN

A recent report in this *Journal* drew attention to the prevalence of tuberculosis in domestic animals. Those wishing to learn more of this subject will find it well discussed in *Tuberculosis in Animals and Man—A Study in Comparative Pathology* (Cassell and Co. Ltd., 5 gns.), by Dr. John Francis, professor of veterinary preventive medicine in the University of Queensland. About one-third of this book of 380 pages is given up to the subject of bovine tuberculosis. The next section of the book, the longest, describes tuberculosis in animals other than bovines (including wild animals), and there is a final chapter comparing the pathology and epidemiology of tuberculosis in animals and man. The book is well illustrated, and contains a list of about 600 references.

PROGNOSIS FOR CHILDREN OF LOW BIRTH WEIGHT

The better survival rates for prematurely born infants, and particularly for those of very low birth weight, result from skilled care by experienced staff in well-equipped units. But improved survival rates do not provide ground for great satisfaction unless proof exists that the survivors live to be happy and to give happiness. Such a shrewd clinician as Sir Robert Hutchison¹ remarked almost twenty years ago: "I have a strong suspicion that, of those who survive, a large proportion turn out defective either physically or mentally." Should this prove to be so, then more efforts must be put into preventing premature births and into developing better treatment, possibly quite revolutionary treatment, for those whose premature delivery is inevitable. A bold attempt to assess the physical and intellectual development of prematurely born children was planned by the Joint Committee of the Institute of Child Health (University of London), the Society of Medical Officers of Health, and the Population Investigation Committee. All premature babies born during a single week in 1946 in England, Wales, and Scotland were matched with a control group of full-term children. The results of this survey have been published in four papers describing their health,² their growth,³ their age at walking,⁴ and their mental ability and school achievement at 8 years of age.⁵ A higher morbidity and mortality extending beyond the first month of life existed in the premature group, the surviving members of which spent 3½ times as many days in hospital during the first two years as did the controls. Although rather shorter and lighter than the controls at 2 and 4 years, almost 40% were of normal or above normal proportions. Babies who weighed less than 4 lb. (1.8 kg.) at birth gained rather better than the others, except

a group whose small size was thought to be genetic. When examined at 8 years the premature children scored slightly but significantly less than their controls at tests of reading, vocabulary, and picture interpretation, this handicap being most obvious in reading. The handicaps did not increase significantly with either falling birth weight or decreasing length of gestation. A small group emerged which was heavily handicapped in all tests and for whose low birth weight no obstetric or genetic explanation was found.

This study on prematurity began with a total of 676 matched pairs. From this, however, 177 were lost by the death of one or other member of a pair, 49 by emigration, 11 by refusal, 16 were untraced in time for testing, 8 were untested because they were educationally subnormal, and 8 because they were ill or handicapped. The final examination of mental ability was carried out on 407 pairs, or 60% of the original sample. Loss from the series of more seriously handicapped children is at least possible. J. W. B. Douglas³ states that "in general the mental handicaps of premature children are small if we exclude those with a history of birth injury or cerebral damage." Although these clinical diagnoses are often made, paediatricians cannot always be certain that damage was sustained before, at, or after birth, and in any event such abnormality is a hazard of prematurity which must be fully taken into account when considering the fate of the prematurely born.

The immediate mortality is still much higher among infants of very low birth weight, and their progress during the first few weeks of life is more commonly interfered with by cyanotic attacks, the pulmonary syndrome, oedema, jaundice, and infection than is that of full-term infants. The mental development of this relatively small group may not be accurately reflected in the mean figures obtained from a large series of prematurely born babies. Of the premature infants studied in Edinburgh by C. M. Drillien and F. Richmond,⁶ 57% were in the range 4 lb. 9 oz. (2 kg.) to 5 lb. 8 oz. (2.5 kg.), and Drillien⁷ showed that among primiparous mothers 49% of infants of 38 weeks' or more gestation were premature by weight, and that among the higher parities the figure was 37%. Most of such babies were in the range 5 lb. (2.25 kg.) to 5 lb. 8 oz. (2.5 kg.). J. H. Hess and E. C. Lundeen⁸ have described the progress of 82% of 259 infants who weighed from 1 lb. 10 oz. (0.75 kg.) to 2 lb. 8 oz. (1.13 kg.). They considered physical development to be average in 43% and mental development in 59%, but gave no details of the criteria of normality. Of 70 surviving

babies weighing less than 3 lb. 4 oz. (1.5 kg.) at birth, B. D. Corner⁹ reported that 76% were absolutely normal physically and mentally. H. Knobloch and colleagues¹⁰ found that, out of 57 infants whose birth weight had been 3 lb. 4 oz. (1.5 kg.) or less, 44% had an abnormal condition of sufficient severity to cause concern about future development—a figure which contrasted with 8.6% for the rest of the premature infants studied and 2.6% for full-term infants.

The present studies of C. M. Drilien¹¹ are all the more valuable in that she has maintained almost intact a group of 75 infants weighing 3 lb. (1.36 kg.) or less at birth and has personally examined each of the survivors, some only once, but otherwise every six months. Five died before the age of 2 years (one from bronchopneumonia), two were found dead in bed, and two died suddenly before medical assistance could be obtained. The great majority of survivors were considerably below average in both weight and height, the children being disproportionately underweight for height. Poor mental ability was distressingly common. Developmental quotients of 90 or over were found in only 37% of the pre-school group, and of the children of school age only 3 of 21 were of average intelligence. Four children omitted from the published figures have since been found to have intelligence quotients of 92, 90, 67, and 67. Only two surviving children of the original series have not been tested. No correlation was found between particular clinical disturbances in the newborn period and later mental development. Six children suffered from cerebral diplegia. Half the children had a visual defect, amounting to handicap in one-third. The incidence of respiratory infections in the first three years was four times higher than in a matched control group of full-term children. Emotional disorder was found in one-third. Mental damage was less apparent in the children of school age than in those a year or two younger. Drilien suspects that this is a result of improvement in the survival rate in recent years rather than of recovery with age, and further study of her group may supply the answer. The need for well-financed and well-planned research in this field is clear.

DELAYED AUDITORY FEEDBACK

Does the sound of a person's own voice have any effect on how he speaks? This question has been argued from a theoretical standpoint for many years. It has been suggested, for instance, that we may unconsciously control or "monitor" what we are saying by attending carefully to our utterances while we speak, and that certain abnormalities of speech may

result if this process is disturbed. On this view the disorder known as jargon aphasia, in which words are strung together so as to constitute meaningless nonsense or jargon, is the result of a breakdown in the monitoring mechanism. It is assumed that, because these patients cannot understand what is said to them, they also cannot understand what they themselves are saying, and therefore they speak jargon. Against this view it has been pointed out that people with bilateral cochlear or nerve deafness, who also cannot hear what they themselves are saying, do not speak jargon, and conversely that patients who suffer from word deafness, though unable to understand what is said to them and, presumably, what they say themselves, nevertheless have normal spontaneous speech. Such arguments have previously been carried on in a climate sheltered from the cold winds of experimental proof. But the discovery in recent years of the effects of delayed auditory feedback has thrown much light on the question.

Delayed auditory feedback may be explained in the following terms. Normally while we are speaking the sound of our voice reaches the internal ears by conduction through bone and air. The speed of conduction by these two routes has been estimated by C. A. Stromsta¹ as 0.0003 second for bone conduction and 0.001 second for air conduction; normally the aerial route is by far the most important. It may be said, therefore, that we hear our own words 0.001 second after we have uttered them, and this information about the sounds we are uttering constitutes auditory feedback. This is in contrast to kinaesthetic feedback, which consists of proprioceptive information arising from the activity of the organs of speech. If this almost instantaneous auditory feedback is delayed to between 0.09 and 0.3 second, as it can be by electro-mechanical methods, curious effects are produced on the speech of normal subjects. Such a delay in auditory feedback can be achieved by recording the subject's voice through a microphone on to a magnetic tape, from which it is played back after a delay to headphones worn by the subject. In order to be effective in this way, the circuits which produce the delay in auditory feedback must permit of adequate volume and clarity in the voice as transmitted to the subject through headphones. B. S. Lee in 1950² and 1951³ described the artificial stutter produced by this delay in speech feedback, and J. W.

Black⁴ found that the most effective delay period was 0.18 second.

Since this time interest in the technique has grown and several papers have appeared describing the results obtained in normal subjects. B. Spilka⁵ found that when delayed auditory feedback was imposed there were increases in the average duration of syllables, the percentage phonation time, the mean vocal intensity, and in variations of vocal intensity. To these effects may be added a raising of pitch of the voice, flattening of intonation, alterations of stress and disturbance of rhythm, reduplications of consonants and syllables, and substitutions of wrong consonants, syllables, or even words. Sometimes a complete block in speech utterance occurs, resembling that found in severe stammering. J. T. Beaumont and B. M. Foss,⁶ investigating individual differences in susceptibility to delayed auditory feedback, found that, while all normal subjects appear susceptible, adaptation may occur in two ways: first, if the subject speaks very slowly, and secondly if he speaks in short rapid bursts. The rapidity with which adaptation occurs appears to differ between individuals, and Beaumont and Foss conclude that people who are particularly susceptible to the effects of delayed auditory feedback may have something in common with natural stammerers. B. Spilka⁷ attempted to correlate the susceptibility to auditory feedback with various personality types, and concluded that schizoid personalities are not so easily disturbed as others.

These observations show that disturbance in the time relationships between the utterance of speech and the hearing of the sounds uttered may produce a considerable disorganization in speech, and they strengthen the view that auditory monitoring plays a part in normal spoken speech. It would appear that delayed auditory feedback is a spanner which may be thrown into the workings of normal speech, disorganizing it in a predictable way. Some of the uses to which this technique may be put have been illustrated in recent publications. C. N. Hanley and W. R. Tiffany⁸ have used the method for detecting psychogenic deafness and malingering. J. B. Stanton,⁹ in a lecture in 1957 recently published, reviews the speech disturbances produced in normal subjects, and reports the effects of delayed auditory feedback in dysphasic patients. In this study delayed auditory feedback was used as a tool to probe the underlying physiological disturbance in the dysphasic patients. Stanton finds that, unlike the normal subjects, the patients with dysphasia do not all respond in the same manner to delayed auditory feedback. While some of the patients (those with predominantly

expressive dysphasia) showed similar disturbances to those of normal subjects, the speech of others who suffered from mainly receptive dysphasia was actually improved by delayed auditory feedback. A third group with expressive or receptive speech disorders of recent onset was relatively unaffected. This use of delayed auditory feedback as an analytical tool may well lead to a more dynamic concept of the mechanisms of aphasia.

The application of delayed auditory feedback to treatment is not yet clear. E. C. Cherry and colleagues¹⁰ have shown that many stammerers are enabled to speak normally when their auditory feedback is blocked by a loud noise. This effect of neutral noise would seem to be the explanation of the similar results obtained with delayed auditory feedback in stammerers. Possibly the reported improvement⁹ in speech of patients with receptive aphasia while subjected to delayed auditory feedback may have some application to speech therapy. Finally, the results obtained with this interesting new technique also suggest that the traditional distinction between disturbances of formulation and comprehension of speech (the aphasias) and disturbances of utterance of speech (dysarthria, stammering) may be less real than had previously been supposed.

ACCURACY OF DEATH CERTIFICATES

How accurate are death certificates is a question that has been debated more often than investigated. Clearly some causes of death are easier to diagnose precisely than others, and some categories are easier to define unambiguously than others. The statistics are generally believed to be sufficiently accurate for practical use, and by grouping some categories errors can be made to cancel out. A small but interesting study of this problem, including references to previous work on it, has now been published by the Registrar-General for England and Wales.¹

Ten large English hospitals arranged for a double death certificate to be completed on every patient dying in the hospital between February 1, 1955, and July 31, 1955. A clinician completed the first half before necropsy was carried out, and a pathologist completed the second half in the light of his post-mortem findings. In these six months 1,404 cases were accepted into the investigation from the ten hospitals, and pathologist agreed with clinician on the cause of death in 51% of them. To this figure it seems reasonable to add 28% of cases in which the disagreement between pathologist and clinician seemed to the investigators to be verbal rather than factual. In short, about 80% of these deaths were correctly certified by the clinicians.

¹⁰ Cherry, E. C., Marland, P. M., and Sayers, B. McA., *Nature (Lond.)*, 1955, 176, 874.

The 19% of cases in which the pathologist found fresh evidence at necropsy were chiefly among newborn babies and old people. The difficulty of identifying the exact cause of death in these groups is well known, and the figures show that the difficulty does increase throughout adulthood into old age. Agreement was highest on deaths of patients aged 15-44.

When the various causes of death were considered to see which groups evoked most agreement or disagreement, some striking figures were obtained for cancer of the lung, which was notably under-diagnosed, especially in old patients. Of 87 cases assigned to this cause 8 were found at necropsy to have another cause, and in 30% of the remainder the pathologist found a previously unsuspected cancer of lung or bronchus. Though the doctors who took part in this investigation are not put forward as a representative sample of the profession (they were all members of hospital staffs, for instance), their results suggest that the much higher death rate from lung cancer in Great Britain than in the U.S.A. cannot be attributed to over-reporting of it here, as has recently been conjectured.² Arteriosclerotic and coronary heart disease was another group that caused disagreement, for on 227 certificates clinician and pathologist agreed in only 41%. This agrees closely with the figure of 44% accuracy rate for myocardial infarction found by B. C. Paton³ in a review of necropsies at the Edinburgh Royal Infirmary, discussed recently in these columns.⁴ In the Registrar-General's investigation a particularly notable cause of death which clinicians mistook for coronary disease was pulmonary embolism.

While disagreement about facts was prominent in the diagnosis of coronary disease, disagreement about words largely confused the diagnoses of death from hypertensive disease. Among 86 cases in which this was given as the diagnosis, disagreement between clinician and pathologist was noted in 66 cases (77%). But in 52 of these cases (60%) wording was the cause of difference. This is a natural consequence of the association apt to be found between hypertension and renal or cerebrovascular disease.

TREATMENT OF CARBON MONOXIDE POISONING

An important communication from the Medical Research Council on the use of carbon dioxide in the treatment of carbon monoxide poisoning appears at p. 1408 of the *Journal* this week. After studying the results of some recent experiments by the M.R.C.'s Breathing Apparatus Committee, and of data obtained from independent work on human volunteers, the M.R.C. concludes that "the administration of a mixture of carbon dioxide in oxygen leads to the more rapid elimination of carbon monoxide from the blood than does the administration of oxygen alone."

² Donald, K. W., and Paton, W. D. M., *Brit. med. J.*, 1955, 1, 313.

³ Marriott, H. L., *ibid.*, 1955, 1, 664.

⁴ Hill, A. B., *ibid.*, 1956, 2, 1220.

Three years ago a committee of the M.R.C. considered the problem of whether or not carbon dioxide should be given with the oxygen as a first-aid measure to patients poisoned by carbon monoxide, and recommended that it should not be.⁵ The reasons for this decision were fully set out and are complex, but an important one was that, in the uncontrolled conditions of first aid, carbon dioxide might accumulate dangerously in the patient's tissues. Dr. H. L. Marriott⁶ challenged the committee's conclusion, because he considered, as others have done, that the administration of oxygen and carbon dioxide stimulates the depressed breathing of patients severely gassed with carbon monoxide. It is this view that the M.R.C. endorses in its latest statement.

Though the difference in the results obtained by the two methods of treatment may be small—and none was found in an analysis of some admittedly imperfect statistics⁷—clearly nothing short of the very best is good enough for patients hovering between life and death, as these usually are. And, so far as it can be ascertained, the best treatment does seem to be a mixture of 5% carbon dioxide with 95% oxygen when the patient is suffering from carbon monoxide poisoning. For the treatment of other types of asphyxia and anoxia the M.R.C. continues to advocate pure oxygen.

EPIDEMIC NEPHRITIS

The typing of *Streptococcus pyogenes* has been used for many years as a useful epidemiological device for determining the origin of outbreaks of streptococcal disease and in studies of the spread of streptococcal infection in communities. The type of organism found may also have clinical significance. It has been noticed that certain types, and particularly type 12, are more often associated with the development of nephritis than others. In 1954 M. J. Wilmers, A. C. Cunliffe, and R. E. O. Williams⁸ found that of 31 strains of *Streptococcus pyogenes* recovered from cases of acute glomerulonephritis 28 were of type 12. This is taken a stage further by two articles appearing in this issue. Dr. J. T. A. George and his colleagues describe the finding of four cases of acute nephritis among 24 boys in a residential school who had suffered from acute pharyngitis 10 to 19 days previously. About two months after the sore throats had occurred seven of the boys were still harbouring *Streptococcus pyogenes* type 12, and at this stage red cells were found in the urine of five children not previously suspected of having nephritis. Investigations carried out in neighbouring schools showed type 12 or related strains to be present in some of them; red-blood cells and casts were found in some specimens of urine, but only in the infected schools. Nearly a year later, when there were signs that further cases of nephritis were occurring, letters were sent to all doctors practising in York and the

⁸ Wilmers, M. J., Cunliffe, A. C., and Williams, R. E. O., *Lancet*, 1954, 2, 17.

⁹ Report of Ministry of Health for the Year 1957, Part 2, p. 42. H.M.S.O., 1958.

North Riding. This brought to light 48 cases. In spite of the fact that many of them were not examined bacteriologically until some time after onset of the infection, type 12 streptococci were recovered from a substantial proportion of them. The disease was found most commonly in children of school age, and this was the finding also in the other survey reported by Drs. M. J. Pleydell and W. J. A. Hall-Turner from Northamptonshire. Here investigation of the circumstances of a small outbreak of nephritis in a village school suggested that the disease might be more widespread. Again all doctors practising in the county were circularized by the medical officer of health and asked to report any cases under their care. As a result 89 cases of nephritis, occurring over a period of three years, were brought to notice, and type 12 streptococci were recovered from a high percentage of the cases.

In both these investigations information on the local distribution of nephritis was obtained by asking doctors in the locality to notify cases, and this method was successful in demonstrating the distribution of the disease in the area. Whether such a procedure should be adopted more generally may depend partly on the use that can be made of the information so obtained. It has been suggested that the existence of a case of acute nephritis may justify the use of energetic preventive measures against the spread of streptococcal infection, including the giving of prophylactic penicillin to close contacts.⁹ Pleydell and Hall-Turner mention the advisability of protecting nephritic children from reinfection: one way of doing this would be to exclude them from school when upper respiratory infections were present.

MEDICAL SERVICES REVIEW COMMITTEE

The first meeting of the Medical Services Review Committee, sponsored by the Royal Colleges, the Scottish Royal Corporations, the College of General Practitioners, the Society of Medical Officers of Health, and the British Medical Association, was held on November 27. Sir Arthur Porritt, the chairman, presided, and the following have been appointed as members of the committee: Dr. T. Anderson; Dr. W. Ferguson Anderson; Dr. J. T. Baldwin; Dr. I. R. C. Batchelor; Sir Harold Boldero; Mr. W. S. Braidwood; Mr. R. Brearley; Professor J. Bruce, P.R.C.S.Ed.; Dr. H. D. Chalke; Professor A. M. Claye, P.R.C.O.G.; Mr. E. Cope; Dr. A. B. Davies; Dr. T. B. S. Dick; Miss A. M. Dickens; Dr. J. Fry; Dr. A. Rae Gilchrist, P.R.C.P.Ed.; Dr. I. D. Grant; Dr. C. F. Hawkins; Mr. W. Hawksworth; Mr. R. G. Henderson; Dr. J. H. Hunt; Mr. Arthur Jacobs, P.R.F.P.S.; Dr. A. M. Maiden; Mr. D. F. E. Nash; Dr. I. Rannie; Dr. T. Ferguson Rodger; Dr. J. M. Rogan; Mr. J. A. Ross; Sir James Paterson Ross, P.R.C.S.; Mr. T. Holmes Sellors; Dr. G. Swift; Sir Tudor Thomas; Dr. J. B. Tilley; Dr. F. G. Tomlins; Dr. S. Wand; Professor R. C. Wofinden. The committee's terms of reference are to review the provision of medical services

to the public, and their organization, in the light of ten years' experience of the National Health Service, and to make recommendations.

RE-STENOSIS OF THE MITRAL VALVE

The surgical treatment of mitral stenosis has now been practised for a decade,¹ and with the publication from various centres of reports on patients observed for five years or more the early results of this operation can be assessed. A disappointing outcome in some cases is re-stenosis of the mitral valve, and in a recent article J. R. Belcher² discusses this eventuality. It is too early yet for accurate figures to be obtainable, but a re-stenosis rate of between 2 and 5% is usually quoted. Glover and his colleagues,³ among others, believe that if complete division of both fused commissures has been done at the first operation re-stenosis will not occur: they have not found a case in their own series. Most authors agree that there are two main groups of patients with mitral valve disease who may need a second operation. The first and larger is that described by Belcher as "false re-stenosis," believed to be the result of an inadequate first operation. This may be due to the surgeon's inexperience, and is consequently higher in the earlier cases of his series, but it may also be due to pathological changes such as gross calcification in the valve. It will be interesting to see whether improved surgical techniques in mitral valve surgery, such as C. P. Bailey's⁴ right-sided approach or the transventricular dilatation advocated by A. Logan,⁵ will lower the incidence of re-stenosis in the next few years. Since a rigid valve is more likely to give trouble, division of both commissures, if at all possible beyond R. C. Brock's⁶ critical area of tendon insertion, should restore the valve to maximum mobility and reduce the chances of re-stenosis. Coincident with commissural fusion is the matting together of chordae tendineae below the valve, and the surgeon must ensure that they are separated at operation. Some suggest that if a satisfactory opening of 2½ to 3 fingerbreadths can be obtained by splitting the anterolateral commissure alone the posterior commissure can be left, unless it splits easily. This may reduce the operative mortality, but may also lead to a higher recurrence rate. Belcher found that in his series no second operation was needed in 186 patients who had had good commissural division; but out of 43 patients at whose operations the split was classified as fair five needed second operations, while out of eleven patients with a poor split six had to be operated on again.

Cases of true re-stenosis of the valve after a satisfactory first operation form the second main group, though a much smaller one than those with false

re-stenosis. The cause of this is not certain, but continued rheumatic activity or an attack of subacute bacterial endocarditis is usually blamed. It is not clear how an avascular valve can lay down further fibrous tissue, but F. R. Magarey⁷ has suggested that a platelet and fibrin thrombus forms between the roughened edges, so sticking them together. It is difficult to be certain of the occurrence of true re-stenosis unless the same surgeon does both operations and has accurate records of the state of the valve, or unless the valve can be inspected at necropsy. Ideally, simultaneous estimations of pressure gradients across the mitral valve and of the cardiac output before and after each operation are the only sure way of supporting the evidence of the surgeon's finger *in vivo*. F. Soulié and colleagues⁸ noted that the second operation was always harder owing to increased rigidity and thickening of the valve leaflets and that instrumental dilatation was always needed. In spite of a satisfactory original operation, true re-stenosis may be expected to occur in from 2 to 5% of cases.

E. G. L. Bywaters and his co-workers⁹ recommend the prevention of further attacks of rheumatic fever in children by long courses of antibiotics, and in the United States it is common practice to give penicillin for long periods to patients who have had a mitral valvotomy. The administration of antibiotics might therefore be one possible way of reducing the incidence of re-stenosis. Before a second operation for stenosis of the mitral valve is performed the degree of damage to the myocardium by the rheumatic process, the amount of mitral incompetence present, and the height of the pulmonary vascular resistance should all be assessed, since any of these may be responsible for a poor post-operative result. Operation can only relieve valvular obstruction if proved to be present, and, if successful, it may lessen the severity of these other defects.

FOOTBALL AND THE HEART

The problem of preventing coronary arterial disease is of central importance in cardiology to-day. So far we have only faint clues to its solution, important among these being the effect of diet on the healthy state of the coronary arterial tree, and occupational and possibly racial factors.

Whether exercise, or lack of it, is a factor in the causation of the disease is also an important consideration. Recently William C. Pomeroy and Paul D. White¹ investigated a group of 355 men who had distinguished themselves athletically at football while at Harvard University between the years 1901 and 1930. Coronary arterial disease as a cause of death was only slightly less frequent among this group of athletes than in all adult white males in the State of Massachusetts in the year 1940, chosen arbitrarily as a comparison. More accurate comparison with Harvard graduates of the same age who had not played football was desirable, but the necessary data were not available. Interesting differences, however, were observed within the group of

athletes. One was the higher incidence of "unfavourable family health," which usually meant coronary arterial disease, in the relatives of those athletes developing coronary disease themselves in later life. Another interesting finding was that no member of the group of athletes developed coronary arterial disease who continued to take active and strenuous exercise throughout the rest of his life after leaving the university. It might be supposed that this was a reflection of their good health rather than the cause of it, but against this was the fact that in most cases the habit of active exercise, or abandonment of it, was formed quite early in life, before the onset of the first symptoms of coronary arterial disease. No very significant differences in other factors investigated were noted between those athletes who did, or did not, develop disease of the coronary arteries: these included consumption of alcohol, smoking, diet (about which data were inadequate), and body build. More work is needed to determine the significance of these findings in this small group of athletes, but the tentative conclusion from this study is that an athlete who continues to take active exercise throughout his life is unlikely to develop coronary arterial disease.

RICHARD BRIGHT, 1789-1858

"Richard Bright was an extraordinary man. It is impossible to place geniuses in order, but he would certainly be among the first five or six in our profession." This is what Sir William Hale-White wrote in the *Guy's Hospital Reports* thirty-seven years ago. This article is now reprinted in a special number of this most notable among hospital periodicals, middle in age between the *Lancet* and the *B.M.J.*, as Dr. E. R. Boland told us at a commemorative dinner given by Guy's Hospital Medical School on Monday in the Royal College of Physicians, where Bright was admitted as a Licentiate in 1816 and as a Fellow in 1832. An Englishman who qualified in Edinburgh in 1813, Richard Bright's association with Guy's began as early as 1811. In 1820 he was elected assistant physician to the hospital, and in 1824 full physician. He died on December 16, 1858. It was his "Reports of Medical Cases" in 1827, in which albuminuria and dropsy were causally linked with pathological changes in the kidney, that gave him his fitting place in the history of medicine, and two long papers on what has since been commonly known as "Bright's disease" appeared in 1836 in the first volume of *Guy's Hospital Reports*, the current number of which, in its gold and blue cover, completes the 107th volume with an act of filial piety that will be a delight to all and a collector's piece for the medical historian. We learn from it that when he was 24 Bright wrote to his father, "You must know that surgery is at this moment rising very fast at the expense of medicine—and we must do our best to keep our ground." One of the signs that surgery is still rising very fast is the fact that the editor of this special number dedicated to Richard Bright is a surgeon, Sir Russell Brock.

Drug Treatment of Disease

DRUG TREATMENT OF NEURITIS

BY

J. W. ALDREN TURNER, D.M., F.R.C.P.

Neurologist, St. Bartholomew's Hospital

Neuritis is a much misused term. Many of the conditions to which it is sometimes applied are in fact of mechanical origin. For instance, brachial neuritis may be used as a diagnostic label for pain in the arm accompanied by paraesthesiae and neurological signs when in fact the basic cause is compression or irritation of posterior roots by a protruding intervertebral disk or cervical spondylosis, pressure on the brachial plexus by a cervical rib or by drooping of the shoulder girdle in the axillary-inlet syndrome, or injury of a peripheral nerve, as by compression of the median nerve in the carpal tunnel or friction to the ulnar nerve at the elbow in association with cubitus valgus or osteoarthritis of the elbow. Similarly, in the lower limb, sciatic neuritis and femoral neuritis probably do not exist, the majority of cases of sciatica and anterior crural pain being due to mechanical causes, such as protrusion of intervertebral disk or other lesions compressing the nerves or posterior roots. In such cases drug treatment can only be of very limited value and consists of suitable analgesics. The essential treatment for the condition—immobilization, physiotherapy of various types, manipulation, or surgical treatment—varies with the aetiology. The administration of vitamin-B preparations for such conditions has no rational place in treatment.

Multiple peripheral neuritis or polyneuritis is to some extent also a misnomer, but in many of such cases there are changes in the parenchyma of the peripheral nerves. There are many possible causes of polyneuritis, and in some of them drug treatment is of value.

Deficiency of Vitamin B₁

Deficiency of aneurine (vitamin B₁) in relation to the carbohydrate intake may cause peripheral neuritis as a result of disturbance of carbohydrate metabolism in the nervous system at the pyruvate stage. In such cases the amount of pyruvate in the blood is increased, and this can, if necessary, be shown by a pyruvate tolerance curve. Actual deficiency of aneurine in the diet is rare in the United Kingdom, but defective absorption may occur in cases of steatorrhoea, long-continued diarrhoea, extensive resection of the small intestine, and long-continued fever; and a deficiency peripheral neuritis may occur in these conditions. The peripheral neuritis of alcoholism is to a large extent due to aneurine deficiency in relation to the carbohydrate intake.

In such cases treatment should be started at the earliest opportunity before degenerative changes have occurred in the peripheral nerves and when the lesion is still a biochemical one. The first essential is large doses of aneurine by injection, and, as in many cases there is also a deficiency of other elements of the vitamin-B complex, and of vitamin C, these should be given in addition, together with a normal diet. A suitable preparation for starting treatment is "parentrovite" high potency intramuscular injection, each injection of 7 ml. containing aneurine hydrochloride 250 mg., nicotinamide 160 mg., riboflavin 4 mg., pyridoxine 50 mg., and ascorbic acid 500 mg. After daily injections have been given for a week oral treatment should be continued with tab. aneurin. co. fort. (B.N.F.), which contains aneurine hydrochloride 5 mg., riboflavin 2 mg., nicotinamide 20 mg., and pyridoxine 2 mg., a tablet being taken four times a day.

Acute Infectious, Toxic, or Febrile Polyneuritis (Guillain-Barré Syndrome)

Although the aetiology of this type of polyneuritis is uncertain, the evidence suggests that it may be allergic in nature. For this reason it has been treated with cortisone or prednisone. The natural history of the disease is for rapid deterioration to take place over the course of a few days up to two to three weeks; if the patient survives the acute stage, rapid recovery of function usually occurs. This type of natural history makes it difficult to estimate the value of cortisone therapy, but published cases and personal experience certainly suggest that it is of value in stopping deterioration and possibly in hastening recovery. Cortisone should be given as early as possible, and a suitable dosage for an adult is 300 mg. (in divided doses) daily for two days, 200 mg. for two days, and then 100 mg. daily for ten days, the dosage then being gradually tailed off. Prednisone is less likely to cause retention of salt, and for this reason is usually the preferable preparation to give (5 mg. of prednisone being equivalent to 25 mg. of cortisone).

Lead "Neuritis"

This condition is probably the result of a disturbance of resynthesis of phosphocreatine in the muscles affected rather than a disorder of the peripheral nerves. In the last few years the treatment of acute lead-poisoning, such as lead encephalopathy, has been greatly improved by the introduction of the chelating agent calcium disodium ethylenediamine tetra-acetic acid, or sodium calciumedetate ("calcium disodium versenate"), and though reports of its use in lead "neuritis" are scanty it would seem to be the rational method of removing the lead from the body in this condition. When this chelate is administered to a patient with lead-poisoning, the lead replaces calcium in the chelate, the resulting compound being excreted in the urine. The chelated lead compound does not ionize and so there is little danger of causing symptoms of acute lead-poisoning, which was always a risk with the older methods of removing lead from the body.

The preparation is supplied in 5-ml. ampoules containing 1 g. in a 20% aqueous solution; this should be diluted in 250-500 ml. of injection of sodium chloride B.P. or injection of dextrose B.P. and administered by intravenous drip over the course of an hour. For adults this dose should be given twice daily for five days; then there should be a rest for two days, followed by a further five days of treatment. Calcium disodium versenate can be given by mouth, but it is not yet clear how effective this method of administration is in removing lead from the body.

Diabetic Neuritis

The most essential treatment in the peripheral neuritis associated with diabetes mellitus is the adequate control of the disease by diet and in most cases insulin. Patients suffering much pain may sometimes have this alleviated by injections of vitamin B₁₂, a suitable dose being 1,000 µg. daily for a week. In the minority of cases where there is burning pain in the feet, calcium pantothenate 50 mg. three times a day by mouth is sometimes helpful.

Other Types of Polyneuritis

In the rare cases of polyneuritis due to ingestion of arsenic, dimercaprol (B.A.L.) is the best treatment. This

* Total period of four years and nine months.

cannot be sworn. "The unsworn evidence of a child of tender years is admissible, but when this is given on behalf of the prosecution the accused shall *not* be liable to be convicted unless that evidence is corroborated by some other evidence . . . implicating him." It is allowable to accept as such evidence what was said in way of complaint, provided it was made at "the earliest possible moment." In many cases, however, one cannot use this complaint because there was delay, perhaps because the child did not know the first person met, or the man may have threatened her if she told anyone. As the man is unlikely to assault the child where he can be seen, the case often falls through lack of corroboration.

Difficulty has also arisen where the witness of an offence has been a child under 7 and the unsworn evidence has been disallowed, although the child made a good statement and had obviously been telling the truth. Unless the man admits the offence the case may not be taken to court or it may be dismissed. One bad case concerned a man who kept a shop and bribed little girls into the back room by giving sweets or pennies. He usually took one or two at a time, but it went on for some considerable period, so that, although five or six girls were involved, the statement of each was corroborated by one or more other children. The man was defended in the police court, and he elected to be tried by a jury; but when the case went on to the Sessions the Recorder turned it down, without hearing, because there was no sworn evidence, all the girls being under 7 years, and no complaint had been made.

This problem needs very careful consideration, among others concerning children's evidence in general. One must respect the rights of the individual, but it should not always have to be those of the accused that are respected and those of the injured that are ignored.

Suspected Carnal Knowledge

Apart from the initial rise in the first period after my appointment (Fig. 1) the numbers for carnal knowledge remained fairly steady at about 10 to 14, with the exception of 1937, up to the early war years. After 1940, however, we had many of the Forces of our own and other countries stationed in and around Manchester, and there were always many of them to be found wandering about the city streets. They were met by many young women, including the 14- to 16-year-old girls, with the result that the carnal knowledge cases increased and reached a peak of 32 in 1945. After the end of the war the figure fell to almost pre-war level, but as people settled into peacetime life in the 1950's with greater freedoms, so also did the carnal knowledge cases rise again to 29 in 1952, with an average of nearly 20 cases a year in the last five-year period. They also formed a higher percentage of all the cases seen during the last few years (Fig. 2).

As one would expect, the largest number of cases are found in the 15-year-old group (Table I and Fig. 3). A comparison of the numbers seen in each period of years is given in Table III, in which the increase in the 1950-4 period is clearly shown.

For carnal knowledge it is only necessary to prove penetration with the penis if the girl is under 16 years, as it is an offence whether she gives consent or not. What the graphs cannot show was the change in the type of case history which developed during and after the war. Previously

there were not only fewer cases but in most of them the girl was not a willing partner and had been taken advantage of, possibly because she had been a bit slow in the uptake. But during the war almost all the girls had been going out with members of the Forces or deliberately meeting them in town or near the camps. They were seldom found after the first offence, and, as many of the men were known to

TABLE III.—*Carnal Knowledge Cases, Giving Ages in Groups of Years, 1937-54*

Ages:	11	12	13	14	15	16	17	18+	Total	Yearly Average

the girls only as Charlie or Johnny, etc., it was often impossible to track them and take steps against them. These girls therefore were being seen more as being "in moral danger" or "in need of care and protection" than as ordinary police cases.

The voluntary homes run by the various religious denominations to which these girls had to be sent were soon full to overflowing, so the Home Office had to open more remand homes and approved schools in 1942 and 1943. The remand home in Manchester, to which I was appointed as M.O., was fortunately equipped for the treatment of venereal disease, and most of these girls needed such treatment. However, the majority of them went direct from the courts for medical reports and therefore are not included in this survey. Their background was nearly always a broken home of some kind or bad parental influence or example, and their I.Q.s lay on the low side of normal, usually between 70 and 90, though there were some of 60 and under.

The men concerned were for the most part the poorer type of the average man in the Forces, who may have thought that by going with a young girl he might avoid V.D., etc.; but as he was not always the first, he might catch infection which she had acquired from an earlier partner.

The carnal knowledge cases involving girls of 11 and 12 years were mostly those of boys under 16 years. Where girls of 16, and therefore over the age of consent, were concerned, they were either suspected to be pregnant or the history suggested that intercourse had taken place before the age of 16. Over the period 1937-54 there were 70 who were pregnant, about 23% of the cases of carnal knowledge seen. Those girls who were 17 years or over were very mentally slow or known to be defective, and should therefore have had some protection in law; but if they went to court this never seemed to apply. That is one of the points which should have further investigation.

There were also cases of procuration by proprietors of immoral houses, perhaps sending out young girls to be picked up by car kerb-crawlers. Some of these and the remand-home type of girl, even after an approved-school training, may revert to the "streets" and the easy money obtained there, and their treatment is a hard problem. It would be easier if people would believe that extramarital intercourse was wrong and promiscuousness in men was not accepted as a normal occurrence. If there was no demand

for females the supply would go down. It is therefore necessary to raise the moral standard of the community as well as make the laws applicable equally to men and women.

Suspected Incest Cases

Included in these figures are those of indecent assault by relatives (see Figs. 1, 2, and 3). One to three of the five cases seen each year would be true incest with penetration by the penis; and here again since the war the numbers went up to 6.5 a year for the 1945-9 period and to 8.6 a year for 1950-4. Of the total 114 cases, 37 showed penetration (see Table I). The age distribution is also given, 14 years being the most frequent time.

In the majority of cases the father had assaulted the daughter, but in some the offence had been between brother and sister. Where the girl was over 16 years, the men seemed to have taken advantage of the fact that she was a bit mentally slow and more easily intimidated.

Suspected Rape Cases

A similar kind of picture is seen here, with a steady number of 2.2 to 3.8 a year in each of the earlier periods, and a definite rise after the war to 5.6 and 7.1 a year respectively for the last two periods (Fig. 2). Police records for the city show that on only one occasion since 1927 did figures for rape reach 10, and that was in 1950. Table I gives the numbers seen in each age group.

Before the war there were fewer suspected cases, and most of them were genuine, though not always proved to the satisfaction of the court. One of my earlier cases fell through because the girl waited till the next day before complaining to her sister of the attack made on her when she answered an office advertisement. It was not considered to be "the earliest possible moment," so there was no corroboration. No account was taken of the fact that the girl was shy and lived alone and was unable at once to see her sister, who lived on the other side of the city.

Since the war there have been more of the doubtful cases, such as one where it seemed more an excuse because she had not been paid and the man had gone off with her handbag.

Cases difficult to assess included those where the woman was slow or mentally backward and did not realize what the man was up to until it was too late to resist penetration properly.

Suspected Common Assault and Miscellaneous Cases

Some of these include borderline cases between rape and assault, but there were two cases of women over 70 years attacked in their rooms, one being in bed at the time. The cases in children were mainly those of cruelty by the parents or chastisement by adults. The numbers rose after the war to between 4 and 5 a year.

The miscellaneous cases were usually odd cases of abduction, of criminal abortion, of infanticide and abandoned babies, and of neglected and ill-treated children. One condition seen only since the war was sodomy, and in each case the man stated he had learnt the practice in the Army and had continued it with his wife or family after demobilization.

The Offenders

Apart from the men in the Forces, already referred to, the offenders range in age from young boys of 8 or 9 years to men of 70. With many of the lads it often seemed to be more inquisitive and experimental behaviour rather than real badness, but of course it does mean lack of training and teaching of decent behaviour at home. Then there are the old men and wrecks of men who are apt to hang round the parks, conveniences, and cinemas, and whose poor mental faculties are apt to be associated with somewhat perverted sexual feelings.

In the middle age groups there are a large number with I.Q.s probably between 70 and 80 who lack interests and occupations (which they got in wartime) and give way to various sexual urges, normal and abnormal. The majority

of the cases of indecent assault are done by the hand only, though some are with the penis between the legs, and they chiefly involve sexually immature little girls of under 12 years (mostly only 5 or 6 years), so there is no advance or sexual response by the child. This indicates that some form of mental abnormality, defect, or perversion must be present—and these conditions are unlikely to respond to prison treatment.

Another type was the emotionally and sexually uncontrolled man who would rape the office girl or someone he had met at a dance or in the public-house as they went home. In many cases the effects of alcohol undoubtedly entered into the picture.

However much one feels that the men should be severely punished, the fact remains that prison will not cure a sexual perversion, though sometimes it may be necessary as a form of shock treatment to begin with. In a certain number, some form of psychiatric treatment may be possible, but the kind of condition likely to respond is limited. Moreover, the man must not only be willing but also mentally capable of co-operating with the doctor.

This makes it all the more necessary for the court to receive a medical and psychiatric report on the accused before sentence is passed, as was strongly advocated by the joint committee of the B.M.A. and Magistrates' Association in 1949 in their report on the criminal law and sexual offenders. Among other recommendations they suggested that, after guilt had been decided but before the sentence was passed, the courts "should be under an obligation, wherever possible, to seek the advice of a duly qualified medical practitioner with experience of this type of case, as it is only when furnished with an adequate report that it is possible to pass a suitable sentence. Possibly a team such as is found in a child-guidance clinic would give the best results." They also felt that more practitioners with the necessary qualifications and experience should be available.

Some cases could be dealt with by probation, with or without a condition of special treatment; but, again, to get good results it would need more psychiatrists and more probation officers to give adequate supervision.

There still remain the mentally and physically poor types who really need to be "cared for" rather than punished, as prison will not prevent further trouble arising. For these, as for some other types of mental defectives, I feel that the best place would be small homes within a colony where they could work and live according to their ability, protected and under supervision, and yet the public would be protected from their bad habits. Though expensive to set up and difficult to staff, in the long run it would probably prevent much damage and crime in the general community and eventually help to cut down the prison population and reduce the number of recidivists.

Points Arising

1. *Women Police and Woman Police Surgeon.*—It is clear that a large proportion of the examinations are of sexually immature girls under 12 years, of whom more than half are under 7. To take statements from these children that are accurate and full needs special qualities, and it is here that women police have shown their worth. A policewoman was always in the room with me, often before the statement was taken, as it is very important to get the examination done as soon as possible or slight corroborative signs may have gone for ever. Both of us being women, I am sure the child gave a better story, and one nearer the truth, than would have been given if either of us had been a man. Experience gained over the years by the surgeon can prove very useful in doubtful cases, and I feel very strongly that a woman doctor should be called in all cases of sexual assault. Women doctors, available now in almost all districts, could be given part-time appointments, as I was. And yet after 30 years I believe Manchester still remains the only place outside London where such an appointment

has been made, though there are a few places like the Manchester Division of Lancashire County where a woman is called in "in suitable cases." But as experience is very helpful and it is not everyone who wants to be bothered with possible court cases, a definite appointment probably gives best results.

2.—*Court Procedure.*—The aim should be to make conditions at court at least as good for the child witness as it is for the child delinquent, especially as in these cases she is often the most important witness. Everything should be done to reduce any further emotional damage. The following practices are helpful, and should be carried out in more courts than is done at present.

(a) In the cases of an adult offender where the juvenile court cannot be used, there is usually available a small room where there can be less formality, no dock, with everyone on the same level, and no great distance between the magistrates and the witness-box. Otherwise the atmosphere of a large court, the fencing round the dock, the high witness-box and magistrates' bench, and the numbers of strange folk present can be overwhelming for the child or young girl, who, in any case needs courage to give the unpleasant details of what has happened. It makes her more likely to get nervous and easily confused, and therefore more liable to appear to be an unreliable witness.

(b) A woman magistrate and policewoman should be required to be present in court in all cases of sexual assault.

(c) It should not only be possible, but compulsory, to clear the court in these cases, and publication of the names of the child witnesses should be prohibited, as with child delinquents.

(d) The cases should be brought to court as soon as possible. Delay in hearing or reference to sessions or assizes, with a wait of maybe weeks or even months, means that the child forgets the details of time and sequence and therefore gives a wrong impression, especially with a hard cross-examination. This holds good, too, where the witness is mentally slow or defective. The evidence while fresh in the mind can make such witnesses quite reliable, but the impression soon becomes hazy and then very patchy. Unfortunately the defence are not beyond taking advantage of this, as delay gives the accused a better chance of getting off. But it is bad for the injured persons, as a second appearance in court and repetition of their evidence tends to increase the psychological trauma from which they were possibly beginning to recover.

(e) An alteration in the law might be made so that a child who could not be sworn might be allowed "to affirm" the truth in suitable cases.

(f) Another alteration should make it possible to accept the unsworn evidence of a child if corroborated by one or more other children who have not been sworn.

3. *Disposal of Accused.*—As many of the accused are mentally slow or suffering from sexual perversion of some kind, it is clear that no amount of prison sentence is likely to stop them doing the same thing again on discharge. It is treatment of some sort with a view to prevention that is needed, rather than punishment, and this approach needs to be more fully realized by both the public and the courts. This means that it should be compulsory in sexual cases for the magistrates to get, before sentence, a medical and psychological report on the accused, in order that they can decide what is likely to be the best way of dealing with him.

Summary

This survey of cases seen over a period of about 27 years shows a large amount of sexual misbehaviour, particularly affecting girls of under 7 years.

Its management is helped by the presence of women in the Police Force. The necessity for the appointment of a woman police surgeon is pointed out if further trauma to the children is to be avoided.

The legal position of the child under 7 years and also the older mentally backward person needs careful consideration, and legal practice altered in some way if justice is to be done by them.

However, without further legislation much could be done to improve the way in which these cases are handled, both in and out of court.

CARBON-MONOXIDE POISONING

USE OF CARBON-DIOXIDE-OXYGEN MIXTURE

Statement by the Medical Research Council

In February, 1955, a report under the title of "Gases Administered in Artificial Respiration with Particular Reference to the Use of Carbon Dioxide" was published (*Brit. med. J.*, 1955, 1, 313) by the Medical Research Council's Committee for Research on Breathing Apparatus for Protection against Dangerous Fumes and Gases, to explain the reasons that had earlier led the Council, on the advice of the Committee, to recommend the abandonment of the practice of carrying cylinders of carbogen (oxygen containing carbon dioxide) in ambulances.

The report confined itself to consideration of the first-aid treatment of patients in respiratory failure. The possible adverse effects on such cases of even comparatively low percentages of carbon dioxide in the inspired air were stressed and the report concluded with the recommendation "... that in first-aid practice carbon dioxide should not be administered with oxygen in the resuscitation of subjects requiring and receiving artificial respiration."

While accepting that pure oxygen was preferable to oxygen and carbon dioxide in the treatment of many cases of respiratory failure, Dr. H. L. Marriott (*Brit. med. J.*, 1955, 1, 664) challenged this recommendation in so far as it related to carbon-monoxide poisoning, on the grounds that the administration of an oxygen-carbon-dioxide mixture caused increased elimination of carbon monoxide and quicker recovery.

The Medical Research Council accordingly set up a special subcommittee of Council to "review all available evidence and to prepare for Council a statement for publication in the medical press." The following were appointed to this subcommittee: Professor Robert Platt (chairman), Sir Lindor Brown, Professor R. C. Garry, Professor J. McMichael, Sir George Pickering, Professor F. J. W. Roughton, Professor G. Payling Wright, and the Secretary of the Council, Sir Harold Himsworth.

Statistical Evidence

In view of the fact that mixtures of oxygen and carbon dioxide had been withdrawn from local authority ambulances in favour of pure oxygen as a result of the advice that they had received from their Breathing Apparatus Committee, the Medical Research Council had already asked Professor A. Bradford Hill to analyse the available mortality statistics on carbon-monoxide poisoning. If one method of treatment had any considerable advantage over the other, whether in patients with respiratory failure or not, it would be expected that the difference would be revealed in the statistics. Professor Bradford Hill published his report in the *British Medical Journal* (1956, 2, 1220). After drawing attention to the limitations of the available data, and emphasizing that they were clearly not precise enough to prove the relative advantages (or disadvantages) of the oxygen-carbon-dioxide mixture compared with pure oxygen, he concluded that there was no evidence of any association between the number of registered deaths from carbon-monoxide poisoning and any change of practice in the treatment of such cases.

Respiratory Failure in Carbon-monoxide Poisoning

Members of the Council's Breathing Apparatus Committee have recently completed experiments on a number of species of laboratory animals in order to try to induce a state of respiratory failure by the administration of carbon monoxide. Although it is theoretically possible for an animal with carbon-monoxide poisoning to pass through a stage before death when respiration has failed but the circulation is still maintained, the experiments indicate by actual observation that, both in pure carbon-monoxide poisoning and in carbon-monoxide poisoning complicated by the prior administration of respiratory depressants, this stage either does not exist or is so short that it provides no opportunity for special treatment. Similarly, inquiries which the Council's subcommittee have made of those experienced in treating patients suffering from carbon-monoxide poisoning indicate that respiratory failure without circulatory

failure, as a definite clinical stage following carbon-monoxide poisoning, is very rare, if indeed it ever occurs; in the subcommittee's view, it is certainly not common enough to serve as the basis for deciding the method of treatment for all cases.

On the other hand, the results of the recent animal experiments, and of independent work on human volunteers poisoned with carbon monoxide but not to the point of respiratory failure, fully endorse the older evidence that the administration of a mixture of carbon dioxide and oxygen leads to a more rapid elimination of carbon monoxide from the blood than does the administration of oxygen alone.

Conclusions

After carefully weighing all the available evidence, the Council's subcommittee have concluded that the differences in practice between the effectiveness of the two methods of treatment are almost certainly small, but that, on balance, the evidence favours the use of a mixture of 5% carbon dioxide in oxygen for the treatment of carbon-monoxide poisoning. In the light of present knowledge the subcommittee do not consider that there is anything to be gained by the use of higher percentages of carbon dioxide in oxygen. The Medical Research Council have accepted the advice of their subcommittee and wish to issue the following statement:

Experiments have clearly shown that, with either spontaneous or artificial respiration, the administration of a mixture of 5% carbon dioxide in oxygen leads to the more rapid elimination of carbon monoxide from the blood than does the administration of oxygen alone. The use of 5% carbon dioxide in oxygen for the first-aid treatment of carbon-monoxide poisoning would therefore appear to be preferable to treatment by oxygen alone. Pure oxygen, however, would appear to be preferable, as recommended by the Breathing Apparatus Committee in their report, for the treatment of those suffering from asphyxia and anoxia due to other causes, in which the administration of carbon-dioxide mixtures is contra-indicated. The Council have been assured by those with wide responsibilities for the supervision of first-aid services that it should not in practice be difficult for first-aid workers to distinguish between these two groups of patients; the circumstances in which the case is discovered will usually suffice to reveal its nature.

Motoring News

WINTER MOTORING ABROAD

While the majority of British motorists prefer to take their holidays during the summer months, there are many parts of Europe which enjoy mild weather during our winter. January and February are perhaps the two coldest months in Britain and those in which it is most desirable to travel south and seek the sun. It is unfortunate that the winter is not the easiest time for medical men to leave their patients, but, nevertheless, it is the best time financially to travel abroad. Hotels, restaurants, and all other facilities are cheaper, resorts are less crowded, and sunshine, if you go far enough south, is obviously beneficial to health, especially if it is at a time when it is lacking in Britain.

Ski-ing, skating, and other traditional winter holiday sports are, of course, available quite near at hand, but for the motorist there is little enjoyment in visiting a country which is well and truly snow-bound. An alternative is to go south on one of the regular steamships plying between Britain, East Africa, the Far East, and South America and alight at the first port of call. Passenger liners on these routes stop at such places as Vigo, Lisbon, Gibraltar, Casablanca, Genoa, and other Mediterranean ports.

Services to Vigo and Lisbon are maintained by Royal Mail, Blue Star, and Fanu Lines en route for South America. Each of these companies has one or two sailings a month

from either London or Southampton. Passenger fares vary from £12 third class to £38 first for single rates, while there are special rates for children. The cost of taking a car amounts to approximately £23, on top of which dock dues and local taxes have to be paid. Sailings to Gibraltar may be made on Union Castle, Orient, and P. & O. ships en route for East Africa and the Far East. One or two sailings a month are made by each company and single fares are from £14. Cars can be carried at rates from £14 to £20 depending on size. Vessels of the Batavier line call at Casablanca and other ports in the vicinity. Passengers must, however, join the ship at Rotterdam, though cars are loaded at London. Passenger fares are £33 and cars £30, one way.

For sailings to Marseilles and Naples the Orient Line provide what are known as "amphibian tickets" which allow sea and land travel for passengers taking their cars. Single journeys to Marseilles and Naples with car and one passenger first-class amount to £81 and £89 respectively; four passengers on the same trip would be charged £160 and £189 for the same two ports, but in this case the car is transported free. A full car load is therefore desirable on this route, where, for under £50 a head, passengers enjoy a luxury Mediterranean cruise, travelling first-class, with the cost of transporting the car included. Naples, after all, is a long drive for motorists even after leaving the Channel ports. Incidentally, the cost of taking the car to or from France by the Lydd-Le Touquet air ferry is also included in these fares so that the holiday can begin or end with a sea cruise. Sailings are scheduled monthly to and from London.

To Genoa by the Union Castle Line first-class passenger accommodation costs £43 per person and a good tourist-class cabin £28. Cars are accepted at an approximate figure of £25 for a medium-sized model, but considerable reductions are to be made next year for passengers travelling first-class and taking a car with them. For motorists going to Spain, car freight is not so cheap. To Valencia and Barcelona a one-way passage for a car would amount to between £35 and £40, with passenger fares from £28. Sailings are made fortnightly from London and Liverpool by MacAndrews and Co. Ltd., and the ships also call at Bilbao, Lisbon, and Gibraltar.

Further information about these and other sailings is, of course, available from the national tourist offices of the countries concerned, and, while voyages of this sort seem expensive on paper at first, it is surprising what costs the motorist incurs when travelling hundreds of miles on Continental roads. A sea journey can obviate a lot of these incidental expenses, give each member of the party a five to eight day luxury cruise, and allow them to start motoring, fresh and relaxed, at some interesting southern port. Alternatively such trips can form an excellent substitute for the sometimes depressing homeward journey at the conclusion of the holiday.

IAIN GELLATLY.

Dr. William A. Horne, medical officer of health of the City of Glasgow, writes in his Annual Report for 1957 of the city-wide x-ray campaign, carried out between March 11 and April 12. During the five weeks of the campaign some 715,000 persons were x-rayed, of whom 622,349 were Glasgow residents. Among the Glasgow residents 2,369 active cases of pulmonary tuberculosis were found, giving a rate of 3.7 per 1,000 over 14 years of age. The total number of new cases of pulmonary tuberculosis notified during the year was 3,925 compared with 2,024 in 1956. The highest incidences were in young adult women and in men in the older age groups. During the five weeks of the campaign 30,506 persons were recalled for further examination on large films—a recall rate of 4.3 per 1,000. Some 58% of these presented evidence of significant radiological abnormality requiring further investigation or medical supervision. 347 sufferers from lung cancer were found, the highest incidence being in men over 60.

To-day's Drugs

With the help of expert contributors we publish below notes on a selection of drugs in current use.

Influenza Virus A (Asian) Vaccine (Parke, Davis and Co., Ltd.).—This is a vaccine made by growing the 1957 (Asian) strain of influenza A in fertile eggs, inactivating with formaldehyde, and making up in aluminium phosphate suspension. It is prepared at the Wright-Fleming Institute, St. Mary's Hospital.

Invirin (Glaxo Laboratories Ltd.).—This is a similar preparation containing in addition to the Asian strain a 1956 A strain and a B strain. Since it is likely that most of any serious influenza occurring in the general population in the near future will be caused by a strain related to the Asian, the usefulness of the other two viruses is doubtful.

Such vaccines are best given in 1-ml. doses, deeply subcutaneously; children require smaller doses. They should not be given to persons sensitive to egg protein. The vaccines are stable only if kept in the cold (2-10° C.—35-50° F.). They are best given in December, since, in contrast to 1957, most influenza outbreaks occur in January and February. Recent trials in several countries indicated that vaccination led to a reduction in incidence of influenza to one-third of that in controls: better results than that cannot be expected at present. Immunity is not likely to last for more than one winter. As indicated lately (*Journal*, September 20, p. 732), there are grounds for hoping that we may escape a major outbreak of influenza this winter.

N.H.S. basic price: Influenza virus A (Asian) vaccine, 1 ml., 4s. 1½d.; invirin, 1 ml., 7s. 6d.

Ilotycin Glucoheptonate I.V. (Eli Lilly & Co.).—This is a preparation of erythromycin for intravenous injection. The contents of a 250-mg. ampoule are dissolved in 10 ml. "water for injection" (not saline). This solution can be injected slowly without further dilution or added to saline or dextrose solution for continuous infusion. A dose of 250 mg. or more up to 1 g., according to the severity of the infection, is administered every six hours. Dilute solutions can be instilled into body cavities. The preparation is not suitable for intramuscular or intrathecal administration.

This form of the drug is indicated when oral administration is impracticable for the time being; it has the added advantage of producing high concentrations in blood and tissues certainly and rapidly. Erythromycin has a similar range of activity against ordinary bacteria to that of penicillin, and may be indicated for the same infections (e.g., lobar pneumonia, any haemolytic streptococcal infection) when the use of penicillin is contraindicated as, for instance, in sensitized patients, or when the causative organism is resistant to penicillin, as is now frequently the case in staphylococcal infections.

N.H.S. basic price: 250 mg., 15s.

"It was interesting to read that a doctor who is police surgeon at South Shields, and has one of the largest practices there, has been given the sub-postmastership of an area of the town. . . . Any solicitor who wishes to engage in other professions or businesses will find guidance as to what he may and may not do in a lecture on professional conduct and etiquette, delivered by the secretary of the Law Society. The broad principle is that he may carry on any honourable profession or business, for example as a stockbroker, or coal merchant, or manager of a theatre. But apparently not as a publican, or licensed moneylender or pawnbroker, or bookmaker."—*Law Notes*, November, 1958, p. 263.

Correspondence

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

Medical Charities

SIR,—The registration of the Charities Trust Fund of the Association as a charity, resolved by the Council during last session and announced at the A.R.M. at Birmingham, is complete. The most important consequence is that the Trust is enabled to receive covenanted subscriptions which when a promise of seven consecutive years' payment is made allow income tax to be recovered at standard rate. Herein lies a great opportunity to increase the receipts of the charities of the profession without extra cost to the donor.

We are deeply appreciative of the generous support of members of the profession, and we understand that many already subscribe, under covenant, to the various charities of the profession. We suggest, however, that those who do not already subscribe under covenant should consider carefully whether they could not do so, whatever the amount. Most contributions are made when the annual subscription to the Association is paid, and on the application form this year will be found a "box" for indicating that the donor will undertake a covenant. If this is filled in, the necessary forms will be sent for completion of the formal promise.

Applications for help from the aged and sick members of the profession and from widows and orphans are greater than ever, and the need in each case is increasing. We appeal to all members to support the worthy cause of medical benevolence, especially by covenant through the Charities Trust Fund. The B.M.A. Charities Committee is a collecting body which advises the Council on the best method of distributing to other charities the moneys it collects in the Charities Trust Fund.—We are, etc.,

S. WAND,
Chairman of Council.
L. DOUGAL CALLANDER,
Treasurer.
H. M. GOLDING,
Chairman of Charities Committee.

Trypanosoma rhodesiense in Bushbuck

SIR,—I have just read with great interest the paper by Dr. R. B. Heisch, Mr. J. P. MacMahon, and Dr. P. E. C. Manson-Bahr and your annotation thereon (*Journal*, November 15, pp. 1203 and 1211). As one long interested in this subject, will you allow me to submit some comments that may help in reviewing the available evidence on the nature and origin of the trypanosomes of man? On the inoculation of game trypanosomes into man you write: "This essential test was not applied by the early workers." The following facts are, I think, relevant. In 1919 Taute and Huber, in German East Africa, inoculated 129 Africans with *T. brucei*; none of these men became infected.¹ In 1930, in Tanganyika, Corson was accidentally infected with *T. rhodesiense*; a year or so later he infected himself with *T. rhodesiense*. On each occasion treatment was fully effective.² In 1932, in Uganda, I exposed three Africans and one European to cyclically infective *G. palpalis* carrying a polymorphic trypanosome obtained from a situtunga antelope on the Sesse Islands on Lake Victoria. None of the men became infected.³ In 1933 Fairburn in Tanganyika infected himself with *T. rhodesiense*; and again drugs effected a prompt cure.⁴ Both Corson and Fairburn also employed African volunteers.

Turning now to the paper, which records the first recovery from wild African game of a trypanosome pathogenic to man. That "only one serious attempt to isolate polymorphic trypanosomes from game animals has hitherto been made" is, however, an understatement. The Royal

Society's Commission early in the century, and later on the Trypanosomiasis Research Institute and the League of Nations Commission, were all engaged in this line of research in Uganda. In the present authors' successful experiment a polymorphic strain was recovered from each of two bushbuck. One of these strains proved infective to man and the other was not. The successful inoculum into man consisted of 25 ml. of rat's blood, heavily infected with parasites (over 100 per oil-immersion field). Note the mode of infection—direct blood inoculation as distinct from fly transmission. My experience of cyclical transmission strongly suggests that development in the fly may influence the host-propensities of a strain. Moreover, cyclical transmission is the natural mode of infection, and it is extremely doubtful whether anything like the concentration of parasites present in the 25 ml. used in the experiment would be introduced by a feeding tsetse. In other words, flies infected with this strain might fail to infect man and the trypanosome would then be regarded as *T. brucei*.

An experiment carried out in Uganda is of interest here. Two antelopes were infected, each with a different strain of *T. rhodesiense*, and each animal was then exposed to clean tsetse. Each fly-cage being fed on the one antelope only. These flies subsequently proved invariably infective to laboratory animals and non-infective to human volunteers. When, however, the blood of the antelope, taken at the same time as the fly-feeds, was inoculated into monkeys, clean tsetse infected from these monkeys infected the majority, but not all, of the volunteers on whom they were fed.⁵ Another experiment illustrated still further the variability of the factors involved. A strain of trypanosome taken from a man's blood was introduced into an antelope. Monkeys, and small laboratory animals and studied for some years at the Trypanosomiasis Research Institute. During that time nine different volunteers were exposed to infection with this strain by the cyclical route, many of the flies having acquired their infection from monkeys; none of these men became infected. A bushbuck was also infected with this strain, and some 2½ years later this animal's blood was injected into two volunteers and both became infected.⁶ Yet another variable factor is the susceptibility to infection of different species of antelope. Corson⁷ found one species of reedbuck more susceptible than another, and in Uganda we found bushbuck and reedbuck more liable to infection than situtunga and oribi.⁸

All these observations suggest that the balance between susceptibility and resistance to trypanosomes in man very finely adjusted and sensitive to minute physiological changes in host and parasite and possibly tsetse. In view of all these variables I submit that it is not yet possible to decide whether *T. gambiense*, *T. rhodesiense*, and *T. brucei* are one or different species. My own view still is that *T. brucei* is a potential parasite of man; that its normal hosts are game animals; but that, given adequate opportunity, it can adapt itself to man. Its supreme achievement in this direction is the form known as *T. gambiense*.—I am, etc.,

H. L. DUKE.

Pharmaceutical Houses and the Doctor

SIR,—I read Dr. Mary M. Rayner's letter (*Journal*, November 22, p. 1291) with a mixture of astonishment coupled with a sense of despair, and finally cynicism. I really wonder if, in addition to completing questionnaires and writing letters to the *Journal*, your correspondent reads it. If she does, I fail to understand how, in her letter outlining her difficulties, she can fail to refer to the *British National Formulary*, now in its fourth edition, the alternative edition of which was favourably commented upon in your columns a few weeks ago (*Journal*, September 6, p. 601). The Joint Formulary Committee of the B.M.A. and the Pharmaceutical Society, established in 1946 and on which I have served for more years than I care to remember, has

the task of compiling, reviewing, and making appropriate additions and deletions of drugs and preparations of value for use in hospitals and proved in medical practice throughout the kingdom. Of course the doctor is still left free to prescribe outside the *Formulary* if he considers it to be in the best interests of his patient.

The *British National Formulary* is a cheap, small, pocket-size book, and in it Dr. Rayner will find 9/10ths of what she so plaintively requests. The 4th edition, 1957, and the amendment, 1958, puts into the hands of practitioners a proved useful list of preparations adequate for all purposes. There is no need for Dr. Rayner to attempt to compare the "more expensive proprietary antibiotics": she can, I submit, select from the *British National Formulary* all that is required for her sick patients, and this without reference to the charming young representatives of the pharmaceutical houses whom—in her innate courtesy—she finds so difficult to resist. Nor need she refer to the postal advertising efforts, with or without samples, all of which could be consigned to the waste-paper basket and her patients none the worse. If she feels that she may be a little behind the times in her prescribing, she can be assured that any proved and worthwhile preparation will quickly find its place in the *British National Formulary*. In the alternative edition she will find the same material classified upon a pharmaceutical basis, and brief introductory monographs usefully discuss the pros and cons of the particular choice of drug within the group to be used. In both editions lists of proprietary drugs with their equivalent official names and *per contra* lists of official names with the corresponding proprietary names will be found.

Dr. Rayner should also find the *Prescribers' Notes*, issued regularly by the Ministry of Health since 1952 and sent to all doctors on the executive council lists, of considerable help. If this is not enough, reference may be made to the Ministry of Health publication *Proprietary Medicines*, compiled by the Standing Joint Committee on the classification of proprietary preparations and prescribing (Cohen Committee). Surely this is exactly the "body of men to deal with all these proprietary products" for which Dr. Rayner pines. They too have been working for many years. Their latest list was published in 1957. Of the six categories of preparations listed, Dr. Rayner should be particularly interested in: Category 1—"New drugs of proved value not yet standard," and Category 5—"Preparations not in the B.P., B.P. Codex, or B.N.F." which in the Committee's view have not been proved of therapeutic value. The *British Pharmacopoeia*, the neglect of which Dr. Rayner deplores, is essentially a book of standards, invaluable for occasional reference, but not likely to appeal to the busy general practitioner.

Finally, I can assure Dr. Rayner that a large number of final-year students now walk round the wards with the *B.N.F.* alternative edition in their pockets, are encouraged to write prescriptions from it and to use official names. Moreover, the Ministry of Health, concerned about prescribing costs, and following part of the advice given by the Hinchliffe Committee on prescribing, is about to provide every final-year student with the *B.N.F.* (alternative edition, I hope). He will then be "the proud possessor of a good (if compact) pharmacopoeia" as Dr. Rayner hopes, and able to "hold his uncovered head high in general practice," and if he so chooses to resist the blandishments of both the representatives and the advertising methods of the pharmaceutical houses if he finds them objectionable.—I am, etc.,

Department of Clinical Medicine,
University of Leeds.

S. J. HARTFALL.

** Professor Hartfall might have added "To-day's Drugs" and the series on "Drug Treatment of Disease," appearing each week in the *British Medical Journal*, to his list of up-to-date sources of information on drugs.—Ed., B.M.J.

SIR,—Dr. Mary M. Rayner (*Journal*, November 22, p. 1291) describes herself as a simple family doctor, and certainly her polemic against the pharmaceutical industry is unreal and inaccurate. She and some other critics of that industry have a blind spot for two basic facts. First, we live in a relatively free economy; and for as long as we do, for so long will the structure and mode of operation of the industry conform by and large to their present pattern. If Dr. Rayner wants a controlled economy, let her say so; but

it would be invidious and impracticable to single out the production and selling of drugs for a treatment not also to be given to, say, the motor-car or farming industries or—dare I say it?—to the medical profession. Second, this *Journal* and others often contain justified grouches from doctors that they are not paid enough by the N.H.S. A Royal Commission is sitting on the topic at the moment, and evidence is being most skilfully given to it by doctors: that is, the profession wants more money, and is using all legitimate means to ensure that it will get it. Why is it wrong for a pharmaceutical manufacturer to do the same? Dr. Rayner really cannot have it both ways. Simple business men often say to me, "You doctors do a better public relations job for yourselves than any other group in the country"; and, of course, the present Minister in charge of Government propaganda is an ex-secretary of the Association.

Dr. Rayner suggests there should be some central body to assess the value of drugs for the simple general practitioner. Well, there is "To-day's Drugs"—in my view an earnest and well-meant feature. There is the *National Formulary*; there are *Prescribers' Notes*; there are the opinions of consultants, praised by Dr. Rayner but often in my experience based on a careful study of the glossy pharmaceutical literature decried by her. (What, by the way, is wrong with its being glossy? Should it be the kind of economy paper we had during the war in a controlled economy?) Excessive centralization in the matter of assessing new drugs might have drawbacks worse than its possible advantages. Most people, and many doctors, hate innovation; so do official and authorized bodies. That is why most major advances in any field come from a single man with a single "crackpot" idea: a new and embryo penicillin would hardly survive scrutiny by a Government committee ("Think of the cost . . .", "Importance of the body's natural defence mechanisms . . .", "Current Ministerial thinking . . .", "Over-population . . ."). I experienced official therapeutics when in the Army. While appreciating the need for it in wartime, I disliked it, and so did every other doctor I met.

Let pharmaceutical firms, says Dr. Rayner, "start measuring their products against each other's scientifically." They already try to do so. Clinical trials are an essential element in scientific assessment of a drug; but every pharmaceutical manufacturer daily laments the difficulty of obtaining those clinical trials that will provide the very evidence on a drug that doctors demand from him. I am *inter alia* medical adviser to a pharmaceutical firm, and have it as a rule of thumb that, if one desires a single paper on a new and interesting drug, one must initiate at least six separate clinical trials. Five, started in good faith by both manufacturer and clinician, and at some cost to the former, fall by the wayside. Why? Not because of any lack of enthusiasm in the firm making the drug. This may be an unpalatable fact, but it is a fact.

Dr. Rayner deprecates salesmen and advertisement psychologists (whatever they may be) and free gifts. The use of all these is merely a way of bringing the attention of doctors to a new and useful drug, and of securing their good will. Only if a substantial demand develops does manufacture of a drug become economically worthwhile—with the possibility of price reduction. The best drug in the world will never be used widely unless it is advertised in the fullest sense: we hate innovation. Aspirin was discovered 30 years before any doctor began to prescribe it; and paracetamol for 40. D.D.T. lingered, unused, for as long; the discovery of penicillin went unexploited for 12 years. "Exploitation," what a dreadful word?—but it meant lives saved by penicillin as well as profits for its manufacturers. Dr. Rayner may not like the implications of these facts; but she ought to face them. And may I suggest that advertisement, perhaps of a more discreet and subtle kind than any practised by the industry, is not unknown in the profession? Have we not a thing called a bedside manner? Do doctors, having published a good paper in a good journal, disown it? Or do they very properly see that the right quarters are at the right time appraised of the paper's existence? Dr. Rayner criticized the shiny new cars of pharmaceutical representatives. Should she really prefer dirty old cars? Of course the cars cost money, and of course the good manufacturer makes the money by selling drugs; but that is what life, in the material sense, is about in this country in 1958.

I should like to end with a few more facts. The *British Pharmacopoeia* (and Dr. Rayner thinks it good for a doctor to have one, and I agree) is now largely written with the gladly given assistance of the pharmaceutical manufacturers. They have discovered the new drugs that are to be canonized by inclusion in the B.P., and they know more about those drugs than anyone else. The "rising drug bill": between 1949 and 1957 it increased from 35 to 73 million pounds; in the same period hospital costs went up from 219 to 421 millions. I leave Dr. Rayner to draw a simple conclusion. The pharmaceutical industry in this country says it can afford to spend only 4 million pounds a year on research: the figure in Switzerland [*sic*] is 7 millions. The British industry sells 45 million pounds' worth of drugs to the N.H.S. at manufacturers' prices: it exports 40 million pounds' worth. (Does Dr. Rayner favour exports? And does she think foreign countries are influenced to order drugs from the British industry when it is stigmatized by a British doctor as trying "to degrade our profession," and by practising "wiles and subtleties"?) Between 1953 and 1957 the index of prices for branded drugs fell from 100 to 82: the index of general retail prices rose in the same period from 100 to 116. A voluntary price regulation scheme for branded drugs has already been formulated by the industry and the Government. It affects 90% of the cost of all N.H.S. proprietary drugs. The estimated saving?—about £350,000 a year. Will Dr. Rayner agree that the smallness of the saving may mean that the previous prices were not in fact excessive? Or does she accuse the Treasury of a lack of financial acumen?

Dr. Rayner and Dr. Charles S. Thomson (*Journal*, November 22, p. 1291) imply that pharmaceutical manufacturers are lacking in responsibility, unlike doctors. Who do they imagine these dreadful manufacturers are? They are in fact ordinary men and women, getting considerable satisfaction from the making and selling of drugs that will save lives and shorten disability; and they have as much sense of responsibility as any other citizen. The pharmaceutical industry, for instance, is well known to give more, relative to its size, to charitable and academic good causes than any other industry in this country. Far from inciting her colleagues to "unite and fight these pharmaceutical firms," Dr. Rayner should try to realize that without them present-day medicine simply could not exist. The industry and the profession are partners in a great enterprise, not enemies. Of course the industry has some defects, as we all have. It knows it has them. But they will not be remedied by ill-informed criticisms or by suggestions of sweeping Utopian alternatives, dreamt up perhaps "on a Monday morning, during a crowded surgery."—I am, etc.,

Near Guildford.

S. BRADSHAW,
Medical Adviser,
Aspro-Nicholas Ltd.,
Ethical Pharmaceuticals Division.

SIR,—I would like to thank Dr. Mary M. Rayner (*Journal*, November 22, p. 1291) for a very excellent letter regarding the effect of high pressure advertising on the G.P. She is a shrewd observer and has placed a very adept finger on the main cause of the cost of the drug bill. The possession of Martindale's *Extra Pharmacopoeia* is, in my opinion, an absolute must in general practice, and if the Ministry were to supply each G.P. with one gratis it would at the very least earn its keep and at the best would save pounds per head per annum.

However, I would not like it to be felt that this means that all the drug houses are selling useless products at high prices. This of course, as all know full well, is far from the truth; indeed, a casual perusal of "Martindale" will show, if prices in the *Drug Tariff* are compared, that many of the proprietary preparations are cheaper and better, and in many cases that no equivalent is available. However, many readers will be as staggered as I have been recently to find that many of the so-called "new" pain-killers are no more than our old pals aspirin and phenacetin when the mumbo jumbo of their chemical formulae is reduced to an intelligent level. There has been in some instances a definite attempt to blind us with science in the form of chemical *noms de plume*. Reference to "Martindale" will show

at once to which particular section or type a particular substance belongs.

Pharmacology and *Materia Medica* have now grown so vast and vital that a serious attempt should be made to offer to G.P.s either refresher courses—with adequate locum coverage—or a monthly "digest" compiled and edited in an attractive way to combat "Big Brother" techniques.—I am, etc.,

Shipley, Yorkshire.

J. A. FRAIS.

SIR,—As a representative for the last 44 years with a firm of surgical instrument and equipment manufacturers, I feel that drug house representatives who visit the general practitioners have been handed out rather a raw deal in your correspondence columns during the last year, and now one of your latest correspondents, a lady doctor (Dr. Mary M. Rayner, *Journal*, November 22, p. 1291) considers them ideal companions at a dance or cocktail party, but can give them only two minutes, out of courtesy, for a discussion on new medical preparations.

My experience suggests that most of the representatives are qualified chemists and members of the Pharmaceutical Society, and rank with hospital pharmacists, from whom the doctors are glad to obtain information on new drugs, dosages, etc., when working in hospitals.—I am, etc.,

Stockport, Cheshire.

R. MERRYWEATHER SHAW,
Pharmaceutical Chemist.

Pharmaceutical Houses and the Postman

SIR,—During October I kept all the advertising matter which arrived at the surgery used by our partnership of three. Not counting the duplicates which arrived at our home addresses, I collected 235 packets which weighed in all exactly 14 lb. (6.4 kg.), and on which the total postage was £2 2s.

What an opportunity for the statistician! If we are 1/7,000th part of the N.H.S. practitioners, it works out during the course of one year that 21,000 doctors receive 19,740,000 packets weighing 525 tons (1 ton = 1,016 kg.), and on which the postage is £176,400. Or, to make it even more fantastic, let us take 63,000 registered medical practitioners receiving 59,220,000 packets weighing 1,575 tons and the postage is then £529,000. Imagine the numbers of postmen carrying this mountain of paper! Imagine the numbers of refuse collectors carrying it all back again (probably mostly unopened)! Imagine the chemists getting in supplies of the new wonder drugs, only using them once, and then keeping them on their shelves.

I wonder how much of this enormous expense goes on the national drug bill, or alternatively reduces the drug firms' taxation? And do our patients get any better treatment because of it?—I am, etc.,

Tynemouth.

J. PHILLIPS.

SIR,—May I plead that all those many firms who send us advertisements should respect the very difficult task of the postal authorities during the fortnight before Christmas, and refrain from advertising their products during this period.—I am, etc.,

London, S.W.1.

FRANCIS LESLIE.

Rational Use of Drugs

SIR,—I have followed with great interest recent comment on drug pricings and overprescribing. Contrary to a recent observation on the teaching of medical students in the use of *National Formulary* preparations, I was taught to use the N.F. whenever possible. However, on my first "sedative round" I found tab. butobarbiton. was not available. The next day the hospital pharmacist told me that "soneryl" tablets were bought by the hospital group on a bulk contract, and were thus cheaper than tab. butobarbiton.. N.F. Similarly, in another hospital my attempt to order

caps. vitaminor. was frustrated. "Multivite" was the available preparation, again on bulk contract.

It is difficult to find up to date and authoritative information on the new preparations as they become available. The *Practitioner* publishes an excellent series on new drugs, and this I find most helpful. Your new series "Drug Treatment of Disease" similarly has been very helpful, but like Dr. D. R. Laurence (*Journal*, October 11, p. 914) I was disappointed in "To-day's Drugs."

Occasionally having access to the *Journal of the American Medical Association*, I find the pronouncements of the Council on Pharmacy and Chemistry are authoritative and without bias, either commercial or political. Surely we could well do with a similar organization here? I would like to press for the formation of a Council on Pharmacy and Chemistry, under the auspices of the B.M.A., modelled on the lines of the American one, submitting regular reports on drug action and uses to the *British Medical Journal*. How else may we sort our present problems, which increase each day with the morning post?—I am, etc.,

Blandford, Dorset.

GEOFFREY F. BAINES.

Petrol-vapour Poisoning

SIR,—It would seem from the comments made by Dr. Reed Aidin in his article (*Journal*, August 9, p. 369), and Dr. B. George in his letter (*Journal*, October 18, p. 979) concerning the dearth of published accounts of petrol-vapour poisoning that this form of intoxication may be less well known in civil life than it is in the Royal Navy. During the second world war fairly frequent cases of petrol vapour poisoning were reported, but once the nature of this hazard was recognized and the methods of protecting against it were promulgated it usually ceased to be a hazard.

Typical incidents are cited in the *History of the Second World War* in His Majesty's Ships *Victorious*, *Activity*, *Glenroy*, *Empress*, and *Arbiter*, in which there were several fatalities. Attention is drawn in the *History* to the insidious danger of a steadily rising concentration of petrol vapour which, in contrast to sudden exposure to an irritant high concentration of vapour which is quickly recognized, deadens the sense of smell so greatly that the danger is not detected by the unwary; and also to the fact that complete protection is only afforded by a self-contained breathing apparatus which does not rely on the ambient air for its support, such as the Salvus, although the conventional Service respirator for protection against chemical warfare agents, which every Service man has in his possession, affords good protection for the very useful period of 10 minutes. The need is emphasized for efficient ventilation arrangements in the construction of petrol control compartments, and for ensuring that ventilation systems are cleaned and maintained efficiently.

Dr. Aidin's comment that the accident he reports happened on a warm day is of particular interest, and underlines the need for increased caution when those exposed to petrol vapour are working in a warm atmosphere indoors or in a hot climate.—I am, etc.,

Advising the Bronchitic

SIR,—Personal experience is of much greater value than second-hand information. Having suffered from chronic bronchitis almost all my life, I consider myself able to speak with authority on this important subject. It is indeed a very sad fact that only a small percentage of the medical profession realize that certain "chesty people" are hypersensitive to any forms of tobacco smoke (especially pipe tobacco).

During my daily work as a chest physician I often inquire from my smoking patients if they can travel on the top of

a bus or tram. The bronchitic and asthmatic invariably reply, "No. Because it makes me cough." Yet these same people admit to smoking 10 to 15 cigarettes per day. Is it any wonder they cough? They fail to see that they are producing the very same atmosphere they cannot tolerate on a bus. Patients are always ready to blame the weather or their employment but never their smoking habits. If these patients were advised to stop smoking, there would be less of them suffering from chronic bronchitis and persistent coughs. Cutting down is not enough, they must stop smoking altogether and avoid smoky atmospheres. I am also often asked, "Shall I stop smoking cigarettes and start pipe smoking?" I always reply that from the health point of view pipe smoking is worse because it produces four or five times the amount of irritating fumes.

But what of the other unfortunate victims who do not smoke and yet have to inhale these fumes? The greatest calamity which can befall them is to be admitted to a hospital ward or convalescent home in this country. Recently an emphysematous patient was admitted to a local convalescent home. She was compelled to sit half-way up the stairs during the daytime, this being the only place free from tobacco smoke. Another patient was compelled to forgo her hospital gastro-intestinal investigations—because of the smoke from the other female patients. It is high time the hospital management committees throughout the country woke up to these facts and provided side wards on every medical and surgical ward where patients who so desire may have their treatment in an atmosphere free from pollution with tobacco smoke.—I am, etc.,

Leeds, 8.

DAVID A. HERD.

Qualified Pen-names

SIR,—I was intrigued when I first read about the B.M.A. booklet on nutrition by John Clyde, M.D., etc., and when my wife obtained a copy my curiosity got the better of me. I looked him up in the *Directory*. Imagine my surprise when I found no such name. There only were the three of us. One I have met, the other I have not had the pleasure of meeting. I wondered what mysterious motive the B.M.A. could have in sponsoring work done by some nebulous nobody, and I must admit that my confidence in the integrity of the B.M.A. received a little jolt on discovering their apparent duplicity (or quadruplicity). Should the booklet not have contained the usual writer's disclaimer that all characters mentioned in this book are purely fictitious and have no reference to any person living or dead?

As Sir Stewart Duke-Elder implies in his letter (*Journal*, November 29, p. 1355), I also feel that you cannot escape some responsibility for helping to make three into four and thereby reducing each by a third, because if I remember right I first saw reference to this new member of our clan in the columns of the *British Medical Journal*. Has the B.M.A. been doing some roamin' in the gloamin' by the bonny banks?—I am, etc.,

Bordon, Hants.

Poliomyelitis Vaccines

SIR,—Dr. Ritchie Russell (*Journal*, November 29, p. 1354) in discussing our review of the present position of live poliovirus vaccines (*Journal*, November 15, p. 1184) says that it is doubtful if we presented a balanced analysis of the present position. We did not, as he suggested, condemn live poliovirus vaccines, nor did we take a strong line against trials. We said that it was unlikely that any country with the finances available to undertake a vaccination programme using formalized vaccines would use or switch to attenuated virus vaccines until it has been shown that they are as safe as, or safer than, formalized vaccines and produce as good or better levels of immunity. We said that live virus vaccines appear suitable for trial in countries where formalized vaccines cannot be afforded, and we said that in our opinion carefully conducted trials of attenuated virus vaccines should be undertaken in such countries if there is a genuine need for vaccination.

We tried to indicate that human vaccine viruses which (a) change their characteristics after growth in the human host and (b) spread readily to contacts are a new concept and therefore may not be easy to evaluate.

Dr. Ritchie Russell apparently thinks that we place more weight on the results of monkey pathogenicity tests as an indicator of potential neurotropism in man than in fact we do. Admittedly we are worried when the laboratory characteristics of excreted virus resemble those of some wild viruses the stability of which is at least questionable. What is important is that the virus excreted by some vaccines differs from the original virus and can spread to contacts. With this knowledge, we consider that the safety of the excreted virus should be subject to the same type of preliminary clinical trial as the original vaccine virus.

Dr. Ritchie Russell discusses the effect which different vaccines may have on the natural history of the poliovirus. We, too, are interested in this problem but like him can only speculate.

Dr. Ritchie Russell asks us to clarify our hopes and fears. Our hopes as far as vaccination against poliomyelitis is concerned are the same as his—namely, that, safe, efficient cheap vaccines will be available in all countries. We cannot see that a live vaccine must necessarily fill this bill, and we think that improvements will certainly be made to the inactive virus vaccines at present in use. Our fears are that, unless trials are carefully conducted to test the safety of living virus vaccines, the future of these vaccines and perhaps public confidence in all poliovaccines may be jeopardized.

Dr. Ritchie Russell must be irritated by the many delays and alarms that have accompanied the development and trials of oral vaccines. He would like to see the oral vaccines put to the test quickly and decisively. We share his sense of urgency, but obviously disagree on methods of assessing safety and effectiveness, neither of which we take for granted.—We are, etc.,

Onset Enuresis

SIR,—The excellent publication by Drs. J. D. Paulett and E. Tuckman (*Journal*, November 22, p. 1266) prompts me to mention a case of enuresis which I have always considered one of those we would like to meet more frequently.

It was 1942, and we had well over 200 unbillable enuretic evacuees in various hostels in Cornwall. Onset enuresis was not a major problem, for out of that segregated number only one had failed to give a positive answer to my stock question: "And what did your mother say when you wetted your bed at home?" The last batch of children had been sorted out, and six months had passed without any further complaint from a billetee. I was therefore all the more annoyed when a 12-year-old boy was reported to have started wetting his bed.

I found a healthy and intelligent youngster waiting for me, who was obviously greatly upset over his misbehaviour. He admitted having wetted till the age of 5, but there had been no lapses after he had started school. He had an elder sister who had remained with his parents. Neither at his school nor at his billet could any cause for this sudden change be found, and he had appeared to all and sundry as happy as ever. Yet for the past six nights he had never once been dry. He was clearly eager to give me every assistance, but, after my inquiries had drawn a blank all round, his face began to assume a look of helpless resignation. It was then that I fired my last shot: "When did you get your last letter from home?" "A week ago to-day." "And what did it say?" "Mum said I had a baby sister."

—I am, etc.,

London, W.1.

W. E. R. MONS.

SIR,—In their interesting study (*Journal*, November 22, p. 1266) Drs. J. D. Paulett and E. Tuckman state that there is "no information in the literature on the prevalence of the onset type of enuresis." They are evidently unaware of the important studies of Dr. Bertil Hallgren, of Stockholm. In the first of these Hallgren reported the results of a survey of 1,992 unselected primary school children. Of these, 20% of 4 at least once a month, mostly several times a week, and of these children 86 (42%) had earlier been dry. The frequency of onset enuresis in this sample of schoolchildren

aged 7 was therefore 4.3%, as against 2.9% in Paulett and Tuckman's 677 children under the age of 21. Hallgren made a detailed inquiry into the social factors.

In his second study, Hallgren examined the clinical, social, and genetic aspects of 213 cases of nocturnal enuresis severe enough to have been referred to the psychiatric out-patient department of a paediatric hospital or as in-patients to a children's psychiatric ward. Of these, 15% were onset cases, with a significantly higher proportion of girls than of boys. Emotional stress (disturbance of the relationship between mother and child, or unsatisfactory home) seemed to be connected with the onset especially when the child also showed diurnal enuresis. This finding is in accordance with my own observations at the Mersham Reception Centre, where the high incidence of reported enuresis on admission (32% of those over 3 years of age) seemed closely related to their unsatisfactory home conditions. Whether the familiar improvement that rapidly occurs when "deprived" children are happily settled in suitable homes is restricted to onset cases has not been determined.—I am, etc.,

London, S.W.13.

Munchausen Syndrome

SIR,—I must congratulate Drs. J. C. Barker and T. G. Grygier (*Journal*, November 22, p. 1274) on their lucid description of six cases of Munchausen's syndrome. I have only one small correction: it was a horse doctor, not a house doctor, who is alleged to have operated on Elsie Packoma¹—an experience much more typical of Baron Munchausen's adventures.

It is interesting that every one of these patients has been at this hospital within the last few years, because this shows that the apparent commonness of the syndrome is an illusion caused by a very few cases visiting a very large number of hospitals. Putting it another way, in the last five years nearly every hospital doctor has met two or three cases of Munchausen's syndrome, but during that time very few people have met any other cases except those listed by Drs. Barker and Grygier. Never in the history of hospitals have so many doctors been so much annoyed by so few patients.—I am, etc.,

Central Middlesex Hospital,
London, N.W.10.

Sex Education for Students

SIR,—With Dr. Edward J. R. Rossiter's excellent letter on the above subject (*Journal*, November 8, p. 1164) I am in complete agreement. But the implementing of Dr. Rossiter's suggestions poses I think a number of problems. If students are to receive sex education, what will they be taught, and by whom?

Recently, probably stimulated by the controversy over the Wolfenden Report, I read a number of books and articles on homosexuality, and I can only say that I was quite appalled by the lack of even an elementary knowledge of sexual physiology and psychopathology displayed by the writers. One of these authors cited, as a typical case of "neurosis supervening on homosexuality," a young man who felt sexually attracted to girls but who was unable to have irregular unions with them on account of an earlier warning by his mother and his subsequent "fear of making them pregnant." Was this such a very abnormal reaction? Was it in fact a neurosis at all, or merely the very normal reaction of a sensitive and morally sound young man? And, instead of this patient being told that his reaction was both normal and understandable, he was apparently dismissed as an intractable homosexual.

The treatment, too, offered to these unfortunate people was almost negligible. A minute percentage was selected for Freudian analysis, which nearly all the writers, with two exceptions, found disappointing. Very strangely, too, continence seemed to be advised only "if it did not seem likely to lead to neurosis," otherwise it was not advised. But in not one single instance did any author advise mental continence, or any attempt by the patient

to control his sexual fantasy-life, which of course must be the beginning and foundation stone of all attempts to reach sexual maturation. Nor, again, was there a single attempt by any author to teach the patient that his sex life must eventually (for any normality or stability) be linked with and dependent upon his tender emotions, which must always be his sole guide to any sex-expression, and that such a linking may require (if he really wants to reach maturity) months of abstinence, self-sacrifice, complete abolition of fantasies, and a sustained desire to allow the growth of all tender sentiments regarding the opposite sex.

Therefore, while I endorse the ideal set forth by Dr. Rossiter, I am greatly at a loss to know how it could be achieved. Sex education which is based upon utterly wrong premises is probably much worse than no education at all. It is proverbially much more difficult to teach a person who has been badly taught than one who knows nothing about the subject.—I am, etc.,

Pinner Middlesex.

ROBERT THOMPSON.

Costs of Notification

SIR,—I should like to point out to Drs. E. O. Gibson and R. M. Emrys-Roberts (*Journal*, November 15, p. 1229) that the saving from the abolition of fees for notification of diseases might not be great. For all moneys earned by G.P.s outside the Pool, a corresponding deduction is made from the Pool. So, if fees from notifying diseases ceased, a corresponding increase would take place in the Pool, and this, unlike notification fees, would count as pensionable income.—I am, etc.,

Devonport.

J. LAWRENCE HENRY.

SIR,—I feel that the letter of Dr. E. O. Gibson and Dr. R. M. Emrys-Roberts (*Journal*, November 15, p. 1229) concerning notifications has put this subject into its proper perspective. A recent experience of mine shows how farcical the whole thing can become. While working in a hospital in England, I was responsible for the medical care of the staff. My opinion was asked as to whether a cleaner whose child had scarlet fever should continue her duties. I advised that she should, provided that she had no symptoms and was not working in the children's ward. The following day the hospital secretary received a message from the M.O.H. passing on the notification. I therefore contacted the M.O.H. and stated the position. The outcome of this was that the M.O.H. insisted on the woman remaining at home during the period of infection.

Pondering on this rather drastic move, I can see only two logical conclusions. One is that sore throat should be made notifiable and treated in isolation; this is surely absurd. The alternative is to delete scarlet fever from the list of notifiable infectious diseases. I feel that this move is long overdue and would strongly support the plea that it should be done as soon as possible.—I am, etc.,

Edinburgh, 10.

BRYAN ASHWORTH.

Blood Groups in Cyprus and the Near East

SIR,—I read with great interest your leading article on blood groups in Cyprus and the Near East (*Journal*, October 18, p. 959) in which it is said: "Nothing is known of the Rh groups in this area" (Syria and Lebanon). I have studied this question in Beirut with Dr. J. Mouacdie.

We found the following incidence of Rh negatives: 4.4% for Moslem Arabs; 6.4% for Armenians; and 7.0% for Christian Arabs.—I am, etc.,

Beirut, Lebanon

Combined Gastric and Duodenal Ulceration

SIR,—I was most interested to read the paper by Dr. R. Mangold in your issue of November 15 (p. 1193), confirming most of my findings reported in 1955¹ and 1956,² particularly in regard to the great frequency of haemorrhage

and other complications in patients with combined ulcers. However, there is one point on which we have differed. This is the matter of the importance of gastric retention in the pathogenesis of the gastric ulcer, which, we both agree, is nearly always secondary to the duodenal ulcer.

Dr. Mangold recorded an incidence of 9.2% of cases of frank pyloric stenosis in his own series (28% when minor evidence suggesting obstruction was included). He concluded "pyloric stenosis does not appear to be a major factor in the pathogenesis of combined ulcers." But frank pyloric stenosis is only the final stage of a slowly developing lesion, and radiology is too crude a method to detect the earlier stages, many of which are surely almost certainly present as well in any series containing a number in the final stage. Dr. Mangold's own figures imply that the proportion of his own patients with some degree of pyloric obstruction was substantial, even if he does not accept the belief held by many that active duodenal ulcers always cause some degree of functional pyloric obstruction. Frank organic stenosis is quite a different matter and develops slowly over the years. Either kind of pyloric obstruction, or indeed, gastric retention from any cause, can promote a secondary gastric ulcer—I have given reasons and examples in the papers referred to. My view was further supported by the finding of often unsuspected associated gastric ulcers in a substantial proportion of patients known to have pyloric obstruction from another cause.

Marie Stopes

SIR,—By arrangement with the executors of the late Dr. Marie Stopes we have commissioned Mr. Keith Briant to write her official biography. We shall be most grateful if any of your readers who possess letters from Dr. Stopes, or who could provide personal recollections of her, would be kind enough to make them available to Mr. Briant through us. All original documents will be carefully copied and returned without delay.—I am, etc.,

40, William IV Street,
London, W.C.2.

IAN PARSONS,
Chairman,
The Hogarth Press.

SIR,—I am writing a book about the character, life, and struggles of the late Dr. Marie Stopes. Any help from your readers in the form of letters, reminiscences, press cuttings, or any other relevant information would be most gratefully received. Any items lent will be treated most carefully and returned promptly, and may be sent to me either at the address below, or care of my publishers, Messrs. Barrie Books Ltd., 3 and 4, Clement's Inn, London, W.C.2.—I am, etc.,

9, Westbourne Terrace,
London, W.2.

ELIZABETH SMART.

POINTS FROM LETTERS

Hazards of Sport

Dr. K. E. JOLLES (West Bromwich) writes: Dr. E. Brauer states (*Journal*, November 22, p. 1296) that he has seen more fatalities amongst spectators than players of football. That it is, certainly, not always the combatant who dies was forcibly brought home to me on an occasion earlier this year when I was officiating as medical officer at a "speed hill climb" competition. A driver had successfully and quite creditably completed his three practice runs as well as his two competition ones and, his task of the day done, had repaired to the paddock to watch his fellow competitors. An hour later, whilst thus engaged in "spectating" quietly, he suddenly collapsed and died almost instantaneously of coronary thrombosis. The interest of this case lay in the fact that this man had actively competed earlier that day and suffered no ill-effect, but died an hour later whilst watching others.

Obituary

A. HOWARD CUTTING, M.B., B.S.

The tragic death of Dr. A. Howard Cutting in a car accident on the evening of November 25 was a great loss to the general-practitioner service of south Cambridgeshire. The death of his wife, Margery Cutting, at the same time was a sad and bitter blow not only to the family but also to the village of Balsham, in which they lived.

Educated at King's College School, Wimbledon, Alfred Howard Cutting, who was born on December 28, 1914, proceeded to London University and King's College Hospital, graduating M.B., B.S. in 1939. He served as a house-surgeon at King's and also as clinical assistant to the department of urology and as resident medical officer at St. Luke's Hostel. At the outbreak of war in 1939 he was attached to the Emergency Medical Service and served in it until he joined the R.A.F. in 1940. Here he proved not only his medical worth but also his ability to turn his hand to other skills. He was for a long time with a squadron in Gibraltar and also served in North Africa, as well as at stations in England.

Dr. A. BROWN writes: In July, 1946, Dr. A. Howard Cutting joined a practice based on Linton in south Cambridgeshire, and was a partner there when he died. During the twelve years he helped to build up a group practice and became not only the doctor but the counsellor and friend of the patients. The technical knowledge of building which he possessed was invaluable when the group practice centre was being built. He will be greatly missed in Balsham, where he took a great interest in village affairs. The regard and esteem in which he was held not only by the patients but also by the medical profession were evidenced by the very large congregation which was present at the funeral service in Balsham Church.

Although not medically qualified, Dr. Margery Cutting was before her marriage doing work directly connected with medicine, and she obtained the degree of Ph.D. for her work on the sulphur content of food. She was awarded a Beit Memorial Fellowship at Cambridge and worked under and with Professor R. A. McCance before and after her marriage. She took a great interest and a very active part in the village life and also in the Women's Institute and the work of the Girl Guides in the district. She will be sorely missed by all with whom and for whom she worked. To both sets of parents and to the three young sons who are left we all extend our most sincere sympathy.

Mr. JOHN HESKETH writes: I first met Dr. A. Howard Cutting when he was a squadron medical officer in the R.A.F. in 1943. Being more senior and experienced, Flight-lieutenant Cutting (as he then was) became my guide, counsellor, and friend in all matters of a Service nature. My association continued for some 18 months as our respective squadrons kept fairly close together, and he was always willing to help in any way he could. He had already been on an overseas posting, and when my turn came nothing was too much trouble to him in advising or instructing me in every possible detail. I still have in my possession a "primus" stove in working order which he personally modified for my use. Although a doctor, he could, I found, turn his hand to things other than medicine, and in later years I came to realize how much of a handy-man he was, particularly in respect of houses, boats, and cars. It was not until 1948 that chance again threw our paths together, by which time he was established in general practice near Cambridge. Over the last 10 years he and his family and mine have remained friends, and at all times I have found him eager to help others and always of a cheerful disposition. He could not tolerate inefficiency, particularly when rules and regulations were involved, and

he never lost an opportunity to bring anything of this nature to light, especially if the occurrence had been to the detriment of his patients. Although somewhat dogmatic in his clinical approach, he was in every sense a conscientious general practitioner. Outside medicine, sailing was a hobby which gave endless delight both to himself and to his family. By his untimely death his colleagues, and particularly his own village of Balsham, have lost a very dear friend. The death of his wife at the same time was another bitter blow to the family. Three young sons are left, and to them and the parents of the deceased our deepest sympathy is extended.

T. C. CLARE, M.D., F.R.C.S., F.R.C.O.G.

Mr. T. C. Clare, who was honorary surgeon to the Leicester Royal Infirmary for many years, died on November 12 at the age of 77.

Thomas Charles Clare was born in Birmingham, where his father was city treasurer. From King Edward's School he went on to study medicine at Birmingham University and St. Bartholomew's Hospital, qualifying in 1905 and graduating B.S. a year later. After being house-surgeon to Mr. Jordan Lloyd at the Queen's Hospital, Birmingham, he later became resident medical officer under Sir John Bland Sutton at the Chelsea Hospital for Women. In 1909, the year he came to Leicester, he obtained the F.R.C.S. and proceeded to the M.D. (London) in gynaecology in the following year. For three or four years he was in single-handed general practice, and in 1913 he was appointed to the honorary surgical staff of the Leicester Royal Infirmary. At the outbreak of the first world war he joined the R.A.M.C. and served in the 5th Northern General Hospital at Leicester until 1916, when he was sent out to Mesopotamia. While there he contracted sandfly fever and dysentery and was transferred to Bombay to convalesce, spending the next two years in the North-West Frontier Province. It was there that he did his original work on the effect of heat on the red blood corpuscles, later publishing his paper "On the Toxic Nature of the Stroma of the Red Blood Corpuscles." It was characteristic of him that he did most of the experimental work on himself. As a result of this work he devised a method of treatment of certain bacterial infections. Some years after resuming his work at the Leicester Royal Infirmary he published a paper on "Gastromyotomy—an Operation for the Cure of Chronic Gastric Ulcer." He became president of the Leicester Medical Society in 1929 and read his address on "The Physiology of Cancer." After working for two or three years as honorary secretary of the Leicestershire and Rutland Division of the B.M.A., he was its chairman in 1932-3. In 1938, the year he was elected F.R.C.O.G., he delivered his presidential address to the Midland Obstetrical and Gynaecological Society, giving it the title "A Socratic Dialogue on Cancer." He had previously given a paper to this Society on "The Keloid Ovary," basing his hypothesis on clinical and physiological evidence. Although he was due to retire in 1941, he carried on until the end of the war, and his appointment was further extended owing to the rather long illness of a colleague, so that ultimately he gave 39 years' service to his hospital. He is remembered with great admiration and affection by a long line of house-surgeons, several of whom have achieved distinction. Among doctors' families he was in great demand as an obstetrician and gynaecologist.

In his younger days Mr. Clare was a keen cricketer and rugby player, but in later years his chief recreations were golf, fly-fishing, bridge, and reading. He possessed a very fine and extensive library. It gave him great pleasure when in 1937 he was elected captain of the Leicestershire Golf Club, a position which he held until 1941. Four years later he became president and was eventually elected a life member as a tribute to his great popularity. He was a Freemason of 40 years' standing. Unassuming modesty and charm were the outstanding characteristics of his personality which endeared him to his colleagues, nursing

staff, and patients alike. He possessed a fine original mind and had the unique faculty of expressing *multum in parvo*. Our deepest sympathy is extended to his wife and only son, the Rev. Thomas Charles Hunter Clare.

M. W. PATERSON, O.B.E., M.C., M.R.C.S., L.R.C.P.

Dr. M. W. Paterson, who was in general practice at Hyde, Cheshire, for nearly thirty years, died at Llandudno Hospital on November 15. He was 71 years of age.

Matthew Wallace Paterson was born at Tinsley, Yorkshire, on September 3, 1887, and was educated at Glasgow High School and Manchester Grammar School. He went on to St. John's College, Cambridge, where he took his B.A. in 1908. Receiving his clinical training at Manchester Royal Infirmary, he qualified M.R.C.S., L.R.C.P. in 1913, and then held the appointments of house-surgeon at Alnwick Infirmary and at Manchester Royal Infirmary and senior resident medical officer at Hope Hospital, Salford. On the outbreak of the first world war he joined the R.A.M.C. and served with distinction in France, attaining the rank of major. He was awarded the Military Cross in 1917 and was appointed O.B.E. in 1919. He was also decorated by the French Government, receiving the Médaille d'Honneur, with crossed swords. After the war he settled in Hyde, where he remained for the whole of his working life, taking an active part in local medical affairs. He was chairman of the Hyde Division of the B.M.A. in 1930-1, and had served on a number of Headquarters committees. When the Association held its Annual Meeting at Manchester in 1929 he acted as one of the honorary secretaries of the Section of Occupational Diseases, and in the following year he was honorary secretary of the Association of Certifying Factory Surgeons. Rheumatoid arthritis and overwork entailed his retirement from practice in 1947, when he moved to Drayton Parslow, Buckinghamshire, where he lived until a month or two before his death.

F. V. G. P. writes: "Pat," as Dr. M. W. Paterson was known in Hyde, had a charming personality and inspired great affection in patients and friends alike. His patients loved him, knowing that they could be sure of his interest and sympathy, and that he would do all he could to help them. As a young man he was an excellent hockey player, but his real love was for fishing and he spent many hours on the banks of the Dove, in Derbyshire. He was also a keen amateur painter. For the last 30 years of his life rheumatoid arthritis limited these pleasures to a great extent and made his work increasingly tiring and difficult. During all this time he was devotedly helped by his wife, who acted as his chauffeur for many years, and nursed him to the end. Our sympathy goes out to her, and to his son and daughter.

H. S. ROBERTS, M.D.

Dr. H. S. Roberts, formerly one of Southport's oldest practitioners, died at a nursing-home at Wilmslow, Cheshire, on November 9. He was 84 years of age.

Hubert Shearwood Roberts was born on May 23, 1872, the son of Dr. A. Morton Roberts, of Sheffield. He received his medical education in North America, graduating M.D. from New York University in 1895. After a period as house-surgeon at the Bellevue Hospital, New York, he went on to obtain the Toronto degrees of M.D., C.M. in 1896, and then returned to the United Kingdom to take the Scottish triple qualification in 1897. After working for some time as a ship surgeon he settled at Southport in 1900 and was in practice there until he retired to Wilmslow two years ago. In addition to the work of his practice he assumed a heavy list of public duties, being medical officer to several convalescent and children's holiday homes. During the first world war he served as a captain in the R.A.M.C. in Belgium and France and, later, on recruitment boards. As president of the Southport Medical Society in 1922 he gave an address

on the doctor's car, a subject on which he could speak with some authority. Chairman of the Southport Division of the B.M.A. in 1923-4, he also represented his Division at the Annual Representative Meeting from 1944 to 1947, and was often seen at other Annual Meetings. His death came after a year of ill-health, and he is survived by his wife and a son and daughter. In manner quiet and courteous; in appearance dignified (his dress perhaps a little reminiscent of Edwardian days); assiduous in the care of, and loved by, his patients; devoted to his family—surely the verdict must be "Well done."—W. A. M.

Medical Notes in Parliament

DEBATE ON WOLFENDEN REPORT

The House of Commons put aside its party lines on November 26 to give expression to its opinions on the Report of the Wolfenden Committee on Homosexual Offences and Prostitution. It was asked to do no more on this occasion than "take note" of the report.

Mr. R. A. BUTLER, Leader of the House as well as Home Secretary, in the opening speech put the debate on a serious, human, and at times troubled level. He suggested that the delay of 12 months or so since the report was presented had given a useful opportunity for reflection; and was the first of many speakers to comment that the two parts of the report had not very much to do with one another.

Homosexual Conduct

Their main concern, Mr. BUTLER told the House, would be to decide whether the committee's recommendations for changes in the law were to be accepted. The essence of Mr. Butler's argument was this: the Wolfenden Committee drew a sharp and valid distinction between sin and crime; while private homosexual conduct between consenting adults was commonly regarded as a sin, it ought not to be a crime. The argument that if conduct that was morally wrong was not injurious to society it should be left to the operation of the individual conscience was impressive; but it could be accepted as a reason for leaving homosexuality to the private conscience only if one was convinced that society would not be harmed by so doing. An impression had gained ground, unfair to the Wolfenden Committee, that they desired to legalize homosexual conduct. In fact, what they wished to do was to remove these practices, like adultery and other sins, from the realm of the law. It was clear, however, that there was at present a very large section of the population who strongly repudiated homosexual conduct and whose moral sense would be offended by an alteration of the law which would seem to imply approval or tolerance of what they regarded as a social evil. Therefore the Government were satisfied that they would not be justified, on the basis of opinions expressed so far, in proposing legislation to carry out the committee's recommendations. The committee had drawn attention to the need for research, and, with a reservation related only to heavy demands already imposed on the Home Office, he undertook to follow up the committee's desire.

Legislation on Prostitution

On prostitution, there was probably little disagreement on what was desirable; the question was—what is practicable? Here the principal recommendation was that the law should be reformulated in three ways. The first was to eliminate the requirement to establish annoyance. He thought that was right. The second was that the maximum penalty should be increased, and the system of progressively higher penalties introduced, culminating in sentences of three months' imprisonment for a third and subsequent offences. He had no doubt of the need to clean up the streets. The Wolfenden Committee had made a strong case for its recommendations, and he could now see the lines on which legislation giving effect to them would be

framed. That legislation was being prepared. He was predisposed to sympathize with the view that it was inequitable that the woman should be punished and the man should not. But practical considerations presented real difficulties: the man normally did not loiter; it was not his persistent presence, but that of the woman, that was offensive or injurious; it was almost impossible to identify the man, but it was comparatively easy to identify the woman. It was, further, most important that the law should not be framed in terms that would expose an innocent woman to any danger of arrest for alleged loitering or soliciting. Any new definition of the offences must satisfy two criteria: it must not expose an innocent woman who behaved indiscreetly to arrest; and it must not impose on the police an impossible burden of proof.

On the section of the report relating to living on immoral earnings, Mr. Butler rejected the conclusions as not firm enough and accepted the reservation of three women members that the maximum penalty should be raised to five years' imprisonment. Finally he spoke about the findings on premises used for prostitution, and confessed that on this he did not at present see a way of providing a reasonably speedy and effective remedy that would not at the same time do harm to innocent subtenants.

Dr. Broughton and Dr. Bennett

Two doctors, both with experience of psychiatric work, but as it so happened on opposite sides of the House politically, took part in the debate, and both were opposed to the Wolfenden recommendations on homosexuality.

Dr. A. D. D. BROUGHTON (Batley and Morley, Lab.), after expressing some surprise that the Wolfenden Committee had been asked to investigate two vices so very different, said that he had less knowledge of prostitution because few prostitutes went to psychiatrists. He understood that the psychiatrists who gave evidence regarded prostitution as a social problem and did not supply the committee with any helpful advice. He could see their point of view; but it must be recognized that there was something psychologically abnormal about a woman who chose that way of earning a living. Those whom he had met professionally were women who had been deprived of the love of one or both parents in childhood. He agreed with a view that had been expressed that they were incapable of giving or receiving love. Those he had come across all suffered feelings of isolation and worthlessness. But it would be wrong to generalize from so few cases. There was need for a great deal more research, including research into the mentality of men who resorted to prostitutes. The sight of prostitutes in the streets was displeasing to respectable men, offensive to respectable women, and a thoroughly bad example and temptation to the young. For those reasons he agreed with the recommendations of the committee. But they would not be effecting a cure.

Half a Million Male Homosexuals

Some authorities put the prevalence of homosexuality among males as 4%, others as low as 2%. At the lower figure it would mean that there were half a million male homosexuals in the British Isles. The causes were deeply embedded in a person's mental make-up. Undoubtedly in some cases there were constitutional factors, but it was believed that the environment and upbringing of a child were the most important factors. Normal sexuality was part of the process of growing up, but there were some people in whom the natural process of development was arrested and even reversed.

The homosexuals who took the male or active part appeared of the masculine type. He believed they had been directed along the path of homosexuality by accident: for example, they might in childhood have been made to avoid girls, and therefore have come to regard them with repulsion; or they might, as boys, have had sexual experience with an adult woman and that had filled them with some feeling of disgust. Others had a femaleness

of outlook: they probably had a bad father-image, and because of it had more interest in what the mother and sisters were doing. This type were vain and apt to indulge in exhibitionism. It was in that group that were found the really decadent types and the male prostitutes.

It was true, to a large extent, that it was possible for homosexuals to repress their desires. But the sex urge was not weakened in a man by his being a homosexual. Treatment was extremely difficult. Many homosexuals looked upon the suggestion of becoming heterosexual as quite absurd. It must be realized that it entailed changing their whole life pattern. He agreed with an intervention by Dr. DONALD JOHNSON (Carlisle, Con.) that hormone treatment merely lowered sexuality in general rather than making any change in homosexuality.

Legal Sanctions

The question to be decided was: should the law be modified in the way recommended by the Wolfenden Committee—namely, that homosexual practice among consenting adults should no longer be a criminal offence? If the recommendation was accepted, the general public would gain the impression that Parliament condoned this practice. Homosexuality was biologically wrong. If the recommendation was accepted he had a fear, based on what he knew of homosexuals, that some, not all, would repress their homosexual feelings less. They might go to the extent even of showing some signs of the affection they had for one another in public. He could envisage men walking along the street arm in arm, possibly holding hands, perhaps wishing to dance together, and even caressing in public places.

Mr. S. SILVERMAN (Nelson and Colne, Lab.) said that, supposing Dr. Broughton was right, was that a justification for sending homosexuals to prison, which would be the inevitable result of not changing the law?

Dr. BROUGHTON replied that the law was very savage. He thought the penalties too severe. It was a pity that such heavy penalties were ever imposed. But to alter them at this time, he feared, would be misunderstood and many people would think they were condoning these offences. He would not himself go as far as to send them to prison. Long-term imprisonment was too severe a penalty, and prison was quite the wrong place to send these people. But unless some punishment was imposed there was a danger of others becoming acquainted with the practice and indulging in it. It was a well-known fact that homosexuals banded themselves into groups, and if the law were changed so that they did not have the fear of punishment these groups might elevate the practice of homosexuality to a cult. He had heard of groups in which considerable trouble had been taken by some members in the seduction of others. He was not in favour of accepting the Wolfenden recommendations.

Dr. REGINALD BENNETT (Gosport and Fareham, Con.) welcomed the agreement of Dr. Broughton with his own views, because he felt that few other members of the psychiatric profession agreed. He had thought he was in a minority of one, but saw now that it was a minority of two. He agreed that, on prostitution, what they were trying to do was to take the advertisement of the wares of these people off the streets, even if the practice was historically insuppressible. He would certainly say that the penalties should be raised, but they must beware of doing so to such an extent that every case became defended, and the defence of the women became more and more an undertaking for the "monarchs" of the industry. They should certainly penalize very heavily those who exploited this industry, if they could be caught.

Adolescent Partners

He had done a good deal of practice at the request of the courts in reporting on the state of mind and indeed undertaking the treatment of homosexuals. In the light of his experience he found it difficult to understand why the

Wolfenden Committee came to the conclusions they did. On the strength of expert witnesses, to wit psychiatrists, the report stated (para. 57):

"We are authoritatively informed that a man who has had homosexual relations with an adult partner seldom turns to boys, and *vice versa*, though it is apparent from the police reports we have seen and from other evidence submitted to us that such cases do happen."

That might be true, though he doubted it. They should have much more information before accepting that. He declined to accept that the man who accepted an adult male as his partner would not seek an adolescent male above the age of puberty. He thought they all did. That was why, if indulgence in private was made not an offence, the House would be permitting the spread of an activity that would inevitably lead to a greater evil in proselytizing adolescents.

Mr. F. TOMNEY (Hammersmith, North, Lab.), interrupting, said that in 1947 the Cambridge Institute of Criminal Science made an inquiry covering 1,000 cases from 14 police districts. There were 275 indictable offences for homosexual practices involving 406 accomplices or victims. The majority of the victims were under the age of 16, and only 11% over 21, and only one case of one adult with a consenting adult.

Dr. BENNETT said he was sure that was not far from an average figure. He had seen a fairly large number of homosexuals and he had been struck by the proportion who were adolescents who had been picked up. They were late developers, slow in maturing, uncertain of their sexual direction, and they had been pushed into that direction. He had found it remarkably easy to cure these people with the aid of hormone treatment. This could so suppress sexual tension that a reorientation of ideas had time to take place, so that when sexual desires were allowed to return on the cessation of treatment they were in a more natural form. If patients were suitably selected it seemed that there was a good prospect of cure. That showed that they could not regard homosexuals as incurable, nor as hereditary, congenital, or even environmentally produced people who must have a separate way of life. In his belief a big part in the influencing and curing of these young men had been the fear of the sanction of the law. He would take issue with anyone who said the law was not a deterrent. It was a profound deterrent, especially in those of whom they had the most hope of success. It would be disastrous to abandon the law on that point. For these reasons he could not accept the Wolfenden findings on homosexuality. The evidence produced by the psychiatric profession could not necessarily be accepted as being as sound as it had been accepted as being by the Wolfenden Committee.

ANSWERS TO QUESTIONS

Change of Sex and Divorce Law

Mr. KENNETH ROBINSON (St. Pancras, North, Lab.) asked the Attorney-General if his attention had been called to the legal difficulties arising from the case of *Dolling versus Dolling*, recently before the Court of Appeal; and if he would consider amending the law of divorce to enable marriages to be dissolved on the grounds that a spouse had changed his or her sex. Sir REGINALD MANNINGHAM-BULLER said he was not aware of any legal difficulties. The Court of Appeal held, on the particular facts of that case, that the conduct of the respondent did not amount to cruelty. Sir Reginald did not think there was any need to amend the law by seeking to specify what acts constituted cruelty for the purposes of the law of divorce or by making express provision for the type of case mentioned in the question.

Disparity in Hospital Costs

Dr. DONALD JOHNSON (Carlisle, Con.) asked the Minister if he was aware of the wide disparity of in-patient hospital costs revealed by his department's recently published hospital costing returns, varying in the case of acute

hospitals from £16 0s. 1d. per patient per week for the Middlesbrough General Hospital to £36 9s. 1d. per patient per week for the Royal Northern Hospital, with all gradations of cost in between, showing wide differences even for apparently similar hospitals; and what he proposed to do to find the reason for, and eliminate if possible, such disparities. Mr. WALKER-SMITH replied that some variations were inevitable even in hospitals classified in the same broad category, because of differences in local conditions and in the services provided. It was, however, one of the objects of the new costing arrangements to provide a firmer basis of comparison of detailed hospital costs, and he had asked hospital authorities to make full use of the published information with a view to improving efficiency and securing economies.

Cancer Diagnostic Clinic at Bart's*

Mr. W. HANNAN (Maryhill, Lab.) asked the Secretary of State for Scotland if he was aware of the proposal to establish a clinic at St. Bartholomew's Hospital for free examination for early diagnosis of cancer; and if he would ask for full details of this project and consider taking similar action in Scotland. Mr. JOHN MACLAY: I have noted the proposal and will certainly watch its progress.

Vital Statistics

England and Wales in 1957

The infant mortality rate again reached a record low figure in 1957, being 23 deaths of children aged under 1 year per thousand live births, according to the Registrar-General's Statistical Review of England and Wales for the Year 1957, Part I, Tables, Medical (H.M.S.O., £1). The crude death rate was 11.5 per thousand population, and this too was a record low figure when adjustments are made for the age and sex structure of the population.

The table below contrasts crude death rates for 1947 and 1957 for certain causes of death. The large fall in the death rates for the two infectious diseases listed there is to be seen in the death rates for almost all infectious diseases, including those caused by viruses. In the composite category "Deaths attributable to viruses," for instance, the death rate was 51 in 1947 and 22 in 1957. The principal cause of death in this category in 1957 was infectious hepatitis, with a death rate of 7 per million population.

Crude Death Rate per Million Population, 1947 and 1957.
England and Wales

Cause of Death	1947	1957
Respiratory tuberculosis	473	95
Whooping-cough	22	2
Cancer of:		
Stomach	335	312
Rectum	151	120
Pancreas	61	80
Lung and bronchus, males	(1947) 485	759
females	(1947) 87	116
Breast, females	349	370
Uterus	193	169
Prostate	143	161
Leukaemia	35	53
Chronic rheumatic heart disease	240	183
Arteriosclerotic and coronary disease	895	1,700
Hypertensive disease	352	434
Acute bronchitis	165	63
Ulcer of stomach	71	58
" duodenum	45	53
Appendicitis	36	18
Chronic nephritis	154	76
Suicide	105	118

Scotland in 1957

At 11.9 per thousand population the general death rate in Scotland in 1957 was the lowest for 4 years, but higher than in 1953, when it was 11.5, according to *The Annual Report of the Registrar-General for Scotland for 1957* (H.M.S.O., £1). The infant mortality rate was 28.6 per

*A statement from St. Bartholomew's Hospital is printed at p. 1423.

thousand live births, which was the same as in 1956 and the lowest rate recorded until then.

A comparison of standardized death rates for Scotland and for England and Wales in 1957 shows that for most of the main causes of death Scotland's figures are less favourable. One of the most striking disparities is for diabetes mellitus, the death rate for which was 108 per million in Scotland and 69 in England and Wales. This disparity has increased during recent years, for in 1953 the two rates were 95 and 72. The rate for pulmonary tuberculosis was 136 per million in Scotland and 94 in England and Wales in 1957. The difference between them has remained similar since 1953, when the rates were 235 and 178 respectively.

As usual, the death rate from pneumonia (all forms) was higher in England and Wales (520) than in Scotland (445), and both these figures have increased fairly steadily since 1953, when they were 488 and 363 respectively. Hypertensive disease is also a commoner cause of death in England and Wales, the rate being 429 as compared with 392 in Scotland in 1957. In the large composite group of heart diseases, however, Scotland has the higher rate with 3,999 as against 3,378. In the other two large groups, malignant neoplasms and vascular lesions of the central nervous system, the rates for Scotland are somewhat higher than for England and Wales.

The death rate from syphilis was 20 in Scotland and 29 in England and Wales; these rates have hardly altered in the 5 years 1953-7. An increasing disparity in the death rates from rheumatic fever is notable. In 1953 the rate for Scotland was 8 and for England and Wales 7. Thereafter it did not fall below 8 for Scotland but has steadily diminished in England and Wales, so that in 1957 the two rates were 9 and 4.

18 deaths of reputed centenarians (16 verified) occurred during the year, 1 male and 17 female. The greatest number to be registered in one year is 19—in 1918 and 1950. The greatest age verified was 109 years 14 days of a person who died in 1936.

Week Ending November 22

Infectious diseases were more prevalent in England and Wales during the week ending November 22. The largest rises in the number of notifications were 333 for measles, from 5,779 to 6,112, 133 for dysentery, from 614 to 747, 113 for scarlet fever, from 975 to 1,088, 60 for acute pneumonia, from 309 to 369, and 51 for food-poisoning, from 196 to 247; the only large fall was 48 for whooping-cough, from 805 to 757.

The largest rises in the incidence of measles were 86 in Hampshire, from 81 to 167 (New Forest R.D. 58), 76 in Durham, from 86 to 162 (Stanley U.D. 62), 69 in Wiltshire, from 125 to 194 (Swindon M.B. 67), and 61 in London, from 326 to 387 (Paddington 83); the largest decreases were 56 in Worcestershire, from 96 to 40, and 55 in Buckinghamshire, from 98 to 43. The number of notifications of scarlet fever was the largest for almost 3 years; the largest rises during the week were 30 in Lancashire, from 133 to 163, and 20 in Essex, from 43 to 63. Only small variations were reported in the local returns of whooping-cough. 9 cases of diphtheria were notified, being 3 more than in the preceding week; 5 of these cases were notified in London (Finsbury 4, Hampstead 1) and 2 in Barking M.B., Essex.

4 of the 9 cases of paratyphoid fever were notified in Sussex, Brighton C.B.

The notifications of acute poliomyelitis numbered 72, and these cases were 3 fewer for paralytic and 9 more for non-paralytic cases than in the preceding week. The largest returns were Yorkshire West Riding 14 (Bradford C.B. 2), Huddersfield C.B. 2, Leeds C.B. 2, Pudsey M.B. 2, Lancashire 8 (Manchester C.B. 4), Warwickshire 8 (Birmingham C.B. 6, Rugby M.B. 2), Derbyshire 6 (Bakewell U.D. 2), London 5 (Wandsworth 2).

The largest outbreaks of dysentery were Yorkshire West Riding 98 (Leeds C.B. 53, Thorne R.D. 15), Lancashire 87 (Eccles M.B. 49, Liverpool C.B. 14), Warwickshire 77 (Coventry C.B. 72, Birmingham C.B. 12), London 77

(Lambeth 20, Battersea 12, Deptford 10), Glamorganshire 48 (Rhondda M.B. 14, Cardiff C.B. 12), Cumberland 41 (Carlisle C.B. 25, Millom R.D. 16), Surrey 39 (Godstone R.D. 25, Croydon C.B. 11), Essex 32 (West Ham C.B. 13), Hampshire 27 (Southampton C.B. 14), Nottinghamshire 25, and Middlesex 20 (Hendon M.B. 14).

The largest outbreak of food-poisoning was 58 cases in Crewkerne, Somersetshire.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the years 1949-57 are shown thus -----, the figures for 1958 thus ————. Except for the curves showing notifications in 1958, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending November 15 (No. 46) and corresponding week 1957.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the whole of England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

Medical News

G.M.C. Centenary Dinner.—The General Medical Council held its centenary dinner at the Mansion House, London, on November 27. The president, Sir DAVID CAMPBELL, received the many distinguished guests, who included Viscount KILMUIR, the Lord Chancellor. In proposing the toast of the G.M.C., Sir HAROLD GILLET, Lord Mayor of London, said that the Council could be described as characteristically English, for it was born in Parliamentary compromise and operated as a compromise. It was not a Government department, yet the Crown nominated eight members; nor was it a voluntary association. In reply, Sir DAVID CAMPBELL sketched the Council's achievements over the last 100 years in improving the education, ethics, and social status of the profession of medicine. "To-day I am proud to think that the attainments of the general practitioners in these islands are higher than anywhere else in the world," he said. Such was the prestige of the British Register that last year almost a thousand practitioners from all parts of the Commonwealth sought to have their names inscribed thereon. Sir David said it had been very gratifying to receive the following message from the Vice-Chancellor of an Indian University:

"The General Medical Council has played a vital role in the development of Medical Education not only in the British Isles but throughout the Commonwealth. If we have been able to achieve the present standard of medical education in India, it is largely on account of the guidance that we received from the General Medical Council and the British universities."

Lord COHEN OF BIRKENHEAD, who toasted the guests, welcomed particularly the representatives of the Medical Councils of the Commonwealth and Burma. The reciprocity and temporary registration which enabled practitioners from other countries to work in Britain, and practitioners from Britain to work in the Commonwealth, provided an abiding link of friendship. Speaking as the present head of a sister profession, the Law, Viscount KILMUIR congratulated the Council on the manner in which it dealt with its disciplinary work. "In this mad century and in the odd world in which we have lived," said the Lord Chancellor, "a body that has kept the old, tried, and valued conception of natural justice before it, and has gained respect in its application, can think worthily of itself and of its labours."

Richard Bright Centenary.—The centenary of the death of Richard Bright (1789-1858), physician to Guy's Hospital, was commemorated at Guy's Hospital Medical School on December 1. During the afternoon a number of cases were shown at a combined clinical round illustrating the theme of chronic Bright's disease, attended by many distinguished guests. Dr. W. N. MANN, director of the department of medicine at Guy's, who introduced the round, pointed out the difficulty of establishing the aetiology in many cases of chronic Bright's disease, even after necropsy. He also commented on the rarity of chronic glomerulonephritis, having been unable to find an example in Bright's own hospital for the afternoon's demonstration. After tea Professor M. L. ROSENHEIM delivered the Bright Centenary Lecture before a large audience. Professor Rosenheim discoursed on the syndrome of Bright's disease—which was what Bright had described—rather than a disease entity. He reviewed the remarkable advances made in the investigation of renal disease, and showed how aortography might occasionally uncover abnormalities of one kidney, which could lead to the syndrome of chronic Bright's disease but, if remedied early, offered hope of complete cure. In thanking Professor Rosenheim, Professor ROBERT PLATT said that not only had they heard a brilliant lecture but one by a clinician which would have pleased Richard Bright himself. During the day an exhibition arranged by Dr. C. KEITH SIMPSON was on view in the Gordon Museum. Amongst the many exhibits were the original specimens of the kidney examined by Bright, a copy of *Reports of Medical Cases*,

as well as writings by Bright outside the subject of medicine, and a copy of the original number of the *Guy's Hospital Reports*. In the evening a dinner was given by the Medical School at the Royal College of Physicians, under the chairmanship of Dr. A. C. HAMPSON.

Chair of Medicine, Manchester.—Dr. D. A. K. BLACK is to succeed Professor ROBERT PLATT, P.R.C.P., in the chair of medicine at Manchester University, according to a report in the *Manchester Guardian* (December 2). Dr. Black is the present reader in medicine at Manchester. "Professor Platt," states the report, "has asked to be relieved of his full-time chair of medicine and directorship of the department because of his duties as President of the Royal College of Physicians. Dr. Black graduated B.Sc. at St. Andrews in 1933 and M.B., Ch.B. in 1936, proceeding to the M.D. with honours and the Rutherford gold medal in 1940. He was admitted M.R.C.P. in 1939 and elected F.R.C.P. in 1952. Before going to Manchester Dr. Black was a Beit memorial research fellow at Oxford and Cambridge. In 1953 he was Goulstonian lecturer of the Royal College of Physicians."

Royal College of Obstetricians and Gynaecologists.—At a meeting of the council on November 29, with the president, Professor A. M. CLAYE, in the chair, the William Blair-Bell memorial lectures for 1959 were awarded to Dr. WINIFRED J. A. FRANCIS and Dr. M. L. PATERSON; and the Green-Armytage short-term travelling scholarship for 1959 to Dr. J. C. S. LEVERTON. Congratulations were sent to Professor J. M. MUNRO KERR for his 90th birthday anniversary on December 5.

Feversham Committee.—Mr. R. F. D. SHUFFREY, secretary of the Departmental Committee on Artificial Insemination (Home Office, Whitehall, London, S.W.1), writes: "The committee would welcome the views of any member of the medical profession who may be interested in this subject, and I should be grateful if anyone who is prepared to assist the committee in this way would get in touch with me at the above address." The committee is asked to inquire into the existing practice of human artificial insemination and its legal consequences; and to consider whether, taking account of the interests of individuals involved and of society as a whole, any change in the law is necessary or desirable.

Halliwick Hospital.—On November 27 the DUCHESS OF KENT opened Halliwick Hospital, London, N.11, said to be the first post-war hospital in the London area built specifically for psychiatric purposes. It is a 152-bed unit adjoining Friern Hospital. It cost £260,000 and took two years to build. The Ministry of Health described it as representative of the modern approach to psychiatry—"active treatment of early cases and their quick return to the community." Halliwick Hospital will take, by informal admission, short-stay neurotic patients and patients in the early stages of psychoses. The hospital will be closely linked with community services in its catchment area. Besides providing conventional in-patient facilities, it will also act as a "day hospital" for patients who return to their homes at night after treatment and will allow for evening out-patient treatment of those working during the day. The medical superintendent is Dr. I. SUTTON.

Nuffield Lecture Fund.—The council of the Royal Society of Medicine has accepted from Lord NUFFIELD a sum of £3,513 to establish a Nuffield Lecture Fund. This is the balance of contributions from doctors to an eightieth birthday tribute to Lord Nuffield (see *Journal*, December 28, 1957, p. 1558). The Fund will provide for periodical lectures on the advancement of the science and art of medicine.

Anaesthetist Registrars Prize.—The Scottish Society of Anaesthetists offers a prize of £30 to an anaesthetist not above senior registrar grade for an essay, full particulars of which may be obtained from Dr. M. SHAW, honorary secretary of the Society, at 75, Woodend Drive, Glasgow, W.3.

Mental Health Manual.—The British Red Cross Society has produced a *Mental Health Manual* written by Dr. D. STAFFORD-CLARK, of Guy's Hospital, and illustrated by Miss SYLVIA TREADGOLD. The manual aims at giving "the essentials of a first-aid and nursing approach to all types of illness in which psychological disturbance plays an important part." In part I the author discusses some aspects of normal psychology and describes mental development from infancy through adolescence to adult life. In the second part he shows how this knowledge can be put to use in the care of the sick patient. In a third short part he gives advice on psychological first aid following a major disaster, such as a railway accident, flood, or attack in war. The manual is obtainable from the Society at 14, Grosvenor Crescent, London, S.W.1, for 3s. (3d. postage).

Burden Neurological Institute.—Professor F. L. GOLLA, director of the Burden Neurological Institute, Bristol, since 1936, is retiring. He will be succeeded by Dr. W. ROSS ASHBY, at present director of research at Barnwood House, Gloucester.

Cytology Service at Bart's.—A question was asked in Parliament on November 25 about a cancer diagnostic clinic at St. Bartholomew's Hospital (see p. 1420). The hospital has issued this statement.

"The setting up of a cytology service for the early diagnosis of cancer at St. Bartholomew's Hospital is at present under discussion between the Corporation of London and the Governors of St. Bartholomew's Hospital. A statement giving details of the scheme will be issued, although it may be some time before the service can come into operation."

French Medical Film Prize.—The annual prize for 16-mm. medical films offered by *La Presse Médicale* (value 100,000 francs) will be awarded at the Nouvelle Faculté de Médecine de Paris on March 17. Entries and films should be sent to *La Presse Médicale*, 120, Boulevard Saint Germain, Paris, 6, before February 15.

Sir Walter Mercer has had conferred on him the honorary fellowship of the Royal College of Surgeons in Ireland.

COMING EVENTS

Institute of Dermatology.—Semi-permanent exhibition, December 3 to 30, on "The Skin and Friction."

B.B.C. North Home Service.—"Doctors on Trial," December 10, from 10 to 10.30 p.m.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Saturday, December 6

CAMBRIDGE UNIVERSITY MEDICAL SCHOOL.—At Addenbrooke's Hospital, 10.30 a.m. and 2.30 p.m., symposium: Blood Diseases and Reticuloses. Morning: The Malignant Reticuloses. Papers by Dr. D.A. Kok and Dr. E. M. Kingsley-Pillars and F. G. J. Hayhoe. Afternoon: The Common Anaemias. Papers by Dr. F. G. J. Hayhoe and Mr. S. J. Hopkins.

Sunday, December 7

CAMBRIDGE UNIVERSITY MEDICAL SCHOOL.—At Radiotherapeutic Centre, Addenbrooke's Hospital, 2 p.m., symposium. Papers by Dr. Janet Roscoe, Dr. B. B. Zeitlyn, Dr. C. H. Whittle, and Dr. G. V. Balmforth. **EUGENICS SOCIETY.**—At Royal Society, Burlington House, W., 5.30 p.m., Dr. J. A. Fraser Roberts: Human Genetics at Two International Conferences.

Monday, December 8

GUY'S HOSPITAL.—At Anatomy Lecture Theatre, 5.15 p.m., lecture-demonstration in endocrinology by Dr. P. M. F. Bishop: Diabetes Insipidus.

LONDON UNIVERSITY.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., special university lecture in pathology by Dr. B. Josephson (Stockholm): Examination of Renal Function in Man by Renal Vein Catheterization.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Guest lecture by Professor H. Scarborough: Purpura.

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—4 p.m., Harben Lecture by Sir Samuel P. Bedson, F.R.S.: Psittacosis-Lymphogranuloma Group of Infective Agents—(1) History and the Characters of these Agents.

Tuesday, December 9

ASSOCIATION OF ANAESTHETISTS OF EDINBURGH.—At Surgeons' Hall, Nicolson Street, 7.45 p.m., Dr. C. T. Barry and Dr. J. D. Robertson: Halothane.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. L. Forman: Disturbances of Pigmentation.

INSTITUTE OF NEUROLOGY.—5.30 p.m., Dr. H. Lander (Adelaide): Kuru (The Laughing Disease)—A Recently Discovered Disorder of the Central Nervous System.

MANCHESTER MEDICAL SOCIETY: SECTION OF SURGERY.—At Clinical Sciences Building, York Place, 7.30 for 8 p.m., Mr. H. M. Goldberg: Lesions of the Fundus of the Gall Bladder; Dr. J. R. Edgc: Use of Steroids in Major Surgery for Debilitated Patients with Advanced Tuberculosis.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., FitzPatrick Lecture by Dr. W. S. C. Copeman: Medical Practice in the Tudor Period—Evolution of the Profession.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Erasmus Wilson Demonstration by Dr. L. W. Proger: Aneurysms.

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—4 p.m., Harben Lecture by Sir Samuel P. Bedson, F.R.S.: Psittacosis-Lymphogranuloma Group of Infective Agents—(2) Position of the Agents of Trachoma, Inclusion Conjunctivitis and Cat-scratch Disease. The Ecology of the Agents of the Psittacosis-Lymphogranuloma Group.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Institute Theatre, 5 p.m., Mr. Aleck Bourne: Influence of the Emotional Factor in Gynaecology.

WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Dr. N. G. Hubert: neurological demonstration.

WEST OF ENGLAND CHILD HEALTH GROUP.—At Department of Child Health Lecture Theatre, Children's Hospital, Bristol, 8.30 p.m., Professor A. V. Neale: A Recent Tour Abroad.

Wednesday, December 10

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. H. Haber: Precancerous and Cancerous Conditions of the Skin.

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Mr. Donald Barlow: Surgery of Pulmonary Tuberculosis Viewed in Perspective.

INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—At Chelsea Hospital for Women, 4.30 p.m., Guest lecture by Mr. C. M. Gwillim: Anatomy of Prolax.

INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Dr. A. R. Harrison: Tests of Renal Function.

MANCHESTER MEDICAL SOCIETY: SECTION OF PATHOLOGY.—At Large Anatomy Theatre, Manchester University, 4.30 for 5 p.m., Dr. B. Sandler: Testicular Biopsy: Its Interpretation and Value in Infertility.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Guest lecture by Dr. B. Josephson (Stockholm): Renal Blood Flow Determinations in Man.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH.—3.30 p.m., Mr. D. J. Waterston: Abnormal Development of the Heart and its Surgical Correction.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—5 p.m., Lock Lecture by Sir Eric Riches: New Growths of the Kidney.

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—4 p.m., Harben Lecture by Sir Samuel P. Bedson, F.R.S.: Psittacosis-Lymphogranuloma Group of Infective Agents—(3) Diagnosis, Treatment, and Control of Infection of Man with these Agents. The Taxonomic Position of the Group.

Thursday, December 11

HONYMAN GILLESPIE LECTURES.—At Anatomy Theatre, University New Buildings, Teviot Place, Edinburgh, 5 p.m., Mr. A. B. Wallace: Thoughts on Wound Healing and Wound Care.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., FitzPatrick Lecture by Dr. W. S. C. Copeman: Medical Practice in the Tudor Period—Growth and Status of Medical Practice.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Bradshaw Lecture by Sir Archibald McIndoe: Problem of Facial Burns.

ROYAL MEDICO-PSYCHOLOGICAL ASSOCIATION. PSYCHOTHERAPY AND SOCIAL PSYCHIATRY SECTION.—At 11, Chandos Street, W., 8 p.m., Dr. R. F. Hobson: Analytic Attitude in Psychiatry.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.—7.30 p.m., Professor P. C. C. Garnham and Dr. D. J. Lewis: Parasites of British Honduras, with Special Reference to Leishmaniasis. A discussion will follow.

ST. ANDREWS UNIVERSITY.—At Physiology Department Lecture Theatre, 5 p.m., Professor Dugald Baird: Practical Importance of Clinical Research in Obstetrics.

Friday, December 12

BIOCHEMICAL SOCIETY.—At Department of Biochemistry and Chemistry, Medical College, St. Bartholomew's Hospital, 2 p.m., 378th meeting.

CAMBRIDGE UNIVERSITY POSTGRADUATE MEDICAL SCHOOL.—At Radiotherapeutic Centre, Addenbrooke's Hospital, 4 for 4.15 p.m., clinical and clinicopathological meeting. Discussion to be opened by Dr. A. J. Rook: Melanoma and its Precursors.

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. E. H. Hudson: clinical demonstration.

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—5.30 p.m., special lecture by Professor W. St. C. Symmers: Mycotic Diseases.

KEIGHLEY AND DISTRICT MEDICAL SOCIETY.—At Victoria Hospital, Keighley, 8.30 p.m., Dr. P. M. Addison: The Law as it affects the Doctor.

KENT AND CANTERBURY HOSPITAL.—8 p.m., clinical meeting.

PLYMOUTH MEDICAL SOCIETY.—At Greenbank, 8.30 p.m., clinical evening.

Sunday, December 14

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—10.15 a.m. to 12.30 p.m., Seminar for General Practitioners by Mr. C. Gill-Carey: Common Ear, Nose, and Throat Conditions.

MANCHESTER UNIVERSITY: FACULTY OF MEDICINE AND NORTH-WEST ENGLAND FACULTY, COLLEGE OF GENERAL PRACTITIONERS.—At Theatre J, Clinical Sciences Building, York Place, 11 a.m., Professor E. W. Anderson: Arteriosclerotic Encephalopathy.

BIRTHS, MARRIAGES, AND DEATHS

DEATHS

Clare.—On November 12, 1958, Thomas Charles Clare, M.D., F.R.C.S., F.R.C.O.G., of 19, Central Avenue, Leicester.

Davenport.—On November 15, 1958, Edward Charles Davenport, M.B., of 19, Kirkdale Road, Harpenden, Herts, aged 87.

Eminson.—On November 19, 1958, at 2, Burringham Road, Scunthorpe, Lincs, Ralph Franklin Eminson, D.S.O., M.B., B.S., aged 69.

Guppy.—On November 13, 1958, at The Grove House, Church Stretton, Salop, Francis Henry Guppy, M.C., M.R.C.S., L.R.C.P., D.P.M.

Miles.—On November 10, 1958, at St. Thomas's Hospital, London, S.E., Tudor Miles, M.B., B.S., D.Obst.R.C.O.G., of The Spurriers, Horsell, Woking, Surrey.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Linoleic Acid and Coronary Atheroma

Q.—Does "arcofac" (linoleic acid, pyridoxine HCl, mixed tocopherols) have any beneficial effect on existing atheroma of the coronary vessels?

A.—There is no direct evidence that the administration of linoleic acid has been beneficial to patients with atheroma of the coronary vessels. There is evidence that in animals atheroma can be produced by a diet high in saturated fatty acids and can be prevented by linoleic acid. There is also evidence that in man a diet containing unsaturated fatty acids from vegetable oils such as corn oil, peanut oil, or olive oil leads to a decrease in serum cholesterol, whereas butter, eggs, and beef fat increase it. There is, however, no direct proof that high serum cholesterol levels lead to atheroma in man. Further evidence linking coronary disease with a high consumption of animal fats comes from statistics of the incidence of coronary thrombosis in various countries and groups of people; there is strong evidence of an association, though this does not necessarily imply a causal relationship. This evidence has led some workers to urge strongly that the consumption of more unsaturated fatty acids and less saturated fats should prevent the development of coronary disease; other workers, however, contest this conclusion. The subject is fully discussed in several articles in the *British Medical Bulletin*,¹ which were the subject of an annotation in the *Journal* (October 18, p. 963).

REFERENCE

¹ *Brit. med. Bull.*, 1958, 14, 197-278.

Amphetamine Sulphate and Preludin

Q.—In view of the close similarity in chemical composition between amphetamine sulphate and preludin, why has the former been made a "scheduled" drug and not the latter?

A.—There is indeed a very close similarity in chemical composition and mode of action between amphetamine sulphate and preludin. That the former has been made a "scheduled" drug and not the latter is probably due to the fact that amphetamine has been available for some time and a considerable experience has accumulated, not only of its possible advantages, but also of its dangers and drawbacks. The undesirable effects of preludin, which probably closely approximate to those of amphetamine, have not so far been as thoroughly appreciated. There is a honeymoon period for most new drugs, and perhaps preludin has not as yet settled down into humdrum married life.

Ringworm

Q.—What are the indications for x-ray epilation of the scalp in ringworm due to *Microsporon* infection? Is exclusion from school necessary?

A.—Children with small-spore ringworm of scalp should be excluded from school because of the risk of epidemic spread. If after cultural examination the fungus is found to be *Microsporum canis*, the condition may be expected to clear spontaneously or readily following the application of fungicides. It is important that infected contacts and animals should be dealt with at the same time. Very rarely *Microsporum canis* infection does not clear with such treatment. Infection with *Microsporum audouinii* may similarly clear spontaneously, but in a large proportion of cases is resistant to fungicidal treatment, which should, however, be tried for two or three months. It is these persistent cases of *Microsporum audouinii* which call for x-ray epilation of the scalp.

NOTES AND COMMENTS

P.A.S. and Pulmonary Tuberculosis.—Dr. M. O. J. GIBSON and Dr. M. M. NAGLEY (London, S.E.12) write: We wonder if we could be granted the courtesy of your columns to protest at the answer to the question regarding the effectiveness of Ca B-P.A.S. as opposed to sodium P.A.S. ("Any Questions?" November 8, p. 1174). Your expert maintains that evidence is difficult to obtain regarding the relative values of the two substances and goes on to quote, *in extenso*, a paper in which weighty conclusions are drawn following an analysis of a mere seven cases treated with Ca B-P.A.S. The author of this paper does us the honour of extensively quoting our original paper dealing with this very matter, in which more than two hundred cases treated with Ca B-P.A.S. were analysed, in which the conclusions drawn were that Ca B-P.A.S. seemed to be no less effective than sodium P.A.S. in delaying the emergence of isoniazid-resistant strains when used in combination with isoniazid. In view of the fact that your expert quoted only the most recent paper—that is, that of Lewis—we feel that our original paper should be drawn to the attention of your readers so that the papers and the results may be compared. Briefly, Sir, we would assert that there is no evidence that in clinical use Ca B-P.A.S. is inferior to any other sort of P.A.S. from the point of view of isoniazid resistance, and our follow-up of a three-year period on this very point, proving it to our satisfaction, is in the press and about to be published in another journal. Ca B-P.A.S. is extensively used in this country, and it is therefore important to try and establish its place in the treatment of pulmonary tuberculosis, and we would respectfully suggest, Sir, that this cannot be done on the lines set out by your expert, but can only be done by perusal of the available evidence.

- ² Gibson, M. O. J. and Nagley, M. M., *Ibid.*, 1955, 36, 209.

OUR EXPERT replies: I was, of course, aware of the early paper by Drs. Gibson and Nagley which showed that the administration of calcium B-P.A.S. with streptomycin or isoniazid for the relatively short period of two to four months was followed by the emergence of only a few resistant organisms. However, very much longer periods of treatment are now known to be essential to the effective treatment of pulmonary tuberculosis, and so far as I know the paper by Lewis is the only one which at present gives evidence about the emergence of resistant organisms in patients treated for a more prolonged period with combinations including calcium B-P.A.S. The emergence of resistant strains in three out of seven patients who were known to have had sensitive organisms at the beginning of treatment, and in 20 out of the total of 39 who were investigated but in whom the evidence about initial sensitivity was not so good, is strong evidence of which cognizance must be taken unless it can be controverted. The publication of any further evidence dealing with the rate of emergence of resistant strains in patients treated for periods of a year or more with combinations including calcium B-P.A.S. will be awaited with great interest.

TREATMENT OF ADVANCED CARCINOMA OF THE BREAST*

BY

A. C. CROOKE, M.D., M.R.C.P.

Endocrinologist, United Birmingham Hospitals

Endocrine treatment of carcinoma of the breast has gone through a number of phases from hormonal therapy with androgens, oestrogens, and corticoids to oophorectomy, adrenalectomy, and hypophysectomy, each of which has led on occasion to dramatic improvement but none of which has been shown to be outstandingly the best. It is well known that some tumours of the breast are hormone-dependent while others are not, and that tumours which are hormone-dependent initially will eventually escape from dependence and progress inexorably despite further attempts to alter the hormonal environment. The reasons for these differences are obscure, partly because the factors which are responsible for mammary development and lactation are still not completely understood and partly because hormonal balance is difficult or impossible to assess adequately.

Hormonal Factors in Breast Development

Knowledge of the hormonal factors responsible for development of the breast has accumulated gradually over the past thirty years, aided particularly by the work of Folley (1956) and his group at Reading and by Lyons (1958) and his colleagues at Berkeley, California. These hormonal factors are now becoming more clearly defined owing to the use of experimental animals whose relevant endocrine glands have all been removed, and also to the use of chemically pure hormones. The hormonal factors are grouped broadly under mammogens and lactogens, terms which are in line with the well-known terms oestrogens, progestogens, and androgens.

Mammogens may be defined as hormones which, acting singly or in synergism with other hormones, will induce any of the three main phases of mammary growth—ductal, ducto-alveolar or lobular, and lactational; and lactogens as hormones which, acting singly or in combination with other hormones, will induce milk formation. The term lactogen therefore has a narrower connotation, and it is noteworthy that lactogenic hormone is itself a mammogen (see Diagram on next page). For this reason Lyons prefers the term mammatrophic hormone (M.T.H.), which is also in line with the other trophic hormones—gonadotrophic, thyrotrophic, and adrenocorticotrophic. Likewise the California group prefer to call growth hormone somatotrophic hormone (S.T.H.). S.T.H. is the other main pituitary mammogen. Both M.T.H. and S.T.H. are available as pure proteins by current standards. Both act on the breast in synergism with steroid hormones.

It is well known that oestrogens promote ductal growth in the breast, but they are quite incapable of preventing ductal atrophy which follows hypophysectomy in the young rat. Lyons has shown conclusively that they are dependent on the presence of S.T.H. to prevent this atrophy. S.T.H. is

also incapable of preventing ductal atrophy in the rat which is deprived of its sources of steroidal hormones. The two hormones are therefore said to act in synergism. It is remarkable that substitutes have been discovered for both hormones. The adrenal mineralocorticoid deoxycortone has the same action as oestrone when given in doses five hundred times as great by weight, and smaller amounts enhance the combined action of oestrone and S.T.H. S.T.H. can be replaced by long-acting insulin, but its action is less pronounced (Ahrén and Jacobsohn, 1956; Ahrén and Etienne, 1958).

S.T.H. and oestrogen are incapable of inducing the next stage of development of the breast, but lobular growth will occur in young castrated rats treated simultaneously with the corpus luteum hormone progesterone. This does not occur in the hypophysectomized rat, however, because progesterone, like oestrogen, requires a pituitary hormone as synergist. Lyons has shown that this is M.T.H. There are therefore at least four hormones which are essential for development of the breast up to this stage—oestrogen with S.T.H. and progestogen with M.T.H.—and it is remarkable that the body has no confidence in its ability to produce enough of them for all the requirements of pregnancy. As a result high concentrations of at least three are produced in the placenta, the production of S.T.H. by this organ being still questionable. It is interesting to speculate on the influence of this factor on carcinoma of the breast. Finally, in the rat which has been deprived of its pituitary, gonads, and adrenal glands the addition of an adrenal glucocorticoid like cortisol leads to better development, but still no milk is formed. Curiously, the thyroid gland appears to be unimportant for this development.

Milk Secretion

In the experimental rat, milk secretion depends on the continuation of treatment with M.T.H. and the withdrawal or great reduction of treatment with the sex steroids oestrogen and progestogen. In an animal deprived of its adrenal glands and gonads the addition of corticotrophin or a glucocorticoid like cortisol is essential. Six hormones are therefore ultimately necessary for the production of milk. The transfer of milk from the lobules to the larger ducts is initiated by the posterior pituitary hormone oxytocin, and the suckling stimulus is necessary for its delivery. Suckling probably causes the secretion of oxytocin.

Throughout the development of the breast the ratio of these various hormones to one another is important and is variable from species to species. For instance, in the oophorectomized goat whose pituitary is left intact oestrogen alone in suitable doses can cause extensive development of the udder with lactation, so that progesterone appears to be relatively less important in this species. The ratios of the hormonal factors required for the development of the human breast have still to be established, and clearly these may be of considerable value in the study of carcinoma of the breast.

*Read to the Section of Surgery at the Annual Meeting of the British Medical Association, Birmingham, 1958.

Oestrogens in Relation to Carcinoma

The conception of hormone-dependence of a carcinoma implies that the qualitative character or absolute or relative concentration of certain hormones is important for neoplastic growth, and extensive studies have been made of the concentration of various hormones in blood and urine in an attempt to correlate them with remissions or relapses of the disease. The oestrogens have received most attention partly because the various surgical procedures have been designed primarily to remove the source of oestrogens and partly because there are well-recognized methods for their measurement. The results of a number of investigations on urinary oestrogens were described in a series of papers read at a Conference on Endocrine Aspects of Breast Cancer held at the University of Glasgow in 1957 and published in its *Proceedings*. The methods are, however, by no means simple. There are two ways of dealing with them—by biological assay and by chemical determination.

At first sight the biological method would seem to be the method of choice because it is sensitive and it measures the total biological activity of oestrogens regardless of the

Terminology	Anterior Pituitary Hormones	Ovarian Steroid Hormones	Auxiliary Hormones
Ductal growth 	Growth or somatotrophic hormone (S.T.H.)	Oestrogen (e.g., Oestrone)	Corticotrophin or mineralocorticoid (e.g., deoxycortone)
Ducto-alveolar or lobular growth 	Lactogenic or mammatrophic hormone (M.T.H.)	Progestogen (e.g., Progesterone)	Corticotrophin or glucocorticoid (e.g., cortisol)
Lactation 	Lactogenic or mammatrophic hormone (M.T.H.)	None	Corticotrophin or glucocorticoid (e.g., cortisol) (obligatory)
"Let down" 	Posterior pituitary hormone Oxytocin	Suckling	— stimulus

potency of individual chemical entities. Unfortunately it is necessary first to extract the oestrogens from urine, and the chemical procedures involved may lead to the inactivation of some oestrogenic substances, and also to the activation of some previously non-oestrogenic substances. Moreover, there are substances in urine, like androsterone, which, although not oestrogenic themselves, augment the action of oestrogens in certain assays, and sometimes there are also substances which inhibit the action of oestrogens. We spent a considerable amount of time investigating the biologically active oestrogens and their augmentors and inhibitors in the urine of patients with carcinoma of the breast both before and after operations, including oophorectomy, adrenalectomy, and hypophysectomy. We did not publish our results because we felt that a great deal more academic research was required first in order to elucidate these problems.

If we accept the limitations of the methods, however, we would agree with Scowen (1958) that there appears to be no correlation between the amount of residual oestrogen assayed biologically in urine and the progression or remission of metastatic carcinoma of the breast after endocrine surgery. Indeed, we have been impressed with one patient on whose urine we did a large series of investigations. It consistently contained biologically measurable amounts of oestrogens for nine months after completion of bilateral oophorectomy and adrenalectomy. During this time she had an excellent remission. Then simultaneously with the onset of a relapse the oestrogens disappeared from her urine and were never detectable again.

A method for the chemical determination of the three oestrogens—oestrone, oestradiol-17 β , and oestriol—has been

developed by Brown (1955) which is satisfactory for the concentrations found in the urine of women during the reproductive phase of life. Subsequently it was modified for use with urine of low oestrogenic concentration by Brown, Bulbrook, and Greenwood (1957a, 1957b). Using this procedure, Brown (1958) found that there was no significant difference in the excretion of these three oestrogens by women who had passed the menopause, whether they had carcinoma of the breast or not, and Bulbrook and Greenwood (1957) showed that oophorectomy and adrenalectomy or hypophysectomy (Greenwood and Bulbrook, 1957) in younger women caused a big reduction in excretion, but often failed to abolish it. No comprehensive analysis is available of the relationship between the amount of these oestrogens excreted and the remission or progression of the carcinoma. Perhaps such an analysis would be premature because of the shortcomings of the methods. They do not measure certain other known oestrogens which may be present in significant amounts in urine, like 16-epioestriol, 16 α -hydroxyoestrone, or 2-methoxyoestrone, and studies with radioactive oestrogens indicate that all the known oestrogens represent only a fraction of the total metabolites (Beer and Gallagher, 1955), but apparently they do measure other substances which are not biologically active oestrogens.

Diczfalussy, Birke, Franksson, Hellström, Hultberg, Plantin, and Westman (1958) attempted to characterize substances extracted from the urine of three patients with carcinoma of the breast after bilateral oophorectomy and adrenalectomy. They obtained two substances which behaved like oestrone and like oestradiol-17 β with Brown's procedure, but they behaved quite differently in studies of counter-current distribution and there was a gross discrepancy between the amount of each substance extracted and its biological activity. It is apparent, therefore, that, as in the case of the biological assay, a great deal more fundamental research is needed into the chemistry of the oestrogens and similar substances before the relationship between the production of oestrogens and carcinoma of the breast can be settled.

Progesterone ; 17-Ketosteroids

A considerable amount of attention has been devoted to other steroids. Progesterone, which plays such an important part in the development of the breast, cannot be measured in blood or urine as a routine procedure. Some 20% of circulating progesterone is converted into an inert and more readily soluble steroid, pregnanediol, and a satisfactory method has been developed for its determination in urine (Klopper, Michie, and Brown, 1955). Unfortunately other steroids, including adrenocortical steroids, are also partly converted into pregnanediol, but the amount excreted in urine is commonly regarded as a good reflection of the level of circulating progesterone. Pregnanediol disappears from urine after oophorectomy and adrenalectomy (Strong, Brown, Bruce, Douglas, Klopper, and Loraine, 1956), and its absence is probably a good indication of complete ablation of glandular tissue. No attempt has been made to use this procedure as an indication of hormone dependence in carcinoma of the breast.

The 17-ketosteroids have also received attention. They constitute a conglomeration of substances whose only common denominator is a ketone in position 17 of the steroid nucleus. Some of them are biologically inert, others are androgenic, and yet others have widely different endocrine activities. Measured as a group they are of little or no clinical value now that better and more specific procedures have been developed, especially for the measurement of adrenocortical function. Various methods have been developed for the subdivision of neutral 17-ketosteroids into smaller groups which can be measured separately or for the isolation of individual members of the groups.

A number of workers have applied these procedures to the urine of patients with carcinoma of the breast, but only one group has claimed to show significant differences in

excretion between patients who respond to glandular ablation and those who do not. In a preliminary report Allen, Hayward, and Merivale (1958) showed that the ratio of 11-deoxy-17-ketosteroids to 11-oxy-17-ketosteroids is reduced in patients who subsequently fail to respond to oophorectomy and adrenalectomy or to hypophysectomy. This work has been criticized by Kellie (1958) on the grounds that the method which they employed gives rise to artifacts and certain 11-hydroxylated 17-ketosteroids are hydrated and appear in the 11-deoxy group. Moreover, Plantin, Birke, Diczfalussy, Franksson, Hellström, Hultberg, and Westman (1958), in a similar investigation, found no such differences. If the work of the group at Guy's Hospital is eventually confirmed it would be of considerable clinical value in helping to decide which patients are most suitable for endocrine surgery, and further results are awaited with interest.

Pituitary Hormones

There remains a group of pituitary hormones which play various parts in the development of the normal breast. They comprise S.T.H., M.T.H., corticotrophin, and the gonadotrophins. Various methods have been developed for the assay of S.T.H. and corticotrophin in extracts from animal pituitary glands, but none is suitable for the routine examination of blood or urine. The assay of M.T.H. in human body fluids is little better. The response of the pigeon-crop gland to injections of urinary extracts has been employed by Coppedge and Segaloff (1951) as a measure of M.T.H. Using this method, Segaloff and his co-workers claimed to show changes in the excretion of M.T.H. by patients with cancer of the breast treated with a variety of steroid hormones (Segaloff, Horwitz, Carabasi, Murison, and Schlosser, 1953; Segaloff, Carabasi, Horwitz, Schlosser, and Murison, 1954; Segaloff, Gordon, Carabasi, Horwitz, Schlosser, and Murison, 1954), but it is doubtful if the method is sensitive or reliable enough for clinical use.

Hadfield (1958a) has used the proliferation of the mammary gland of the immature male mouse as an end-point of an assay for what he terms "pituitary mammatrophic substances." The method has been criticized on the grounds that many substances can cause breast development, and there is insufficient evidence about the specificity of this assay. He has partly overcome this difficulty by using hypophysectomized weanling male mice, but very few mice are suitable for the test. He found that only two out of 36 strains examined were satisfactory, and when these two strains were used in another laboratory they were found to have lost their responsiveness (Williams, 1958). Such variation in the sensitivity of a strain to different substances is not uncommon, and sometimes presents considerable difficulty in assay work. The onus lies with the critic to repeat the work until successful. A more serious criticism is that there is insufficient evidence about the precision of the assays performed by Hadfield, but doubtless this information will be forthcoming. Meantime, Hadfield has claimed to be able to demonstrate "mammatrophic substance" in the urine of 57% of women who had passed the menopause and of all younger women during the second half of the menstrual cycle. Recently he (Hadfield, 1958b) has applied the method to the serum of five younger women and found activity in all of them. This work is potentially of such importance in the investigation of cancer of the breast that it warrants considerable effort to repeat it elsewhere.

The assay of urinary gonadotrophins is on rather firmer foundations. The majority of workers use the increase in weight of the uterus of the immature mouse as a measure of the combined effect of follicle-stimulating hormone (F.S.H.) and of luteinizing or interstitial-cell-stimulating hormone (I.C.S.H.). Loraine (1958) used this procedure to measure total gonadotrophins excreted by women with carcinoma of the breast who had passed the menopause. He claimed that those who subsequently failed to respond to treatment with stilboestrol excreted significantly more than those who responded to it. Further studies along these lines are awaited

with interest. The excretion of urinary gonadotrophins has also been employed as an indication of complete hypophysectomy. We have used the test as a semi-quantitative procedure but our interest has been more concerned with the development of assays capable of demonstrating differences in the relative concentrations of F.S.H. and I.C.S.H. These methods have not yet been applied to the problem of cancer.

Persistence of Steroids after Gland Ablation

The discovery that various steroids continue to circulate in the blood and to be excreted in the urine after ablation of the glands which secrete them has led to a reappraisal of the methods of treatment and to a reconsideration of their sources of origin. Incomplete removal of the ovaries or adrenal glands is one possible explanation for the persistence of oestrogens and certain other steroids, and the presence of accessory cortical tissue is another. It has been suggested that stimulation with corticotrophin might demonstrate their presence by causing an increased production of steroids, but it is not generally helpful, possibly because the glandular tissue is already working to its maximum capacity. The incidence of such tissue should be known from necropsy studies, but the remnants may easily be missed unless serial sections are made of large areas. Accessory adrenocortical tissue has been estimated by various workers to occur in some 20% of all subjects. Symington, Grant, O'Donnell, Carr, and Forrest (1958) reviewed the literature on this subject and failed to demonstrate such tissue in a very careful examination of their own material at necropsy. It seems to be unlikely that accessory adrenal glands are a common source of persisting steroids after adrenalectomy, and their origin must be sought elsewhere, possibly from exogenous sources.

The failure of hypophysectomy to relieve all patients with carcinoma of the breast may be due to the presence of accessory anterior pituitary tissue in the roof of the pharynx. This subject has been reviewed by Müller (1958), who found a pharyngeal pituitary consistently in all his own material at necropsy. Its functional significance is uncertain. It contains chromophobe and eosinophil cells and is known to have been the site of an eosinophilic tumour associated with acromegaly. It contains no basophil cells, which might explain the absence of urinary gonadotrophins after hypophysectomy, while S.T.H. and M.T.H. might continue to be produced by the pharyngeal remnant. Ultimately its significance must be established by the development of methods for the assay of the hormones which it produces.

In conclusion we are faced with this challenge. Empirical surgery has established the existence of hormone-dependent carcinoma, and all the biologists, chemists, and pathologists together have so far been unable to explain it.

Summary

Growth hormone acts synergistically with oestrogen to cause ductal growth, and lactogenic hormone acts synergistically with progestogen to cause lobular growth in the breast of immature rats deprived of their pituitary and steroid-producing glands. Little is known, however, of the concentrations of these hormones required for normal breast development in the human subject, but it seems likely that they all may play some part in the development of hormone-sensitive types of breast cancer.

There are several important technical factors which detract from the value of biological and chemical estimations of the various hormone concentrations in blood and urine, and, so far, no convincing correlation has been demonstrated between the remission or progression of cancer and the residual excretion of oestrogens or other steroids. The assay of growth and lactogenic hormones in body fluids is not practicable as a routine procedure at the present time.

The remarkable clinical improvement of patients with breast cancer which sometimes follows hypophysectomy or adrenalectomy and oophorectomy is still not satisfactorily explained.

AN ANALYSIS OF 161 CASES OF CARDIAC INFARCTION WITH ABC ELECTROCARDIOGRAPHIC STUDIES AND 36 NECROPSIES*

BY

E. R. TRETHEWIE, M.D., D.Sc., M.R.A.C.P.

From the Department of Physiology, University of Melbourne and the Royal Melbourne Hospital, Australia

In the *Lancet* (1954), in a section concerning vectorcardiography and referring to the ABC display, it was stated that "satisfactory electrocardiograms have been obtained from cases of known heart disease, but confirmation from larger numbers is needed." In the present paper 161 cases of cardiac infarction observed over a period of 2-8 years by the ABC display have been studied with this end in view. Necropsies were performed on 36 cases of this series.

The standard unipolar limb and chest leads record electrical activity almost solely in the frontal (coronal) plane. The vectorcardiograph is limited with regard to the study of temporal relationships and the acceptance of a standard frame. This simple three-dimensional display, allowing a three-dimensional analysis, is not deficient in these respects. As will be seen from this survey, it detects all changes detected by the present normal leads, and in addition detects changes not demonstrated by the normal leads.

*Technical assistance for this work was aided by a grant from the National Health and Medical Research Council of Australia.

The series of patients is classified into the following groups.

A. (i) Clinically diagnostic, standard E.C.G. diagnostic, ABC leads diagnostic: 127 cases; 32 traced deaths, 25 necropsies. (ii) Clinically diagnostic, standard E.C.G. not diagnostic, ABC leads diagnostic: 24 cases; 5 traced deaths, 5 necropsies.

B. Clinically not obvious, standard E.C.G. not diagnostic, ABC leads diagnostic: (i) fatal cases 4, 2 necropsies. (ii) survivors 2.

C. Infarct totally unexpected, ABC leads diagnostic: 1 case (necropsy positive).

D. Clinical diagnosis infarction, ABC leads negative: 1 case (necropsy negative).

E. Special instances: (i) Minor infarct patterns: 4 cases; 1 traced death, 1 necropsy. (ii) Abnormal T-wave form (also included in A): 1 case. (iii) heart block (also included in A): 17 cases; 12 traced deaths, 9 necropsies.

Method

The majority of the patients were examined personally by me, and the condition of all patients was discussed with at least one physician concerned with the management of each patient.

FIG. 1.—(a) Planar sheet (diagrammatic) of infarction AB at right-angles to YOY. Further details in text. (b) Linear infarction, C, at right-angles to A and B axis. Further details in text. (c) Four dipoles paired and orientated at 180 degrees. Further details in text. (d) Clockwise dipoles. Further details in text. (e) Direction cosines (0,0,1; 1,0,0; 0,1,0) to ABC axis. Further details in text.

E.C.G. recording was usually performed with a Both direct writing electrocardiograph and in some instances with a "cardio-scribe" direct writing machine. A continuous check was made to ensure that the recording apparatus was kept in good condition.

When patients died every endeavour was made to have a necropsy performed, though this was not always possible owing to conditions beyond our control. In some instances the freshly removed intact heart was perfused through the coronary vessels with a gelatin-barium suspension at 37° C. and 120 mm. Hg pressure and then x-rayed as described by Blumgart *et al.* (1940).

ABC electrocardiographic recording was made from the right-angled system: xiphisternum (X), manubrium

sterni (M), left axilla (L), and right chest at the base (R), as described previously (Trethewie, 1953). Lead A is taken from the manubrium and xiphisternum (MX), lead B from the left mid-axilla at the level of the xiphisternum and the xiphisternum (LX), lead C from the right chest at the base at the level of the xiphisternum and the xiphisternum (RX). LX, MX, and RX are all mutually at right angles. The electrode connected to X is positive for upward deflection and thus corresponds to the left leg lead in lead II Einthoven. Thus the right arm lead corresponds to the varying electrode placed successively on the manubrium, left axilla, and right chest at the base. This should define electrical fields in a three-dimensional conductor when these fields emanate from a dipole within the volume, and probably also would analyse whatever combinations of dipoles are present or whatever the characteristic electrical events arising in the conductor. Certain modifications occur owing to the fact that the medium is not homogeneous, though nearly so, and the conductor is not infinite, but bounded by the body surface. The former modification is regarded as minor by most observers. Schmitt (1955) has shown there is a modification, and actually recorded it, with a homogeneous medium containing a dipole inside a model in the shape of the human torso.

Influence of Infarction on the E.C.G.

Let us consider a planar sheet of heart muscle which is infarcted (Fig. 1,a). Such a sheet produces a "current of injury," the injured portion of muscle being at the surface electrically negative compared with the surface of the adjacent healthy muscle. The QRST complex then shows elevation of the RT segment, provided the leads chosen are in the plane of the affected muscle (AB). In the line YOY, at right angles to this plane for all practical purposes, the heart contains only healthy muscle, and segment elevation will not be observed in a lead chosen along this direction—for example, lead C (Fig. 1,a). Depending on the angle formed by the planar sheet to the directions A, B, and C, so we will obtain more or less "weighting" or segment elevation in specific leads.

Let us next consider a linear distribution of infarction (Fig. 1,b). In this instance no effects will be detected in leads A, B, but considerable change will be detected in lead C. If C were only slightly askew to the plane AB there would be relatively little observable effects of the infarction in C. This is the case with V_1 - V_3 with small septal infarcts. Such infarcts do, however, show gross changes in lead C of the ABC display.

Since the posterior aspect of the heart forms a considerable vertical sheet of muscle, infarcts in this area classically produce maximal effects in lead A. The antero-lateral aspect of the left ventricle which recedes posteriorly and cranially is parallel to lead B, and thus infarcts

in this region produce maximal changes in that lead. The septum is almost parallel to lead C, and infarcts in this portion in the heart produce maximal effects in lead C. Likewise the AC pattern indicates posterior septal infarction and the BC pattern indicates anterior septal infarction. This aspect is amplified later with necropsy studies (cf. Fig. 2).

To produce a null effect as referred to above, dipoles would be required to be orientated in opposite directions (Fig. 1,c). However, cardiac infarction simply produces a steady state of "injury" current which gradually subsides over two to three weeks with the development of fibrosis followed by contraction. This latter phenomenon alters the axis of adjacent healthy muscle fibres and may result in a permanent inversion of the T wave in a particular lead. Ischaemia may also affect the T wave. Two areas of infarction would summate this "negativity," not cancel each other out. Similarly a null effect could be produced by a ring of muscle with a clockwise (or anti-clockwise) orientation of dipoles, and dipole α and dipole β (Fig. 1,d) might then cancel out one another; but again the effect of infarction, as before, is to produce

FIG. 2.—Infarct sites, as detected at necropsy. Continuous line, recent infarction; broken line, discrete fibrosis; dotted line, degeneration only. Top left-hand corner, Patient number, E.C.G. infarct pattern designated centrally.

FIG. 3.—(a) Patient 93: Septal infarction extending anteriorly over the left ventricle with fibrotic lamina from older infarction parallel to the right. Further details in text. (b) Roentgenogram of perfused heart from Patient 128. Right coronary block at A and left coronary at B. Further details in text.

a steady "state" of negativity. Contraction of infarcted muscle does not occur with heart beats. In the presumed circus movement of flutter, now not acceptable in its original form, the repetitive firing of the P wave is the diagnostic feature, not injured muscle. Further, the nearer bipolar leads are to the heart the less likely is it that clockwise dipoles would cancel one another out. The ABC leads are close to the heart.

For changing potentials—that is, when currents are produced as distinct from static charge—the field patterns will not be arrived at immediately because there is a degree of impedance in the conductor (that is, the body). However, Kaufman and Johnston (1943) consider these variations in resistance as minor, and that they do not influence potentials greatly. Further preliminary tests on a human torso with a dipole source at the heart position show that the potentials as recorded for leads A, B, and C, while not being at the precise level expected, are nevertheless at 60%, 75%, and 90% of the theoretical value, and, so long as an abnormal contour appears even in part, this should be large enough to have practical significance. Again the particular problem concerning us here is the evaluation of infarcts, and these produce a steady current of injury, so that estimates based on static laws probably do apply here. The problem is best answered by the practical results obtained: namely, do the leads used record significant changes in accord with pathological findings?

It would appear axiomatic that a right-angled distribution of the ABC type is the logical display to choose for electrocardiography because no electrical axis is then unrepresented and more obvious segment elevation must be produced in one lead than is the case with any other display owing to that distribution. In the representation shown in Fig. 1, e, the direction cosines become 0,0,1; 0,1,0; and 1,0,0, when the ABC leads correspond to the axes chosen in the original figure, because $\cos 90^\circ = 0$ and $\cos 0^\circ = 1$. The approximate size of the infarct can then be indicated. In point of fact point X (xiphisternum) is close to 0 (Fig. 1, e), since the heart occupies the anterior part of the mediastinum, and this distribution applies as nearly as is possible practically. Further, this distribution, being located on skeletal points—namely, manubrium and xiphisternum—ensures regularity of repetition of the display from patient to patient.

E.C.G. Pattern and Infarct Site as Revealed at Necropsy

The sites of the infarct in 36 instances where necropsy studies were available are shown in Fig. 2. In these the heart has been cut across horizontally below the level of the atria and observed from above, so that the left ventricular cavity appears on the left and the right cavity on the right. The photographic findings of the heart from Patient 93 are shown in Fig. 3, a, where two parallel septal infarcts of different age are well shown. Leads ABC showed a "Cb" type cardiac infarction, indicating recent septal involvement extending on to the antero-lateral surface. Also, R_A was absent and without segment elevation in A—that is, Q_A form—indicating older infarction in the posterior portion, and in fact there was older septal infarction extending posteriorly to involve both ventricles at a lower level than that shown in Fig. 3, a. It will be observed that, as expected from theory (Trethewie, 1953), "C" type infarcts are largely septal (Fig. 2), "B" type infarcts more commonly involve the antero-lateral aspect (Fig. 2), and "A" type infarcts more commonly involve the posterior aspect of the heart (Fig. 2). Occasionally BC type infarcts involve the posterior and medial aspect of the left ventricle rather than being antero-septal, especially if block is present. Thick black lines indicate recent cardiac infarction, interrupted lines old infarction (with fibrosis), and dotted lines degeneration only (Fig. 2).

X-ray Studies: Radio-opaque Perfusion

In five instances the heart was perfused with radio-opaque material, laid open by incision along the anterior border between the two ventricles, the septum excised, and the whole x-rayed. Fig. 3b was obtained from Patient 128, and a block is shown in the right coronary artery (A) after giving off the inferior interventricular branch and also in the anterior descending branch of the left coronary artery (B). The E.C.G. (Fig. 4) indicated old posterior infarction (Q_A) and recent antero-lateral infarction involving the septum (STBC). At necropsy there was an old posterior infarct, and in the postero-medial aspect of the left ventricle (including the septum) there was recent infarction—that is, parallel, but posterior to the region suggested.

FIG. 4.—E.C.G. of Patient 128, heart depicted in Fig. 3: "Bc" type infarct pattern with old Q_A .

Classified Groups

A. Cardiac Infarction Obvious Clinically

(i) Patients with histories indicative of cardiac infarction associated with typical electrocardiographic tracings.—This aspect need only be discussed quite briefly, and it is sufficient to point out that in 127 patients there was no doubt whatever that the E.C.G. standard display (E_1, E_2, E_3 ; aVR, aVL, aVF; V_1-6) yielded conclusive evidence of infarction. Leads ABC also yielded conclusive evidence of infarction in all 127. One impressive feature has been the magnitude of the segment elevation in the ABC display, which is frequently greater than that of the standard display, and the fact that changes are so commonly seen in a greater proportion of leads with the former. Definite pattern changes are observed

FIG. 5.—E.C.G. of Patient 26: "CBa" type infarct pattern.

surface. This patient developed a second infarction two months later ("Abc" type)—that is, posterior infarction—and he died on the fifth day of the attack. Necropsy was not permitted.

(ii) Patients with histories indicative of cardiac infarction associated with standard display tracings not regarded as indicating evidence of infarction, ABC tracings diagnostic.—Twenty-four patients (15% of cases) came under this heading. In each case leads ABC yielded unequivocal evidence of infarction. Such an instance is recorded with Patient 106. Three days before admission this patient, a male, complained of the sudden onset of severe pain under the sternum, with collapse. He was sweating, and his colour for a time was somewhat greyish. Twelve days after the onset his B.S.R. was 118 mm. in one hour and 128 mm. in two hours. His standard E.C.G. eight days after the onset is recorded in Fig. 6. The ST segment in V_1-3 is not quite normal, but this was not regarded as pathognomonic of infarction. The T-wave in V_5 and V_6 is of low potential and inverted. Leads ABC (Fig. 6), taken at that time, show conclusive evidence of infarction of the Bc type with maximum segment elevation in lead B—that is, antero-lateral cardiac infarction.

The tracing shown in Fig. 7 was obtained from Patient 80, who had attacks of substernal pain on the two days before and on the day of admission to hospital. Four hours before admission the pain was severe, prolonged, and associated with collapse. The standard E.C.G. throughout the course of his illness was recorded as not signifying infarction, but a confident diagnosis of infarction was made on clinical grounds. On the nineteenth day the tracing of leads ABC

FIG. 6.—ABC-E.C.G. and standard E.C.G. of Patient 106. Tracing taken eight days after onset. Note the considerable segment elevation in B not apparent in standard leads.

was taken (Fig. 7). This shows segment elevation in all leads, maximal in lead B with obvious elevation in lead C with "round-shouldering." Elevation is also present in minor form in lead A. This is the distinctive feature confirming the diagnosis of cardiac infarction in contradistinction to left-heart-strain pattern. In this instance, of course, a confident clinical diagnosis was possible, but the value of electrocardiography, especially if it can be shown to be correct regularly in the absence of a clinical history suggesting infarction, is self-evident, and is discussed in the next section. A similar finding is shown in Fig. 8 (Patient 20), where the tracing was obtained 30 hours after the onset of infarction and segment elevation is considerable, while the standard leads E.C.G. did not indicate infarction.

The infarct pattern in the 24 cases coming under the above heading showed the distribution recorded in Table I.

For clarity, a "BC" infarct pattern—that is, marked change in B and C, though greater in B—includes CB (changes greater in C); likewise with BA and CA, and in 12 instances where some change was observed in the third lead also, the notation was recorded as the two leads in which the changes were greater. It is noteworthy that in only one instance in the 161 patients did lead A (indicative of posterior infarction) yield conclusive evidence of infarction when the standard leads did not. In this case block was present which obscured the diagnosis in the standard leads. This

FIG. 7.—E.C.G. of Patient 80, showing typical infarct pattern on the nineteenth day; standard tracing not indicative of infarction throughout course of illness.

TABLE I

No. of tracings	12	5	4	2	1

aspect will be discussed later. On the contrary, in 14 instances (BC and CA type pattern) where the septum or that portion of the left ventricle parallel to it was involved, conclusive evidence of infarction was manifest in leads ABC, while the standard leads did not yield conclusive evidence of infarction. Of ten patients who died and on whom a

FIG. 8.—E.C.G. of Patient 20; typical infarction 30 hours after onset. Standard leads did not indicate infarction.

necropsy was performed where the pattern was of this type—that is, with major involvement in lead C—the septum was found to be involved in seven, and in three instances the postero-lateral part of the left ventricle (parallel to the septum) was involved. Nine other patients were found to have an associated BA or B type infarct pattern (Table I). Since lead B is inclined at about 40 degrees to the frontal plane, this finding could be expected. Standard lead tracings, where minor changes were observed, which were not regarded as presenting evidence of infarction but were nevertheless not normal, involved leads V₁, V₂, or V₃ in four instances, lead 3 in one, and lead V₄ in one. In the remainder changes were quite trivial.

Changes found in lead V₃ of the type referred to above are probably due to the infarct, but since this lead is only slightly askew to the frontal plane, as referred to earlier, infarct pattern changes are not likely to be marked if the frontal plane leads (Einthoven and lateral V leads) show indefinite infarct patterns.

Five of these 24 patients died. Necropsy was performed on all five subjects, and the infarct was found in the site expected for the ABC finding in each instance.

In 5 of these 24 instances (3% of cases) the initial diagnosis made was of cardiac infarction, but considered opinion at a later date was opposed to this diagnosis. In each instance, in the opinion of at least one other physician and in my own, these patients were still regarded as suffering from myocardial infarction. Such a state of affairs is to be expected, especially as it is recognized that some 15% of patients do not show conclusive evidence of infarction in standard lead electrocardiography. Emphasis in such cases must therefore be placed largely on clinical findings.

It is pointed out below that one patient who was not regarded as suffering from myocardial infarction on clinical grounds, and who was not considered to have a myocardial infarct after necropsy (macroscopic) examination, was recorded as clearly associated with myocardial infarct pattern in the lead ABC findings. Subsequent histological examination of the heart, carried out because of the latter findings, revealed the presence of a laminar infarct in the posterior part of the heart. Again in Section D, below, an infarct was diagnosed clinically without support in the E.C.G. findings with leads ABC; and subsequent necropsy, including microscopical examination, did not reveal the

presence of infarction four days later nor was coronary atheroma present. There was also adequate evidence at necropsy for another cause of death. Such findings naturally strengthen one's confidence in the value of leads ABC, and the absence of standard lead confirmation may have played a part in the different clinical opinion expressed in relation to the five patients referred to here. Nevertheless, at the initial examination the clinical picture was regarded by all as being that of cardiac infarction.

The case history of one of these patients is presented as an example.

Patient 53 complained of the sudden onset of tearing pain at the lower end of the sternum and in the epigastrium one week previously. The pain radiated up to the back of the neck. On admission his B.P. was 180/90 mm. Hg. The standard lead E.C.G. was regarded as normal throughout his stay in hospital. Lead 3, obtained on the eighth day after the onset of the pain, showed a minor anomaly considered to be sufficiently like a normal RSR'. The B.S.R. at this time was 35 mm. in one hour and 64 mm. in two hours (Westergren). X-ray examination of the lungs was normal. Leads ABC revealed a classical Pardee curve in leads A and C, indicating a postero-septal infarct.

B. Infarction not Obvious Clinically

(i) Patients who died where leads ABC showed unequivocal infarction but in whom infarction was not certainly diagnosed on clinical grounds, and the standard leads did not yield definite evidence of infarction.—Four patients in whom leads ABC showed unequivocal infarction died, while infarction was not certainly diagnosed on other grounds. In each of these patients standard lead E.C.G.s did not

FIG. 9.—Typical "Bac" type infarct. Clinical history thought to indicate ischaemia only. Standard leads, ischaemia; necropsy, antero-lateral infarct (left ventricle).

confirm infarction. One of the patients had complained for years of abdominal pain on exertion, and, following a more severe attack of pain, dyspnoea at rest appeared. Her B.P. was then 160/120. From a consideration of the clinical picture and the standard E.C.G. leads the consensus of opinion was that the patient suffered from ischaemia. Slight segment elevation was shown in V₄, and this was thought not to be indicative of infarction. In leads ABC, however, a classical Bac type infarct pattern was observed—that is, an antero-lateral infarct (Fig. 9). At necropsy an antero-lateral laminar infarct was found in the left ventricle. This infarct encroached neither on the endocardial nor on the pericardial surface. A histological section is shown in Fig. 10, which shows the infarct clearly.

The second of these patients developed cardiac failure fairly suddenly and was critically ill; it was thought that cardiac infarction could not be excluded. The standard E.C.G. (I, 2, 3, aVL, aVF, V₂, V₃, V₆) did not suggest cardiac infarction, but lead C showed gross segment elevation and also a W-shaped contour, including a well-marked Q wave. At necropsy a recent and an old infarct were found in the septum as expected (lead C lies in the septal axis).

Necropsies were not performed on the other two subjects. (ii) Patients who survived where leads ABC showed unequivocal infarction, but in whom infarction was not certainly diagnosed before electrocardiography and the standard leads did not yield definite evidence of infarction.—There were two patients in this group. One patient, a

woman aged 51, had complained for 15 years of sharp pain near the lower sternum in the evening on walking. She did not stop walking on experiencing the pain. This pain was regarded as not indicative of organic cardiac disease. A standard lead E.C.G. and leads ABC at that time were normal. Her B.P. was 148/80 mm. Hg. Following examination I expressed the opinion that the patient might be suffering from cholelithiasis and advised cholecystography, but that I was not certain whether the patient suffered from angina of effort in addition. Cholecystography revealed the presence of numerous biliary calculi.

FIG. 10.—Microscopical section of heart from patient whose E.C.G. is recorded in Fig. 9. (x543.)

Cholecystectomy was performed. Two years later the patient stated that the pain had become worse. Then six months later, at a second examination, she said that one week previously she experienced a sudden onset of lower sternal pain and sweated, the pain lasting four hours. A standard lead E.C.G. was normal, but lead A in the ABC display revealed the presence of a classical Pardee curve, indicating posterior cardiac infarction.

C. Cardiac Infarction quite Unsuspected on Clinical Grounds but Evident from Leads ABC

This patient was admitted to hospital with hypertension and developed a hemiplegia. He did not complain of cardiac or chest pain. A standard E.C.G. was not done. Leads ABC (Fig. 11a) show segment elevation with round-shouldering in lead A, conclusive evidence of posterior infarction. There is also segment elevation in leads B and C, but in B the elevation is angulated very much as it is in hypertensive strain. With such a degree of elevation in leads B and C in hypertension ordinarily the S waves are

FIG. 11.—(a) Typical posterior infarct pattern in patient with coarctation. (b) Typical tracing of coarctation of the aorta without infarction.

much larger. Here they are normal to reduced in potential. The T waves are unduly large and abnormal. The patient was 38 years of age. At necropsy the heart, other than showing considerable hypertrophy, appeared normal macroscopically. However, more careful examination of the posterior part of the heart, carried out because of the ABC-E.C.G. finding, revealed the presence of a recent laminar infarct. The patient was also found to have coarctation of the aorta, and for interest a tracing obtained from another patient who had coarctation of the aorta (without infarction) is shown in Fig. 11b. Interestingly enough the S waves again are not prominent and there is flutter-fibrillation (lead A). Segment elevation with angulation is seen in leads B and C, but, more significantly, the S-T segment is depressed in lead A. This is the distinctive feature of left-heart-strain pattern. With cardiac infarction the S-T segment in lead A is not depressed or concave upwards at the isoelectric line. Infarct patterns with leads ABC always show elevation, not depression, of the S-T segment when this is abnormal. Further, the round-shouldering of the contour is significant of infarction. In the absence of segment elevation, as with other leads, infarction is of course indicated by a cove-shaped usually inverted T wave and a biphasic R-T interval. Segment elevation pattern may conform to the monophasic type or the high take-off of the Pardee type.

D. Cardiac Infarction Diagnosed Clinically Without Changes in Leads ABC Suggestive of Infarction

This patient complained of shortness of breath and cough for some months and chest pains one week before admission. Retrosternal pain with cyanosis developed on the previous day, and the patient was treated with anticoagulant therapy for cardiac infarction and also treated for cardiac failure, pneumonia, and shock. The prothrombin level fell to 12%.

The standard E.C.G. was recorded as indicating ischaemia only. Leads ABC did not support the clinical diagnosis of cardiac infarction. The ABC-E.C.G. is presented in Fig. 12. Potentials are very low, as is seen sometimes in pericarditis or in approaching death; the T waves are flat. This patient died 72 hours later. The recording made against the ABC leads before death was: "Very low potential, ischaemia apparent in A; I would think the muscle would show degenerative changes microscopically, but the tracing is not of the Pardee type." It was concluded there was no infarction. At necropsy three small foci of old pericarditis were found. The coronary vessels were free of atheroma, as was the proximal aorta. The ventricular muscle was dark brown in colour, but no infarct was found. Microscopical examination at a later date revealed the presence of brown degeneration in the cardiac muscle. Other significant findings at necropsy were gastro-intestinal haemorrhage (gross), pulmonary emphysema, acute bronchiolitis, cholelithiasis, and diverticulitis coli. The gall-bladder was distended with bile and there was impaction of small pigment calculi. If one

FIG. 12.—E.C.G. of patient with old pericarditis and ischaemia. Further details in text.

can apply an electrocardiographic technique which is so complete that infarction can be excluded if the E.C.G. is negative, obviously one has a most valuable tool to aid diagnosis.

E. Special Instances

(i) *Minor E.C.G. "infarct" patterns.*—It is regarded as likely that, since leads ABC record three leads mutually at right angles with a common origin, the grossness of the infarct can be deduced approximately from the degree of segment elevation all three leads. On the contrary, if only the frontal and slightly skew frontal planes are recorded, gross infarcts may sometimes produce little segment elevation in the electrocardiogram.

A tracing may be observed, in the case of a patient considered to be suffering from cardiac infarction on clinical grounds, where the E.C.G. tracing forms a very small though definite "Pardee" complex or other slight segment elevation. If this tracing is magnified, the evidence of infarction electrocardiographically becomes more obvious. It is suggested such patients developing pain at rest show recent degenerative cardiac changes short of infarction. This feature was observed in four patients in the present series, and is seen more often in private practice. For accuracy of recording, an ink writer forming a fine line, or a cathode-ray oscillograph, is required to demonstrate this feature. Multiple T inversions approaching a cove shape also occur in severe acute ischaemia. All of these patients were diagnosed clinically as suffering from cardiac infarction without any doubt. Three survived. The other patient died. The ABC findings in one of the former showed a Pardee curve in lead B, passing to a cove-shaped inverted T wave and a Pardee curve in lead C. The standard E.C.G. appeared normal, showing an RSR' of apparently normal type in lead V₂. In the remaining two, minor monophasic segment elevation was evident in leads ABC. The ABC findings in the fourth patient showed a curve of Pardee type in lead C, leading to an inverted abnormally shaped T wave. This was less evident in lead B, while there was no segment elevation in lead A (Fig. 13). Magnification of the tracing demonstrated the feature more readily. Similar though less obvious findings were observed in V₂ and V₃. This patient died seven days after admission on August 22, 1955. The ABC-E.C.G. diagnosis before death was "Pardee type tracing: septal infarct, very small." At necropsy broad zones of pallor were observed in the left side of the interventricular septum and in the papillary muscles of the anterior wall. Both coronary arteries were almost completely occluded at their origins, and elsewhere were grossly atheromatous. Microscopically, cloudy swelling and some vacuolation were seen in the muscle fibres in the pale zone, but no massive infarction was observed (Fig. 14).

It is considered worth while to follow such cases through with necropsy findings wherever possible, so as to determine if such minor changes as illustrated in these four examples are indicative of degenerative changes in the muscle as distinct from discrete infarct formation. Continued reduced blood supply and oxygen lack can be expected to produce degenerative changes. This has been shown for the liver (Trethewie and Gaffney, 1951). Undoubtedly post-mortem changes

require exclusion, and the interval after death before necropsy examination needs to be kept at a minimum even though the body is placed in the refrigerator. In view of the facts that the second subject died during cold weather (in Melbourne), was placed in the refrigerator on arrival at the necropsy department, that bands of pallor were seen in the heart in the area suggested to be involved previously by the ABC findings, that the

FIG. 14.—Microscopical examination of heart from patient whose E.C.G. is shown in Fig. 13. (×554.)

coronary arteries were almost completely occluded at their origins, and that actual vacuole formation was observed in cells in pyriform areas of degeneration, it is considered very likely that the microscopical changes observed in the heart were of ante-mortem origin.

The incidence of this condition in patients admitted to public hospitals with a diagnosis of cardiac infarction is lower than that found in the general population. For instance, apart from the series of 161 cases reported here, of 139 cases of heart attacks seen privately and thought clinically to be possibly or probably due to cardiac infarction, 115 showed frank evidence of cardiac infarction electrocardiographically with leads ABC, and 24 showed these minor changes of "ischaemia at rest." This feature, recognized at the necropsy referred to above performed in August, 1955, has been re-emphasized recently for the standard leads in relation to S-T depression. The polarity of the ABC leads, since point X is close to zero potential (Nahum, Mauro, Chernoff, and Sikand, 1951), probably accounts for the fact that the current of injury in the degenerated muscle, as with frank infarction, also produces segment elevation in the tracing. Frey (1938) and Oettel (1941) describe elevation of RST during acute coronary insufficiency without infarction at necropsy.

(ii) *Abnormal T-wave forms in cardiac infarction.*—The cove-shaped inverted T wave is commonly seen in cardiac infarction with ABC leads as with standard leads. In addition the cove-shaped upright T wave may also indicate cardiac infarction with leads ABC as with standard leads. Such a case is illustrated in the following. Patient 109 was admitted to hospital with a history of eight hours' duration of sudden severe chest pain passing to the neck and down both arms; he lost consciousness, and on recovery of consciousness was cold and clammy. The ascent of the T wave (Fig. 15) is faster than the descent, it is peaked, and the T wave reaches its maximum after about 50–55% only of the interval from the Q wave to the extreme end of the T wave. Also, it is noticed that the "take-off" is slightly elevated and round-shouldered. This E.C.G. was taken eight hours after the onset.

This type of tracing may be replaced by a more usual pattern later, and in fact five days later this patient's E.C.G. revealed an inverted T wave with well-marked Q wave formation.

(iii) *Electrocardiographic diagnosis of cardiac infarction associated with heart block.*—The diagnosis of cardiac

infarction in the presence of heart block is regarded as a difficult one electrocardiographically. If an earlier tracing free of heart block is available and the E.C.G., taken immediately after symptoms and signs of cardiac infarction appear, shows heart block, this development is generally regarded as due to infarction. Such a case has already been reported with leads ABC (Trethewie, 1953). Right bundle block does not present such difficulty usually, though

FIG. 15.—Cove-shaped upright T wave of cardiac infarction eight hours after onset.

it may be congenital. It was pointed out (Trethewie, 1953) that segment elevation is also evident in such tracings, while in block due to old fibrosis and electrolyte imbalance such segment elevation presents different features. Recently vector-cardiographic work has indicated a feature suggesting infarction associated with block, and this probably depends on the same feature fundamentally. In the present series 17 patients showed varying degrees of block.

There were five cases of left branch bundle block in this series. Three conformed to the pattern seen in hypertension with the gradual production of block following a left strain pattern. In one of these there was no notching of the S wave (first downward complex), but some slurring in leads A and B. In one, notching was present in this complex in A and C, and in one notching in A, B, and C. The B.P. in the first patient was 170/110 on admission. The sedimentation rose and there was a leucocytosis. The history was clinically significant of infarction, and the patient survived.

For comparison the findings in a patient who had no history suggestive of cardiac infarction, but who developed left bundle block associated with aortic regurgitation, are described. The tracing showed slurring only in lead A and not in lead B or C. This patient died two years later, and was shown at necropsy to have aortic incompetence, left ventricular hypertrophy, and some slight general fibrosis without evidence of infarction. Intensive microscopical examination of sections of the heart muscle failed to reveal any evidence of infarction or of sufficiently discrete fibrosis that might have suggested old infarction.

In the other two cases gross notching was present in A. In one the block pattern was also manifest in B and C with gross notching; but in the other leads B and C did not show such a broad biphasic swing pattern. These two, by their elevated segments, clearly indicated infarction. Segment elevation was of the CBa type in one (Patient 36), and the pre-necropsy diagnosis was "infarction: septal, antero-lateral, and slightly on the posterior surface." The standard E.C.G. showed left branch bundle block, which was thought, in view of the history, to be due to infarction but

not conclusive of itself. The patient died 13 days after admission, and the infarct was found to be extensive and in the zones described. In the other (Patient 52) the left branch bundle block was described as atypical, leads B and C not showing the big biphasic swing, and the E.C.G. diagnosis was "antero-lateral infarction: B type, with old posterior infarction." At necropsy, six days later, a yellow gelatinous lamina of infarction was present in the anterior wall of the left ventricle towards the apex. A thrombus was present in the anterior descending branch of the left coronary artery a little below its origin, and there was also another complete occlusion of a small branch of the anterior descending branch. Further details of the distinction between block due to infarction and block due to other causes will form the substance of a separate paper.

Right bundle block patterns were seen in eight instances. Five conformed to a classical infarct pattern (Fig. 16) (Patient 29). This report read: "Old infarct (B) and recent infarct (C): recent septal infarction extending posteriorly with old infarction." At necropsy, 11 days later, "the left ventricle showed extensive recent infarction from the apex into the posterior wall of the left ventricle and anteriorly into the interventricular septum. Between the upper limits of this infarct and the AV junction there was evidence of older infarction." Fig. 17 shows the standard lead findings for this subject. The remaining three patients showed a more marked biphasic swing in the tracings, but segment elevation was present in lead A suggestive of infarction.

Two of the latter patients died, and a necropsy was carried out on one. This showed the presence of septal infarction encroaching on the posterior and also slightly on the anterior surface of the heart. Of the former five, four died within a fortnight of the attack. The other patient was discharged on September 14, 1955, and has not returned to hospital. In one, necropsy was not performed; in the other three, infarcts were found—respectively, in the apex of the left ventricle and septum (Patient 22) in the whole of the apex of the left ventricle extending to the base of the septum (Patient 19); and extensively in the posterior wall of the left ventricle and extending anteriorly into the interventricular septum (Patient 29).

Two further patients showed intermittent right bundle block with classical signs of infarction in leads A and C.

FIG. 16.—ABC-E.C.G. showing right bundle block due to cardiac infarction. Necropsy confirmation.

FIG. 17.—Standard E.C.G. of patient whose ABC-E.C.G. is shown in Fig. 16.

FIG. 17.—Standard E.C.G. of patient whose ABC-E.C.G. is shown in Fig. 16.

Since we know ϕ_1, ϕ_2 , see (p) above, and the denominator of the fraction contains terms we know, $\therefore Q$ is known. Thus the moment (strength) of the dipole is known. Thus leads ABC define the dipole completely.

1. *Modification owing to the fact that the emanation is not precisely that of a dipole.*—Craib (1927) has presented strong evidence that we may regard the field as being produced by a dipole, and, since in the final analysis related ionic migration through muscle membrane is associated with the action current produced, this would appear to be a sound hypothesis. Let us first assume it is a point source at the centre producing an emanation of the type $f(t)$. The above treatment still holds, since we can select any particular instant in the cycle of $f(t)$ which will correspond to a selected dipole as treated above.

2. *The thorax is (a) not a sphere, (b) not a perfect conductor and impedance varies throughout its volume, and (c) the heart is not a point source at the centre.*—(a) If points M, L, and R (ϕ_1, ϕ_2, ϕ_3) are not at equidistance from the centre and the thorax forms an ellipsoid since these variations are known, then the treatment is more complicated; but the actual conclusion—namely, that neither the strength (Q) nor the direction of the dipole (l, m, n) can be changed without producing a reflected change in lead A, B, or C—is a reasonable deduction. (b) This factor is difficult to evaluate. Kaufman and Johnston (1943) consider that variations of this nature, since they are not major, do not affect the recorded potentials greatly. (c) Though the heart is not a point source it is still theoretically possible to treat all the emanating points individually and summate algebraically, and therefore we should still obtain an equation related to the known findings appearing from leads A, B, and C. The final difficulty will arise if and when fields produced can annul one another as in precisely accurate phase difference of 180 degrees. This could not be expected to occur with infarction owing to the type of firing off of the heart muscle, and this has already been discussed.

Summary

A series of 161 cases of cardiac infarction on whom ABC electrocardiograms were performed has been presented. Necropsies were done on 36 of these subjects.

The ABC display detected all cases of infarction detected by the present standard leads, and in addition detected infarction not demonstrated by them.

The correlation of infarct site with pattern changes in the ABC leads was determined theoretically and confirmed by necropsy studies.

E.C.G. patterns indicating cardiac degeneration short of discrete infarct formation, with one necropsy study, are described.

Abnormal T-wave form associated with infarction is illustrated.

Heart-block patterns associated with infarct formation are described and presented.

A theoretical analysis of the significance of the Einthoven, Goldberger, Wilson, and ABC leads is presented.

I thank the honorary staffs of the Royal Melbourne and St. Vincent's Hospitals for access to patients and Dr. Gerard Crook for the radio-opaque heart perfusions. I am indebted to Dr. J. D. Hicks, of the Royal Melbourne Hospital, and Dr. Tate Smith, of St. Vincent's Hospital, for access to and help in their departments of pathology.

INCIDENCE OF CORONARY ISCHAEMIA AFTER PARTIAL GASTRECTOMY

BY

Consultant, Eastern District Hospital, Glasgow

There are many studies relating coronary artery disease to various aspects of lipid metabolism. It has been shown that the incidence is high where the diet contains a large quantity of animal and saturated fat, and low where fat intake is poor (Keys, 1956). Following partial gastrectomy of the Polya type many patients lose weight and most are below their expected weight (Anderson *et al.*, 1955). This is probably due to a low calorie intake and post-gastrectomy symptoms, but impaired digestion and absorption of fat may be a contributory factor. Recent work in gastrectomy patients with labelled fats has shown increased fat excretion and diminished absorption after fatty meals and that fat loss is greater after the Polya operation than after the Billroth I (Everson, 1954; Shingleton *et al.*, 1957). This impaired fat absorption could be reflected in a lower incidence of coronary artery disease in gastrectomy patients.

Material

Of 53 patients who had undergone the Polya type of partial gastrectomy 40 were traced and examined. All were males between 45 and 65 years who had been operated on for severe duodenal ulcer symptoms. The mean lapse of time from operation to interview was 9 years 10 months (range: 7 years 1 month to 13 years 4 months). At the same time, 40 men in the same age group with long-standing symptoms of duodenal ulcer (mean duration 17 years) were studied; 15 of these patients had suffered major complications such as perforation and haemorrhage. As a further control group we examined 40 "normal" males without ulcer or cardiac symptoms admitted for operative treatment of minor surgical and orthopaedic conditions (hernia, varicose veins, haemorrhoids, etc.). In the latter two groups the last five or six patients were selected on an age basis to ensure that the mean ages of each group were closely related (Table I).

Methods

A clinical history and an examination of each patient were undertaken; height, weight, pulse rate, and blood pressure were recorded and a sample of venous blood was withdrawn for haemoglobin and lipoprotein estimations. Electrocardiography was performed, using a direct writer ("mingograph") before and after Master's (1950) double two-step test. The amount of exercise in this test is graduated according to the patient's weight and age. One man

DEC. 13, 1958

with a previous myocardial infarction was not exercised, and in two others the exercise was discontinued because of angina; all others completed the test. To facilitate rapid recording after exercise only nine leads were used—the three standard leads and aVR, aVL, aVF, V₁, V₂, V₄, and V₆. The records were studied independently by two of us without reference to the patient's group, and the findings compared. A further independent opinion was obtained where a difference in interpretation occurred.

It is difficult to apply rigid standards to the interpretation of electrocardiograms, but the following criteria of ischaemia were adopted as a guide: ST depression of 1 mm. or more where the increase in pulse rate did not exceed 20 a minute and of 1.5 mm. or more where it did; flat or inverted T waves in appropriate leads; and multiple extrasystoles. All other abnormalities were noted and care was taken to distinguish changes due to tachycardia alone—namely a low RS-T junction with upward-sloping ST segment. The distinction between the lateral ischaemia of coronary artery disease

FIG. 1.—Posterior ischaemia after exercise.

and that of left ventricular strain is taken into account in the analysis of the results. A typical abnormal record is shown in Fig. 1. Fig. 2 shows alternate ventricular extrasystoles occurring after exercise. This, the only example of its kind, was accepted as evidence of ischaemia. The β : α lipoprotein ratio was estimated by standard methods of electrophoresis, Sudan-black staining, densitometry, and planimetry (Swahn, 1952). Pre- β lipoprotein was noted when present (Besterman, 1957).

FIG. 2.—Alternate ventricular extrasystoles after exercise.

Results

A summary of the principal findings is presented in Table I, and the abnormal electrocardiograms are classified in Table II.

The incidence of myocardial ischaemia in the gastrectomy group (six positive E.C.G.s) is less than in the control group (15 positives), and this difference is significant ($\chi^2 = 5.23$; $0.02 > P > 0.01$). The difference is even more significant when the gastrectomy group is compared with the ulcer group (21 positives) ($\chi^2 = 12.6$ and $P < 0.01$). The difference between the control and ulcer groups is not significant ($\chi^2 = 2.49$). If the electrocardiograms showing left ventricular (L.V.) strain are included in the analysis (Table II) the significance of the data is altered and the difference

between the control and ulcer groups becomes less marked. The number of abnormal in each group becomes gastrectomy 7, control 18, and ulcer 21, so that for gastrectomy and control groups $\chi^2 = 7.05$ ($P < 0.01$) and for the gastrectomy and ulcer groups $\chi^2 = 10.80$ ($P < 0.01$).

TABLE I.—Summary of the Principal Findings. Each Group Contains 40 Patients

Group	Mean Age (Yrs.)	Mean Hb %	Mean Weight		No. of Ischaemic E.C.G.s	Mean β : α Ratio (Lipo-proteins)	No. with pre- β Lipo-protein
			lb.	kg.			
Polya gastrectomy	53.2	88.2	132	59.9	6	2.17	16
Range	45-65	59-103	103-183	46.7-83		1.12-4.00	
Control	53.6	96.7	154	69.9	15	2.42	17
Range	46-64	77-118	114-208	51.7-94.3		1.17-4.24	
Ulcer	53.5	97.7	147	66.7	21	2.49	16
Range	47-64	80-112	110-202	49.9-91.6		1.00-7.20	

TABLE II.—Classification of the Diagnoses of the Abnormal E.C.G.s

	Post. Ischaemia	Post-Lat. Ischaemia	Lat. Ischaemia	Ant-Lat. Ischaemia	Ant. Ischaemia	Infarction	Extrasyst.	Total	L.V. Strain	Misc.
Polya gastrectomy	4	1	—	—	—	—	1	6	1	1 Low voltage with emphysema
Control	7	7	—	—	1	—	—	15	3	1 R.V. strain
Ulcer	11	3	3	2	1	1 Healed post. infarct.	—	21	—	—

These figures suggest that the cardiac status of the gastrectomy patient is better than that of his fellows. Because the gastrectomy group is much lighter than the other two (Table I) and the mean weight of the six ischaemic gastrectomy patients (154 lb.; 69.9 kg.) is greater than the group mean, it seems possible that ischaemia is related to weight. However, no correlation between absolute weight and ischaemia was found in the ulcer and control groups.

Each patient's expected weight, depending on height and age, was calculated from British tables (Levine, 1923), and Fig. 3 shows the deviation from expected weight in each group, with the corresponding distribution of ischaemic E.C.G.s. This demonstrates clearly that the occurrence of myocardial ischaemia is not prevented by being underweight, and that

FIG. 3.—Distribution of ischaemic E.C.G.s and subjects' weights related to expected weights.

this corresponds to the incidence of myocardial ischaemia, weight by itself does not seem to be a specific factor.

There is a difference between the mean $\beta : \alpha$ lipoprotein ratios of each group (Table I). The ratio of the gastrectomy group is 89.5% of the mean control ratio and 87.0% of the mean ulcer ratio, but these differences are not significant ($P > 0.1$ in both cases). There is no difference between the mean ratios of the 42 ischaemic and 78 non-

FIG. 4.—Normal lipoprotein pattern with abnormal E.C.G. (No. 83) and normal E.C.G. with pre- β lipoprotein (No. 98).

the groups, apart from the low mean haemoglobin level of the gastrectomy patients (88.2%). This is actually an adverse factor which would tend to increase the number of positive electrocardiograms in this group.

Discussion

There is inevitably some selection of patients for gastrectomy. Nevertheless only one of the present ulcer group would be refused gastrectomy on a normal assessment of fitness, and all were fit 10 years ago. We consider that there is insufficient evidence of selection in favour of the gastrectomy group to invalidate the findings.

It may be argued that the incidence of abnormal electrocardiograms in this study is suspiciously high. Certainly Master *et al.* (1942) found no significant changes in the electrocardiogram following the double two-step test in 34 normal subjects of unspecified age. Against this, Riseman *et al.* (1940), employing criteria of abnormality more severe than Master's and comparable to our own, found significant changes in 10 of 15 normal patients whose ages ranged from 25 to 73 years. In a review of the literature they drew attention to the divergent findings of a number of authors. We cannot reconcile such differences. Here we are reporting results obtained from a standard test consistently applied to each of the clinical groups.

We believe that the cardiac status of the long-term gastrectomy patients is better than that of his "normal" or "ulcer" counterpart. Electrocardiographic evidence of myocardial ischaemia in the absence of anaemia is usually regarded as indicating coronary artery disease, and presumably the gastrectomy patients show less ischaemia because their coronary arteries are healthier. This suggests that in the time since operation their coronary vessels have either remained healthy and undergone minimal atheromatous change, or have even recovered from such change if initially present. In a pathological study Wilens (1947) concluded that regression of established atherosclerosis occurred in clinical states associated with severe short-term malnutrition and weight loss. This clinical study may support his view.

Weight loss by itself does not seem to be the main factor, and it is tempting to relate the lower incidence of ischaemia in gastrectomy patients to the diminished fat intake and impaired absorption which frequently occurs after a Polya gastrectomy. This, however, has not been reflected in a significantly lowered $\beta : \alpha$ lipoprotein ratio, nor can we demonstrate a relationship between pre- β lipoprotein and myocardial ischaemia. It is true, however, that by the nature of Master's double two-step test we are dealing with coronary artery disease of less severity than that recently studied by Besterman (1957, 1958), and this may explain our inability to demonstrate the lipoprotein changes which he describes.

This study confirms the opinion of Douglas and Melrose (1955) that there is no increase in the incidence of coronary artery disease in ulcer patients compared with the normal individual.

Summary

Evidence is presented which demonstrates a significantly lower incidence of coronary ischaemia in long-term gastrectomy patients compared with "ulcer" and "normal" controls.

This cannot definitely be related to lowering of the $\beta : \alpha$ lipoprotein ratio nor to changes in the pre- β lipoprotein.

Although the gastrectomy patients are much lighter as a group there is no direct relationship between weight and ischaemia.

We thank Professor C. F. W. Illingworth for access to records and for the facilities so readily granted; Miss McCann for assistance with the electrocardiography; Miss Murray for secretarial help; and Mr. Kelly for preparation of the illustrations.

"In these days it is not uncommon to hear in some quarters debates on the relative merits of science and the arts in education. In my own University College of North Staffordshire a regard for both these two branches of learning is considered essential in every undergraduate's studies, and we have, I think, achieved a very happy marriage between them. But it was long ago that Cambridge realized that both are equally important to a true university, and it emphasized its view by creating, in 1702, the Chair of Chemistry as one of the first dozen Chairs in the University. Since that time it has continuously expanded its activities and has established a tradition in natural science which is outstanding among the universities, not of this country alone, but of the world. What other university can match the names of Newton, Darwin, Clerk Maxwell, Thomson, Rutherford, and Hopkins—to mention but a few of its famous men?—H.R.H. PRINCESS MARGARET on the occasion of the opening of the new Chemical Laboratories at Cambridge on November 6 (*Cambridge University Reporter*, November 12).

TEETH OF 5-YEAR-OLD LONDON SCHOOLCHILDREN (1957)

WITH A COMPARISON OF THE RESULTS OBTAINED FROM 1929 TO 1957

BY

MAY MELLANBY, M.A., Sc.D.

W. J. MARTIN, Ph.D., D.Sc.

AND

DAVID BARNES, L.D.S., B.D.S.

With the assistance of GWENNETH NEAL

From 5, East Heath Road, Hampstead, N.W.3, and
Statistical Research Unit, London School of Hygiene
and Tropical Medicine

The first of a series of detailed surveys of the deciduous teeth of 5-year-old children was undertaken by one of us (M.M.) in 1929 at the request of the Board of Education. The children attended London County Council schools representative of the different parts of the Metropolitan area. Inspections at the same, or similar, schools have been made with colleagues at two-yearly intervals from 1943 to 1957, with the exception of 1953. In addition, children living in residential homes (institutions) and those attending private schools were visited in 1945 and 1950 for comparison with the London County Council children. (References to all these are given at the end of this report.)

The probe-and-mirror method of examination has been used throughout, and the criteria for structure and caries employed were those developed by Mellanby (1934). Both the method and the criteria have been described in detail in previous reports of this series.

When the surface of a tooth is smooth and shiny it is said to be hypoplasia-free—that is, the structure is good (Hy). Any roughness is graded according to type and degree, differentiation being made between the comparatively rare gloss hypoplasia (G-Hy) and the common M-hypoplasia (M-Hy) (King, 1940). The surface structure of the teeth is expressed both as the percentage incidence of the different grades of hypoplasia and as the average M-hypoplasia figure (A.H.F.). The latter gives a rough computation of the extent of this type of defect and is obtained by allotting a number to each tooth (1 for M-Hy₁, 2 for

M-Hy₂, and 3 for M-Hy₃) and dividing the sum of these by the number of teeth. Those showing gross hypoplasia and those so carious that assessment is impossible are excluded.

A tooth is regarded as caries-free when no disease can be diagnosed by the method of examination employed. Caries is expressed as a percentage incidence—that is, d.e.f. per 100 teeth—and as the average caries figure (A.C.F.), which is estimated in a similar way to the A.H.F. The numbers 1, 2, and 3, are allotted to carious teeth according to the amount of tooth involved. Missing molars and canines are presumed to have been extracted for severe caries and are included in the C₃ group, while missing incisors (mainly lower centrals) are counted as having been naturally shed and are omitted from the analysis. The maximum value for both A.H.F. and A.C.F. is 3.

The Board of Education (1931) analysed the data obtained in the 1929 investigation, but published only the figures relating to children and not to individual teeth. A child was said to be caries-free who had no recorded decayed teeth, or only one, two, or three teeth with grade 1 caries, the second group being included because such a small proportion of the children were "caries-free." For the purpose of comparison the same classification has been perpetuated throughout these surveys, but, in addition, the results have been analysed for the incidence and extent of hypoplasia and caries in each type of tooth.

Results

Teeth Present.—In 1957 the dental condition of 1,241 children were recorded. All of them had had their fifth but not their sixth birthday. At the time of the inspection there were 22,587 deciduous teeth *in situ* out of a possible 24,820 (91%). The percentage distribution of the individual types was similar to that in 1955 and in the earlier surveys (*Brit. med. J.*, 1957, 2, 318)—namely:

	Upper Jaw	Lower Jaw
Central incisors	90.5	77.6
Lateral incisors	96.4	96.7
Canines	99.4	99.6
1st molars	91.6	82.9
2nd molars	93.6	81.9

Surface Structure.—An examination was made of the surface structure of 98% of the teeth present in the mouth (see above) and the results for individual teeth compared with 1955 figures are given in Table I. All the teeth except the lower molars had a better structure in 1957 than in 1955. In both years the lower teeth had fewer defects than the upper. The best structure of all occurred in the lower incisors, in which 80.3% of the centrals and 64.1% of the laterals were non-hypoplastic, and the worst in the molars,

* A.C.F. = $\frac{\text{Total caries figure}}{\text{Total number of teeth (including extractions)}}$

particularly the uppers, where only 14.6% of the first and 13.7% of the second were free from hypoplasia.

Very few teeth had any mottling, and when present it was very mild. Such teeth were graded for M- and G-hypoplasia in the usual way.

Incidence and Extent of Caries.—Table II compares the incidence and extent of caries for each type of tooth and for all types together in 1957 and 1955. The two series were in close agreement. The proportion of carious teeth and the average caries figures in both upper and lower jaws, separately and combined, was approximately 31% and 0.6%. The lower incisors had the least caries (5.2% in the centrals in both years and 3.7% in the laterals in 1957, as against 5.3% in 1955) and the lower second molars the most (71.8% and 70.2% respectively). The upper first molars had less caries than the other molars (20–30% less in 1957 as compared with 16–29% less in 1955).

TABLE III.—Treatment of Caries (1943 to 1957)

Year	Total No. of Carious Teeth (including Extractions)	Treatment			Total Percentage of Carious Teeth Treated
		% Extracted	% Silver Nitrate	% Filled	
1943	10,886	15.7	6.7	2.7	25.0
1945	3,545	9.6	2.8	2.4	14.8
1947	6,245	15.6	2.4	4.4	22.4
1949	3,553	15.3	0.6	3.9	19.8
1951	7,412	13.0	0.1	6.1	19.2
1955	7,326	16.7	2.3	11.1	30.1
1957	7,510	17.0	0.6	10.7	28.3

The average number of carious teeth per child was 6.1% in both years, but if the "caries-free" children were excluded the figure dropped from 7.2% in 1955 to 6.9% in 1957. The percentage of children caries-free or nearly so was also similar—20.7 in 1957 and 21.2 in 1955—but the percentage of "caries-free" children was less in the last survey—namely, 11.9 compared with 15.5.

Treatment of Caries.—Table III shows that in 1957, as in 1955, rather less than one-third of the carious teeth had been

treated, approximately 17% had been filled, and 11% extracted. Only 0.6% appeared to have been painted with silver nitrate in 1957 compared with 2.3% in 1955, which accounts for the slight difference in the total treated.

TABLE IV.—Caries Related to Superficial Staining of Teeth (1943 to 1957)

Year	Percentage of Carious Teeth in Children with:		
	No Stain	Black or Dark-brown Stain	Green Stain
1943	30.1	19.3	33.4
1945	23.1	15.4	33.0
1947	19.8	12.4	26.0
1949	25.8	16.9	30.0
1951	25.5	14.4	33.6
1955	29.1	20.2	39.2
1957	32.0	22.0	31.2

Caries and Superficial Staining of Teeth.—In the recent examination as in 1955 (Table IV), the children with black or dark-brown stain on any tooth had a smaller percentage of caries (22%) than either the children with no stain (32.0%) or those with green stain (31.2%).

Comments and Conclusions

It may be said, after reviewing these results, that the caries picture of the 5-year-old children in the London County Council schools has shown little or no change since 1955, whether considered per child or per tooth. But, as mentioned in previous reports, there have been many variations both in structure and in caries experience of this age group since the original 1929 investigation.

The proportion of teeth present at examination was, on the whole, similar in the seven inquiries from 1943 to 1957.

The structure of the individual teeth has varied from year to year. There was in general an improvement up to 1947, but, later, variations occurred for which we cannot

TABLE VI.—Comparison of Caries in Upper and Lower Teeth (1943 to 1957)

Year	Percentage of Carious Teeth		A.C.F.	
	Upper Jaw	Lower Jaw	Upper Jaw	Lower Jaw
1943	33.2	26.9	0.69	0.62
1945	28.5	24.5	0.57	0.54
1947	21.0	19.5	0.41	0.44
1949	26.7	26.6	0.52	0.57
1951	26.9	28.2	0.51	0.60
1955	31.4	31.7	0.64	0.71
1957	31.5	31.5	0.63	0.66

account. The present position is similar to that of 1951 for all teeth combined, but there are differences between the types of teeth. As already mentioned, the structure is better in 1957 than in 1955.

The relationship between the external structure of a tooth and caries experience (Table V) was in general the same as in the comparable surveys made since 1943. For all types of teeth grouped together caries was present in only 12.1% of those with no recorded enamel defects (Hy₀), a higher figure than previously found, but with severe defects the disease was much more prevalent. For instance, caries was found in 76.2% of teeth with grade three M-hypoplasia (M-Hy₃) and in 39.2% of those with the gross forms of defect (G-Hy). These figures nevertheless support the con-

Some of the factors which contributed to the marked improvement of the caries picture between 1929 and 1947 and the subsequent deterioration in later years, have been discussed at length in the previous reports. No further evidence has been forthcoming to modify the tentative conclusions given there—namely, that the reduction in the disease was partly the result of more scientifically controlled nutrition of pregnant women and infants during the war and post-war period of rationing, when among other things the calcifying properties of the diet were increased. The subsequent freer choice of diet when cheaper foods, including cereals, were more easily obtainable, together with the reduction in the consumption of milk and cod-liver oil, could account for some of the deterioration from 1947 to 1955. The work of Holloway *et al.* (1958) suggests that some of the increase in the incidence of caries in recent years may be due to the rapid growth in popularity of iced lollies and similar confections. The fluorine in the water could not have been concerned in the changes noted in these reports, as it has remained low and constant throughout.

Our thanks are extended to many who have helped directly or indirectly with the investigations. We are particularly indebted to the London County Council and Dr. J. A. Scott for permission to carry out the survey, to the head teachers and their assistants for the trouble they took to make our visits to the schools such a pleasure, and to the Medical Research Council for

TABLE VII.—Distribution of Caries (1953 to 1957)

Year	Percentage of Carious Teeth									
	Central Incisors		Lateral Incisors		Canines		1st Molars		2nd Molars	
	Upper Jaw	Lower Jaw	Upper Jaw	Lower Jaw	Upper Jaw	Lower Jaw	Upper Jaw	Lower Jaw	Upper Jaw	Lower Jaw
1943	37.6	4.9	20.3	3.7	9.5	6.9	42.0	54.0	56.5	61.0
1945	29.5	1.7	14.9	2.1	7.5	5.9	38.9	48.6	51.4	58.8
1947	22.2	1.7	10.6	1.7	6.9	4.1	30.6	43.3	34.4	43.0
1949	30.1	3.3	14.5	2.6	9.1	5.5	35.7	54.0	44.2	61.3
1951	30.0	3.8	15.4	2.6	7.2	5.6	34.2	56.9	47.7	65.1
1955	27.8	5.2	17.7	3.3	11.1	8.8	41.7	62.5	58.1	70.2
1957	25.6	5.2	17.4	3.7	9.5	7.8	41.5	62.2	62.3	71.8

clusion drawn from earlier work that the better the structure of a tooth, as diagnosed by the method previously described, the less likely is it to become carious.

The incidence and extent of caries declined from 1943 to 1947 but rose after that date until 1955, since when there has been little or no change. A comparison of the carious teeth in the upper and lower jaws from 1943 to 1957 (Table VI) is of interest. In 1943 the upper jaw had 6.3% more carious teeth than the lower. The decrease in the incidence of the disease noted up to 1947 was less in the lower than in the upper jaws, and the difference between the two fell to 1.5%. The rise in the proportion of carious teeth subsequent to 1947 was greater in the lower jaw, and in 1951 the percentage of such teeth in the lower was 1.3% greater than those in the upper jaw. By 1955, and also in 1957, the percentage in the two jaws was the same—namely, 31. This change in distribution of the disease between the two jaws is analysed in Table VII, which shows that the trend is mainly due to a decrease in caries in the upper incisors associated with a larger increase in the lower molars compared with the upper.

The proportion of carious teeth filled has increased from approximately 2.5 to 11.0% since 1943, the rise being most marked in the last two examinations (Table III). Although the percentage of teeth extracted has varied to some extent from year to year, it was also greater in 1955 and 1957 than at any of the previous inspections.

In 1957 the children with black or dark-brown stain had a smaller percentage of carious teeth than the children with no stain or green stain, as in previous surveys. The children with green stain in 1957, however, had approximately the same percentage of diseased teeth as the children with no stain, while in the preceding surveys they had a larger percentage.

financing the work. We would also like to acknowledge gratefully the assistance given by Misses I. Allen and B. Hafner in the tabulation of the data and to Dr. P. J. Holloway for his help and criticism during the preparation of the report.

"It seems to me certain that there should be no strife between science and religion, for the great Creator of living beings was also the Creator of the harsh and ruthless natural laws we call Darwinian evolution. . . . The question arises, does the Creator now content himself with allowing human beings to follow their own dictates as a self-governing colony provided they keep themselves within the natural laws which have been arranged for them; or does He occasionally intervene in an "unnatural" or "supernatural" way? That question I think cannot scientifically be answered. Hardly anything happens which cannot be explained by natural causes, but revelations occur which are sudden and surprising enough to suggest an "unnatural" or "supernatural" origin as if the Creator had Himself directly intervened in the course of a human life. Who would be bold enough absolutely to deny the possibility of such an intervention?"—F. Parkes Weber, *The Advent of Life: an Agnostic's Dream About the Creation* (H. K. Lewis, 1958).

RADIOIODINE TRACER TESTS IN THE DIAGNOSIS OF HYPERTHYROIDISM

BY

K. H. CLARKE,* M.Sc., A.R.C.S., A.Inst.P.

W. E. KING, M.D., F.R.A.C.P., M.R.C.P.

AND

JEAN MILNE,* M.I.R.

From the Radioiodine Unit, Royal Melbourne Hospital,
Melbourne

The use of radioiodine, ^{131}I , has now an established place as an aid in the diagnosis of hyperthyroidism, but there is no agreement on which radioiodine test is best for this purpose. Many indices of thyroid function have been proposed which variously involve the measurement, either serial or at fixed times after the administration of the radioisotope, of its accumulation by the thyroid, excretion by the kidneys, and concentration in whole blood, blood plasma, and saliva.

Indices dependent on measurements of the radioiodine content in the thyroid or in blood are considered preferable to those dependent on urinary excretion because of the problems involved, particularly for out-patients, in urine collection over set periods of time.

Almost all of the radioiodine tests advanced in the literature will distinguish between the frankly thyrotoxic patient and the normal subject, but the real usefulness of a test must lie in its ability to aid the diagnosis in clinically borderline cases, and in its simplicity.

It is often difficult to assess the relative merits of particular proposed indices of thyroid function, as the clinical material varies so widely from one group of workers to another. However, most of the more promising radioiodine indices have been compared with each other, the B.M.R., and the biochemical determination of protein-bound iodine (P.B.I.) by the Royal Melbourne Hospital group (Clarke and Aujard, 1954; Madigan and King, 1954; Winikoff, 1954; Clarke, Sherriff, and Winikoff, 1955) and by others (Goodwin, Macgregor, Miller, and Wayne, 1951; Fryers, 1956; McConahey, Owen, and Keating, 1956).

From the studies in Melbourne it has been concluded that the best single index of thyroid function is the biochemical determination of P.B.I., which separates both the hyperthyroid and hypothyroid groups from the normal or euthyroid group with a high degree of accuracy. Between 90% and 95% of the patients in each group, including a large number of clinically borderline cases, have been correctly classified by this index.

The determination of P.B.I., however, is technically difficult on account of the very low levels of iodine to be measured, and demands the utmost care in keeping the laboratory and apparatus completely free from iodine contamination. For this reason it has been hoped that the use of radioiodine, which is readily detected by its beta and gamma emanations, would provide a simpler index of thyroid activity.

The best radioiodine indices in the Royal Melbourne Hospital studies referred to above have been shown to be

the measurement of plasma protein-bound radioiodine 48 hours after administration of the tracer dose (48-hour P.B. ^{131}I) and a measurement dependent on the early uptake of radioiodine by the thyroid.

The 48-hour P.B. ^{131}I index is the one proposed by Goodwin *et al.* (1951), who have shown that the rapid removal of the radioiodine as iodide from the plasma, and its early reappearance in hormonal form in hyperthyroid patients, can best be distinguished from the much slower process in euthyroid patients 48 hours after the administration of the tracer dose. It is a convenient index in that it does not require intravenous administration of the isotope, but it does necessitate the patient's attendance a second time, and, furthermore, since the measurement of the 24-hour percentage retention of radioiodine by the gland is considered useful in assessing the size of the therapeutic dose in those cases subsequently treated with radioiodine (Fairley, Holman, and King, 1956), patients often have to attend the hospital three days in succession, the first day for the administration of the tracer dose and early thyroid uptake measurements, the second day for a 24-hour percentage thyroidal retention measurement in case subsequent radioiodine therapy is prescribed, and the third day for a blood sample for the 48-hour P.B. ^{131}I determination.

Several early uptake tests have been suggested, and all appear reasonably reliable. The thyroid clearance test of Myant, Pochin, and Goldie (1949), however, is laborious in that it involves serial measurements over the gland and the measurement of radioiodine in the blood plasma; the uptake rate factor of Oddie, Meschan, and Wortham (1955) involves measurements of thyroidal radioiodine at 1, 4, and 24 hours; while the thigh/neck clearance test of Foote and MacLagan (1951) and the uptake rate factors of the earlier studies at the Royal Melbourne Hospital also depend on serial measurements.

Pochin (1950) was the first to observe that a simple but efficient test would be an early comparison of the counting rate over the neck with that over the thigh following the administration of a tracer dose of radioiodine, and Rundle, Seldon, and Indyk (1956) have also found such an index to be useful. In thyrotoxicosis the thyroid rapidly takes up radioiodine from the circulating plasma, so the early neck counts will become higher than normal and the thigh counts will become lower than normal, resulting in the neck/thigh ratio being greatly increased.

In the series of cases reported here the thyroidal uptake and the neck/thigh ratio have been determined two hours after oral administration of the tracer dose, the patient having had nothing to eat for the three hours before the test. The time interval of two hours was chosen because it was considered that by that time the amount of radioiodine secreted from the thyroid and the effect of variations in the absorption rates of radioiodine from the intestinal tract would be small.

The percentage content of radioiodine in the thyroid at 24 hours, which is used in many centres as an index of thyroid function, has not been found to have diagnostic significance in the Royal Melbourne Hospital Unit. In some patients the radioiodine content of the thyroid falls greatly between 2 hours and 24 hours, and the 24-hour measurement is considered useful as a measure of the degree of retention of radioiodine by the gland, which is taken into account when assessing

the size of the therapeutic dose of radioiodine required. This measurement is here referred to as the 24-hour percentage thyroidal retention.

Technique

Certain dietary factors, medications, and special radiographic procedures involving substances containing iodine are known to influence the thyroidal uptake and turnover of radioiodine. In order that the dietary influence shall be minimal a diet which avoids foods with a high iodine content, such as fish foods, is prescribed for one week before the test. With regard to medication, thiourylene derivatives and carbimazole are discontinued for a minimum period of two weeks, and iodine preparations and thyroid for at least four weeks prior to the tracer test.

A tracer dose of 20 μC of radioiodine (^{131}I), carrier-free, is administered orally, the patient having had nothing to eat for the previous three hours. Two hours after administration measurements are made of the radioiodine content of the neck and thigh, using paired G10Pb geiger counters as previously described (Clarke and Aujard, 1954).

Since the accumulation of iodine by tissues other than the thyroid and kidneys is relatively small, it has been assumed that the ^{131}I content of the tissue of the neck, excluding the thyroid, is approximately equal to the ^{131}I content of a similar volume of tissue of the thigh. The geometrical arrangements of the counters in the neck and thigh units are such that the response of the thigh counters to a distributed source of ^{131}I (as in the thigh) is three times the response of the neck counters to a similar source, hence thyroid counting rate = neck counting rate $\times \frac{1}{3}$ thigh counting rate and the neck/thigh ratio, which is here taken to mean

$\frac{^{131}\text{I} \text{ content of the tissue of the neck including thyroid}}{^{131}\text{I} \text{ content of a similar volume of tissue of the thigh}}$
will be equal to $\frac{\text{Neck counting rate}}{\frac{1}{3} \text{ thigh counting rate}}$

In those cases where radioiodine therapy is a considered possibility similar measurements are made at 24 hours.

At 48 hours a blood sample is taken for the determination of P.B. ^{131}I , which is expressed as a percentage of the dose per litre of plasma. The details of the method are given below. The limits for the two-hour uptake, the two-hour neck/thigh ratio, and the 48-hour P.B. ^{131}I determined in this study are given in Table I. The same criteria have been adopted in the clinical assessment of thyrotoxicosis as have been previously described from this unit (Madigan and King, 1954).

Determination of 48-hour P.B. ^{131}I

Two-millilitre samples of plasma are used. The plasma proteins are precipitated by adding 6 ml. of 10% trichloroacetic acid, after which the suspension is centrifuged

and the supernatant liquid poured off. The precipitate is washed twice with 6 ml. of trichloroacetic acid, centrifuged, and the supernatant poured off. To the precipitate is now added 0.5 ml. of 2N sodium carbonate and 0.1 ml. of "teepol" (a commercial wetting agent) and the mixture is agitated with a glass rod until all has dissolved. It is then transferred quantitatively to an aluminium pan, dried gently by means of an infra-red lamp, counted by means of an EHM2 mica-window geiger counter, and compared with a standard radioiodine source.

Results

This study covers all the patients who were referred to the radioiodine unit of the Royal Melbourne Hospital for investigation, and who were given subsequent radioiodine tracer tests during the 15-months period August, 1956, to November, 1957. Some of these were frankly thyrotoxic patients for whom tracer tests were required for the determination of the 24-hour percentage thyroidal retention of radioiodine used in the assessment of the radioiodine therapy dose, but these results are not considered in the final analysis.

Altogether, 156 consecutive tracer tests were carried out on 139 patients. Twelve tests on 12 patients have been excluded from the analysis, as it has not been possible to assign a final diagnosis in these cases. A further 44 tests have been excluded either because medication had not been discontinued for a sufficiently long period, or because the patient was considered to be frankly toxic.

The results of the remaining 100 tracer tests on 96 clinically borderline patients considered free from influencing medication are given in Table II. These 100 tests include 61 in which no known influencing medication had been given at all, 3 post-operative, 17 post- ^{131}I therapy (minimum time interval since therapy being three months), and 19 others in which medication had been discontinued for longer than the prescribed period. In 52 tests the final classification was hyperthyroid and in 48 tests it was euthyroid. The final classification was decided after further observation and in some cases after a trial period of medication.

For various reasons not all the three radioiodine indices—that is, the two-hour uptake, the two-hour neck/thigh ratio,

TABLE I.—Limits for the Three ^{131}I Indices Presented

Classification	Two-Hour Thyroidal Uptake %	Two-Hour Neck/Thigh Ratio	48-Hour P.B. ^{131}I % Dose/Litre of Plasma
Hyperthyroid	> 55	> 50	> 0.5
Indeterminate	$> 50 - < 55$	$> 35 - < 50$	$> 0.45 - < 0.5$
Euthyroid	≤ 50 (lower limit uncertain)	≤ 35 (lower limit uncertain)	$0 - < 0.45$

*At the Peter MacCallum Clinic, Melbourne.

body water and extracellular water determinations were repeated when the gain in body weight appeared to have ceased.

RESULTS

Body Weight

As can be seen from Figs. 1 and 2, in all four cases there was a marked rise in body weight within a few days of the beginning of treatment. This increase in weight continued for a varying period of time—three days for H. F., nine days for J. R., and about 14 days for both H. C. and

FIG. 1.—Diagram showing the relationship between body weight and nitrogen balance. Both cases began treatment with 30 mg. of norethandrolone daily (N3), but this was later increased to 50 mg. daily (N5).

J. McK. After this period of pronounced gain the body weight remained more or less constant. At this stage the daily dose of the drug was increased in patients J. R. and H. F. from 30 mg. to 50 mg. Within several days both patients showed a further increase in body weight, then again the body weight became more or less constant. The two patients (H. C. and J. McK.) who had 50 mg. of norethandrolone daily from the commencement of the treatment period appeared to gain weight more rapidly than did those who started with 30 mg. daily. In these patients, too, the body weight eventually reached a relatively steady state. Unfortunately, in the case of J. McK., measurements had to be interrupted owing to diarrhoea as a result of Sonne dysentery, and, although administration of the drug was continued, no body weights were recorded or urine collected until the infection was controlled.

The increases in weight, expressed as percentages of the body-weight levels during the control period, were 9% (J. R.), 4% (H. F.), 5% (H. C.), and 7% (J. McK.).

Nitrogen Balance

The state of nitrogen balance is shown in Figs. 1 and 2. Nitrogen retention is depicted by the shaded area above the balance line and nitrogen loss by shading below the line. No urines were collected where the balance line is represented by a broken line.

During the control periods all four patients were considered to be in nitrogen balance, within the limits ± 0.5 g. of nitrogen daily, but during treatment there was marked nitrogen retention in three of the cases. The fourth case

(J. McK.) shows marked nitrogen retention until the onset of his diarrhoea, and finally a second nitrogen retention as he gained weight. As expected, in all cases the strongest nitrogen retention occurred where the body weight was increasing most rapidly.

Total Body Water and Extracellular Water Measurements

Total Body Water.—As can be seen from the Table, all four cases showed an absolute increase in the total body water, although in the case of J. McK. this increase was not a significant one. The relative total body water—that is, total body water percentage of body weight—was increased in two cases (H. F. and H. C.); it was unchanged in the case of J. R. and decreased in J. McK.

The Extracellular Water.—The absolute extracellular water increased significantly in three of the four cases but was less for J. McK. The extracellular water percentage of body weight was increased slightly in two cases (J. R. and H. P.), unchanged in one (H. C.), and decreased in one (J. McK.).

Side-Effects

The drug, which was administered orally three times a day in a total dosage of 30–50 mg., was well tolerated. No patients suffered from nausea or vomiting, nor were there any noticeable androgenic effects. An increase in appetite occurred during the treatment period, and the non-protein portion of the diet was increased slightly to cater for it. At the time of maximum gain in weight on the 50-mg. dose all patients were fully satisfied by the amount of food, and it was noted that occasionally some was refused, though all denied having nausea and none vomited. On this evidence it is doubtful whether a further increase in dose would have been well tolerated or desirable.

In the liver-function tests repeated after treatment there was no impairment of function.

FIG. 2.—Diagram showing the relationship between body weight and nitrogen balance. Both cases had 50 mg. of norethandrolone (N5) throughout the treatment period.

Comparison of Total Body Water, Extracellular Water, and Derived Intracellular Water Values Before and After Treatment with the Steroid Norethandrolone

* Intracellular water volume obtained from the difference of the total body water and the extracellular water volumes (i.e., T.B.W. - E.C.W. = I.C.W.).

Discussion

The object of this study was to investigate the anabolic properties of the steroid norethandrolone in elderly underweight patients who consistently failed to gain weight on an adequate diet. From the results it would appear that this substance has definite anabolic properties. The four patients studied showed significant weight gain accompanied by marked nitrogen retention—two necessary requisites for the laying down of new lean body tissue. That this weight gain was in fact due to an increase in the lean body mass and not merely due to fluid retention should be more obvious after consideration of the total body water and extracellular water volumes before and after treatment.

Lean tissue gain is associated with an increase in both the absolute and the relative total body water values, and our results appear to follow this course. In all four cases there is an increase in the absolute total body water; there is an increase in the relative total body water in two of the cases (H. F. and H. C.), one is unchanged (J. R.), and the other (J. McK.) shows a slight decrease. The extracellular water values also support the view that the gain in body weight was lean body tissue and not merely fluid retention, since if the latter were the case we would expect large increases in the extracellular water. The increases which occurred, however, were not large, and in fact are compatible with the weight gain being totally accounted for as lean body tissue. The extracellular water percentage of body weight was increased slightly in two of the cases (J. R. and H. F.); it remained unchanged in one case (H. C.), and was slightly decreased in one (J. McK.). If the weight gain had been due to fluid retention we should have expected the extracellular water percentage of body weight to have increased by as much as 5 or 6% and not only 1 or 2% as we have found.

Fluid retention unaccompanied by an increase in the lean body mass would have had little effect, if any, on the absolute intracellular water volume. Our evaluation of the intracellular water volume—the difference between the total body water and extracellular water volumes—shows an absolute increase in the four cases studied. The intracellular water percentage of body weight is increased in three of the cases and decreased in one case (J. R.). It was unfortunate that J. McK. had acute diarrhoea during part of his treatment period, and this undoubtedly accounts for the decrease in the absolute and relative extracellular water values observed and also for the decrease in the relative total body water. Nevertheless, the increase in the intracellular water volume, together with the marked increase in body weight, shows that in this patient too an increase in the lean body mass occurred.

These results, together with the marked nitrogen retention, indicate that the gain in weight results from an increase in lean tissue and is not due to simple fluid retention. It appears, therefore, that the steroid norethandrolone is an

effective protein tissue-building substance which is well tolerated and has little or no androgenic effects in these aged patients at a dosage of up to 50 mg. daily. According to McSwiney and Prunty (1957), 50 mg. of norethandrolone daily is as effective as 100 mg. Our investigation shows that 30 mg. does not produce the maximum anabolic response (Fig. 2), since a higher level of weight resulted from the administration of 50 mg. daily. The tendency to anorexia observed towards the end of the course suggests that a larger dose might cause nausea and vomiting in patients of the age group and sex investigated in this study.

We were not able to measure the body weight in the immediate post-treatment period, since the subjects were anxious to leave hospital after their prolonged stay, but the two we were able to follow (J. R. and H. C.) have maintained and subsequently increased their weight after seven months. McSwiney and Prunty (1957) reported that after cessation of treatment they have observed immediate nitrogen loss and quote a case in which nitrogen loss after withdrawal of the drug approximated to that previously gained. Kory *et al.* (1957), however, found that in a group of chronically underweight individuals 19 out of 25 subjects, followed for six months after the drug was discontinued, either maintained their weight or continued to gain. Our subjects and those of Kory were chronically underweight individuals, while those of McSwiney and Prunty were well nourished. This may explain the difference in findings. Where there is definite underweight or wasting the nitrogen retention due to treatment is perhaps permanent, but in a well-nourished subject the nitrogen retained may well be lost on withdrawing the drug.

Summary

The anabolic effects of the steroid norethandrolone have been investigated in four elderly underweight patients.

In each case there was a significant gain in body weight associated with marked nitrogen retention.

Total body water and extracellular water measurements were made before and after treatment, and the results supported the view that the weight gain was due to an increase in the lean body mass and not merely due to a simple fluid retention.

No androgenic or other unpleasant effects were observed from use of the drug.

In our opinion norethandrolone has definite anabolic properties and should prove to be of considerable value for increasing the lean body mass in individuals who consistently fail to gain weight on an adequate diet.

Grants in aid of this study have been made to one of us (D.W.) by the Nuffield Foundation and by the Scientific and Research Subcommittee of the Newcastle Regional Hospital Board.

We wish to acknowledge the supply of norethandrolone ("nilevar") from Messrs. G. D. Searle and Co. Ltd.

ACTION OF METHALLENOESTRIL ON THE POST-MENOPAUSAL ENDOMETRIUM AND VAGINAL EPITHELIUM

A COMPARATIVE STUDY

BY

W. K. SUTTON, M.B., B.S., M.R.C.O.G.

Formerly Senior Registrar, Department of Obstetrics and Gynaecology, London Hospital

AND

D. B. BROWN, M.B., Ch.B., M.R.C.O.G.

Senior Registrar, Department of Obstetrics and Gynaecology, London Hospital

Methallenoestril ("vallestril") is a phenolic acid derived from naphthalene that has been shown to be more strongly oestrogenic than oestradiol when administered parenterally in oily solution to castrated female rats (Courrier, Horeau, and Jacques, 1947). It has the descriptive formula 3-(6-methoxy-2-naphthyl)-2,2-dimethylpentanoic acid. It is relatively insoluble in water and gastric contents, but soluble in alcohol, in oil, and in dilute bases such as occur in the intestinal secretions. Sturnick and Gargill (1952) have found methallenoestril to be effective in the control of "menopausal symptoms" and of the pain of post-menopausal osteoporosis, without causing uterine bleeding during treatment or after withdrawal.

Potency studies in the laboratories of the manufacturers have shown that, while the oestrogenic effect of methallenoestril on the vaginal epithelium of spayed mature rats is twice that of oestrone, its influence on uterine growth in immature mice is only one-tenth as potent as that of oestrone. The present investigation was undertaken to determine whether this selective oestrogenic action of methallenoestril was demonstrable in women, and this was done by comparing its action on the endometrium and vaginal epithelium with that of stilboestrol.

The subjects of the investigation were patients awaiting vaginal repair operations for genital prolapse in whom the menopause had occurred five or more years previously. Each of these was given a course of tablets labelled A, B, or C, the nature of which was unknown to the investigators until the study was complete. The course of tablets, one a day, was given for a period of between 40 and 84 days, and the interval between completion of the course and endometrial curettage at the time of the vaginal repair operation was between 4 and 15 days.

The tablets labelled A contained 5 mg. of methallenoestril, those labelled B were inert, and those labelled C contained 0.5 mg. of stilboestrol.

Results

It may be seen from the Table that of the seven patients who received methallenoestril only one experienced withdrawal bleeding. This patient and one other were found to have hyperplastic endometrium. Of the 10 patients in the control group not one had withdrawal bleeding, although in three cases endometrial polypi were found, and in two of these the endometrium was relatively hyperplastic for a post-menopausal woman. Of the eight patients who received stilboestrol, four experienced withdrawal bleeding only, one induced bleeding, and one both induced and withdrawal bleeding. All of these, together with a seventh who did not bleed, were found to have hyperplastic endometrium. One patient had an endometrial polyp.

The diagnosis of "hyperplastic endometrium" was made on the basis of a naked-eye judgment of the amount and thickness of the endometrium confirmed by microscopical evidence of active proliferation or frank cystic hyperplasia. The four endometrial polypi (of which three occurred in the control group) were discrete adenomata arising by slender pedicles within the uterine cavity. They were considered to be innocent neoplasms rather than manifestations of hyperplasia.

The condition of the vagina was compared by noting the presence or otherwise of obvious atrophic changes in the epithelium. This was present in one of the seven methallenoestril cases, five of the 10 controls, and none of the eight stilboestrol cases.

Five patients volunteered the information that they felt better in general health and that their symptoms of prolapse were moderated after taking the tablets. Of these, three received methallenoestril and two the inert tablets.

Summary

A "double blind" trial of methallenoestril (vallestril) and stilboestrol has been carried out on 25 post-menopausal women awaiting vaginal repair operations.

Abnormal bleeding occurred in six out of eight patients who received stilboestrol and in only one of

the seven patients who received methallenoestril. Both macroscopic and microscopical examination of the endometrium has shown a lesser degree of oestrogenic stimulation in those who were given methallenoestril. The results may be largely explained by the fact that methallenoestril is a weaker oestrogen than stilboestrol, but there is some evidence of a selective action by the former which would make it a more suitable preparation for the treatment of post-menopausal vaginitis, post-menopausal osteoporosis, and the symptoms of the climacteric. A healthy vaginal epithelium was observed in all eight of the patients treated with stilboestrol, and all except one of the seven who were given methallenoestril. Five of the 10 controls had obvious atrophic changes.

We wish to thank Mr. Victor Lack, Mr. Alan Brews, and Mr. Robert Percival for permission to treat their patients and for their encouragement. The tablets for the investigation were prepared by G. D. Searle and Co.

A UNIQUE CASE OF AUTO-IMMUNE ERYTHROCYTE SENSITIZATION

BY

J. DARNBOROUGH, M.B., Ch.B.

Deputy Director, National Blood Transfusion Service, Sheffield

Occasionally the red blood cells of an apparently normal person will be found to have a positive reaction when a direct anti-globulin test is carried out. Usually this can be demonstrated to be a "false positive" due to *in vitro* sensitization with the normal cold incomplete antibody. Very rarely is a true positive reaction found in healthy people (Dacie, 1950, 1954). Little has been written on this aspect of the antiglobulin test, and the occurrence in a blood donor of a true positive direct antiglobulin reaction must be very unusual.

Mr. X, group A₁, Rh genotype cde/cde, has given 26 donations of blood since 1941, and since 1948 has attended donor sessions regularly twice or three times each year. No trouble was experienced until his 25th donation in October, 1957. The hospital laboratory, selecting blood for one of their "dangerous" recipients, included an indirect antiglobulin test as well as saline and albumin techniques in the compatibility tests. Mr. X's blood was found to be "incompatible" by the indirect antiglobulin test, but compatible in saline and albumin media. As is the custom, this bottle of blood and the patient's serum were sent to us for investigation, when the donor's blood was found to give a moderately strong positive direct antiglobulin reaction, agglutinates appearing in about one minute. The patient's serum contained no antibodies. The apparent incompatibility on cross-matching was thus explained.

A direct antiglobulin test using serial dilutions of the reagent gave the results shown in Tables I and II. This gave the first surprise. The optimum reactions with Mr. X's cells were in the same range as the optimum for Rh (anti-D) sensitized cells suggesting a "warm" antibody was coating the cells. Inhibition of the reactions with γ -globulin showed the coating antibody was of the γ -globulin type—further confirmation that a "warm" type sensitizing antibody was involved. The second surprise came when a red-cell eluate prepared by Weiner's (1957) method was tested against a

panel of cells of known phenotype and was found to contain the specific auto-antibody anti-c. This was demonstrable by the indirect anti-globulin technique, but not in saline or albumin.

No abnormal antibodies were found in the serum. Tested against a panel of R.B.C.s, no abnormal agglutinins were present apart from a very weak auto- and pan-agglutinin demonstrable at 4° C. only. Neither cold nor warm haemolysins were detected. The Donath-Landsteiner reaction was negative.

The serological findings were those usually associated with a moderately severe haemolytic anaemia.

The haematological findings on January 25, 1958, were as follows: Hb, 92% (13.6 g./100 ml.); R.B.C., 4,510,000 c.mm.; reticulocytes, less than 1%; W.B.C., 4,000 (polymorphs 52%, eosinophils 2%, lymphocytes 40%, monocytes, 6%). R.B.C.s and W.B.C.s apparently normal; platelets, 275,000. Hess test negative. Bleeding- and clotting-times normal. Prothrombin time normal. Red-cell saline fragility—within normal limits. No abnormalities were present, nor were any found on physical examination.

Past medical history included a hernia repair in 1939 and removal of a cartilage from a knee-joint in 1956. No history of any significant illness was given. Particular inquiry into any possible virus infection was made. He has never had a blood transfusion.

In March, 1958, a further donation was taken and the extensive serological tests were repeated. The direct antiglobulin reaction was still positive, and the pattern of the reaction was identical with that previously found. An eluate prepared from the red-cell stroma no longer had an anti-c specificity, having broadened its activity and now being, so-called, non-specific.

Dr. W. Weiner has completely confirmed the later serological findings and had some additional investigations done on the serum. Ultracentrifugal analysis gave perfectly normal results. A haptoglobulin estimation showed these to be definitely deficient, having a level only 50% of normal.

The fate of the man's blood donations since 1952 was investigated by inquiry of the hospitals using them. A particular point was made of asking whether any difficulty had been experienced in performing compatibility tests, particularly when the indirect anti-globulin technique had been used. The most recent occasion when the indirect antiglobulin test was used in a compatibility test was in November, 1955, and this was negative. Knowing that, using a single-dilution antiglobulin test, a positive reaction would have been obtained if present, there is no reason to doubt that in 1955 this donor's erythrocytes were normal. An antiglobulin test was not done on these cells again until the start of this investigation in November, 1957; the present state of autosensitization has therefore developed within the last two years.

Final Dilutions of A.H.G.	4	8	16	32	64	128	256	512	1,000	2,000
Mr. X's Rh-positive cells, sensitized with anti-D	—	—	—	—	—	—	—	—	—	—
Rh-positive cells, sensitized with anti-D	(+)	(+)	?	—	—	—	—	—	—	—
Rh-positive cells, unsensitized	(+)	?	—	—	—	—	—	—	—	—

Mr. X is 44 years old and is a coal-miner working at the coal face. He has no complaints whatsoever. He has two abnormalities—a positive direct antiglobulin reaction and a low haptoglobulin level. An apparently healthy man with this type of true positive direct antiglobulin reaction and no significant previous illness seems to be unique.

This case obviously needs following before a final answer to the present finding can be given. The most likely explanation is that he has an acquired haemolytic "anaemia" which has been detected in a very early stage, and which is at present fully compensated, although one might have expected a higher reticulocyte count. The low haptoglobulins suggest that haemolysis may be active. Nosslin and Nyman (1958) found these levels to be low in haemolytic diseases. The serological findings are those of a haemolytic anaemia; the haematological findings are normal. The picture is very similar to that sometimes seen in known cases of acquired haemolytic anaemia, either during natural remission or after treatment with steroids or by splenectomy. It remains to be seen whether in the course of months or years the present findings will change and show the full picture of an acquired haemolytic anaemia.

A further examination of specimens taken in October, 1958, showed no change. The haemoglobin level was normal and the red cells still showed the same degree of sensitization.

Acknowledgments are due to Dr. W. Weiner for the great interest he has shown in this case, and to Dr. E. K. Blackburn for carrying out the haematological tests.

BILATERAL THROMBOPHLEBITIS AFTER A SINGLE DOSE OF ERGOTAMINE TARTRATE FOR MIGRAINE

BY

ERIC R. CARTER, M.B., Ch.B.

General Practitioner, Runcorn, Cheshire

Although ergotamine tartrate has such a well-established place in the treatment of the acute attack of migraine and the toxic effects of ergot and its alkaloids are so often quoted, the incidence of thrombophlebitis occurring after ergotamine tartrate has not often been recorded; in fact, only one reference has been found—that of Sir Russell Brain (1947), who, writing on the treatment of migraine, states: "Ergotamine tartrate has a highly specific effect on the headache . . . there seems no risk of ergotism, but pregnancy and arteriosclerosis are contraindications, and, rarely, a single dose may cause thrombophlebitis."

Below are given the case histories of three patients who in one practice in the course of two years have developed bilateral thrombophlebitis following a single dose of ergotamine tartrate.

Case 1

A married woman aged 42, with two children, was diagnosed by an ophthalmic surgeon in 1954 as suffering from migraine, precipitated by strong sunlight. The wearing of dark glasses seemed to prevent the recurrence of any severe attacks, but ergotamine tartrate ("femergin") was prescribed in case of need.

On May 11, 1955, she developed an acute attack of migraine and took her first dose of ergotamine (two 1-mg. tablets) at 11 a.m. About 2 p.m. the headache disappeared quite suddenly, but she experienced a cramp-like pain in her right calf. This pain persisted and grew in severity throughout the afternoon and evening. In the night she was very restless with the pain and began to have sharp pains in the left leg. In the early hours of the following morning she was unable to stand up.

Examination later that morning showed that she was afebrile and had no gross varicose veins; but a dull red line, which was very tender, was present over the course of the long saphenous veins in the right leg, extending about a quarter of the way up the right thigh. A similar red line, also very tender, was present in the left leg, but this did not extend above the knee.

Both legs were strapped with "elastoplast," sorbo-rubber strips covering the affected veins, and she was encouraged to be ambulant. Within 24 hours she was much easier, all symptoms had gone within four days, and when the strapping was removed after 12 days there was no evidence of any residual thrombosis. She did show some varicosity of the long saphenous veins, more marked in the right leg.

Case 2

The patient, a married man aged 44, had a history of marked varicose veins in both legs, for which he had had injections in 1942, which had been followed by a troublesome phlebitis. This had dissuaded him from any surgical procedure, and he had resigned himself to a below-knee elastic support. He had also managed to change from a manual occupation to a sedentary job in May, 1956—a change which had relieved his leg symptoms but aggravated his migraine.

On July 19, 1956, he received his first prescription for ergotamine tartrate, and on July 23 he had a typical migraine attack on rising. He took two 1-mg. tablets sublingually about 9 a.m. (it was Sunday) and then had a little breakfast. His headache began to ease and he decided to seek some fresh air in the garden. About 10.30 a.m. he was compelled to return indoors with severe pains in both legs. The pains increased, and by lunch-time he was only capable of lying on his bed. After a restless day and night he found numerous red lines on both legs.

Examination then revealed an intensive network of very tender red lines over both legs and extending half-way up each thigh. He was admitted to hospital, and the following day both long saphenous veins were ligated at the saphenous opening to obviate the danger of pulmonary emboli. He made a steady recovery.

Case 3

A married man, a shop-proprietor aged 44, whose mother had suffered from asthma, was first diagnosed as suffering from migraine in 1952. Codeine tablets usually relieved the attacks, but in February, 1957, they became more frequent and he was subsequently kept on a modified Gowers mixture as a preventive. On March 23 he had his first prescription for ergotamine in the form of "cafergot."

On April 5 he felt a typical attack starting on rising. He returned to bed and swallowed his first dose of ergotamine tartrate (two tablets) at 10.30 a.m. He fell asleep, and awoke at 2 p.m. with his headache gone but having severe pains in the varicose veins in both calves. He remained in bed, and slept through the early part of the night, but found himself unable to stand the next morning owing to severe pains in both legs, the left being the worse.

Examination revealed a tender red line over a vein in his left leg, extending for about 4 in. (10 cm.). He had a small area of tenderness over a vein in the right calf but no redness. Both legs were strapped with elastoplast; he was much better in 48 hours, and when the strapping was removed after one week no signs of thrombosis or phlebitis were present.

Discussion

Von Storch (1938), in a review of an early trial of ergotamine tartrate for migraine, mentions perivascular pains and pains in varicose veins as a rare complication. Spasm of the saphenous vein is referred to by Clarke (1957). The observation of Russell Brain quoted above is, however, the only reference to thrombophlebitis occurring after ergotamine; he mentions it as happening after a single dose, which is confirmed by the above three cases.

The third case is particularly interesting, for the difference between this patient's two legs tends to suggest that the pain which occurs in varicose veins following ergotamine may be the first stage of a thrombophlebitis.

SALT INTAKE AND HYPERTENSION

BY

D. N. PHEAR, M.D., M.R.C.P.

Senior Medical Registrar, Central Middlesex Hospital, London

Hypertension was found by Dahl and Love (1957) to be associated with a high dietary intake of salt. In a group of 1,346 adults, habits of salt intake were classified as follows: (1) low intake—never add salt to the food at table; (2) average intake—add salt to food after tasting if insufficiently salty; and (3) high intake—routinely add salt to foods customarily salted before tasting.

TABLE I.—Correlation of Salt Intake and Hypertension in 1,346 Adults

	No. in Group	No. with Hypertension
Low intake	135	1
Average intake	630	43
High intake	581	61

Hypertension was significantly more frequent among those with a high intake than among the average group (Table I, $p < 0.01$).

Dahl (1957) also studied the sodium excretion in hypertension, assuming that sodium is the important ion and that sodium excretion normally reflects intake with reasonable accuracy. The average sodium excretion of nine hypertensive men was 204.3 ± 27.3 mEq/24 hours, while the average excretion of 19 men with normal blood pressure was 165.7 ± 32.0 mEq/24 hours. The difference is significant ($p < 0.01$). In the present work sodium excretion has been measured in a larger group of men with hypertension.

Method and Results

The 24-hour urinary excretion of sodium has been measured in 20 men with hypertension and in 20 men with normal blood pressures. Blood-pressure levels over 140/90 mm. Hg have been regarded as abnormal. The mean age of the group with hypertension was 49.8 years, and their mean blood-pressure level 218.9/127.3 mm. Hg. The mean age of the normotensive group was 56.3 years. All were out-patients, taking their normal home diet and unaware that their salt intake was being investigated. The work has been confined to men because of the greater difficulty of

collecting samples in women and because of premenstrual sodium retention. Sodium was estimated by flame photometry.

The mean sodium excretion of the 20 men with hypertension was 156.3 mEq/day (S.D.=54.6). The mean excretion in the 20 with normal pressures was 154.1 mEq/day (S.D.=46.2). The difference is not significant.

In this small group little reliance can be placed on differences in the subjects' accounts of their dietary habits. It is of interest, however, that high salt intake was commoner among the men with normal blood pressures (Table II).

TABLE II.—Salt Intake in 20 Men with Hypertension and 20 Men with Normal Blood Pressures

	Salt Intake		
	High	Moderate	Low
Normal blood pressure	9	10	1
Hypertension	4	15	1

Discussion

The present results do not confirm the findings of Dahl and Love (1957) that hypertension is associated with a high sodium intake and excretion.

There is other evidence suggesting that sodium plays an important part in the pathogenesis of hypertension. Hypertension is extremely rare among the Australian aborigines (Hicks and Matterns, 1933), the Cuna Indians of Panama (Kean, 1944), and the tribes from the Szechwan mountains of West China (Morse and Beh, 1937). A factor common to all these peoples is a low sodium intake of 1–2 g. or less a day, but many other factors, nutritional or genetic, may be responsible.

With restriction of dietary salt to less than 250 mg. a day, the blood pressure falls in most hypertensive patients and rises again if more salt is added (Kempner, 1948). Moreover, Perera and Blood (1947) found that the rise in blood pressure of hypertensive subjects resulting from deoxycortone could be prevented by restriction of sodium intake. They showed also that an increase of dietary sodium chloride from 4 to 15 g. daily produced a slight but definite rise in blood pressure in six patients with hypertension.

In rats the use of 2% sodium chloride as drinking-fluid for six weeks produces hypertension and renal hypertrophy (Sapirstein *et al.*, 1950). The feeding of salt also enhances the hypertension resulting from experimental renal ischaemia (Verney and Vogt, 1938), and salt restriction prevents production of hypertension in rats by deoxycortone injection (Braun-Menendez, 1951).

Summary and Conclusions

The sodium excretions of 20 men with hypertension and 20 men with normal blood pressures did not differ significantly. Other evidence suggests that sodium is necessary for the production of hypertension. In our society, however, hypertension cannot be related simply to dietary sodium intake.

I thank Dr. George Discombe for the sodium estimations. This investigation formed part of work awarded the Central Middlesex Hospital Research Prize for 1958.

Medical Memorandum

A Simple Procedure for Early Detection of Hypofibrinogenaemia

For the diagnosis of hypofibrinogenaemia or afibrinogenaemia the Kjeldahl or simpler "fibrindex" (Ortho) method is most frequently used. Weiner *et al.* (1953) suggested a "bedside" method, the so-called "clot-observation test." In cases suspected of afibrinogenaemia blood is withdrawn into a test-tube. If clotting has not occurred in 10 minutes, disturbance of the fibrinogen level can be assumed. One of us (G. L. B.) suggested the incorporation of this method in the admission routine, dispensing with the use of a test-tube. The following procedure has been used in our department for the past year:

In all cases of ante-partum haemorrhage the admitting house-surgeon takes off blood for cross-matching—a routine followed in most maternity units. He notes the time when taken and proceeds with the admission routine. Ten minutes later he observes the sample. If it has not clotted he considers the patient to be suffering from hypofibrinogenaemia. In cases where resuscitative action must be taken immediately—and it is in just such cases that a rapid diagnosis is needed—he can at once proceed and return to the sample later.

We believe hypofibrinogenaemia is not as rare as is usually suggested. Of the 2,176 cases admitted to the maternity unit of the North Middlesex Hospital during 1957, four had proved hypofibrinogenaemia or afibrinogenaemia (an incidence of 1 in 544), and two of these were diagnosed on admission by employing this simple test.

The first case was one of severe post-partum haemorrhage after a spontaneous unexplained stillbirth, where it was noted that the sample taken for cross-matching at the onset of the haemorrhage had not clotted. The patient later developed anuria, from which she subsequently recovered.

In the second case the afibrinogenaemia was associated with a ruptured uterus after external version under anaesthesia (Riedel, 1958). This patient died, and the diagnosis of both ruptured uterus and afibrinogenaemia was made in retrospect.

The third case was one of intrauterine death where the admitting house-surgeon noted poor clot formation, and a low fibrinogen level was subsequently confirmed biochemically. The level rectified itself spontaneously, in keeping with the findings of Hodgkinson *et al.* (1955) of fluctuating fibrinogen levels in those cases.

The fourth case is described in some detail, as it illustrates the efficacy of this method.

ILLUSTRATIVE CASE

An emergency admission was arranged for the patient by her own doctor. He stated that she was a para-1 aged 25, booked for home confinement, who had had a severe ante-partum haemorrhage at 38 weeks' maturity and who was in poor condition. She arrived at 7.30 a.m. in the maternity receiving-room. She was pale and shocked, with a tense, tender uterus, and was losing moderately heavily per vaginam. Her blood pressure was 90/70 mm. Hg and the pulse was feeble and rapid. No foetal heart could be heard. A catheter specimen showed the urine to be solid with albumin. Blood was taken immediately, an intravenous drip of "dextraven" begun, and morphine sulphate, $\frac{1}{4}$ gr. (16 mg.), given subcutaneously. At 7.45 a.m. one of us (J. A. R.) noted that the sample of blood had not clotted. (Subsequently absence of fibrinogen was confirmed.) The following measures were taken: (1) the dextraven was changed to group O, Rh negative blood; (2) 6 pints (3.4 litres) of blood was ordered from the pathological labora-

tory; (3) a solution of fibrinogen was prepared; and (4) two bottles of triple-strength plasma were prepared.

At 8 a.m. infusion of triple-strength plasma was begun after the patient had had 1 pint (570 ml.) of blood. Her pulse was still feeble and rapid. Vaginal bleeding continued, and it was noted that this blood showed no signs of clotting. As she reacted with a rigor to the plasma, given at speed, blood was given immediately afterwards.

At 9 a.m. the second bottle of triple-strength plasma was started. Her blood pressure remained low (105/75 mm. Hg), but the pulse had improved in volume and was 90. The blood then showed signs of clotting. A vaginal examination was carried out; the cervix was four fingerbreadths dilated, and the membranes, which were intact, were artificially ruptured. A second 400 ml. of plasma had been given by 9.15 a.m., and spontaneous delivery of a stillborn infant occurred at this time. Ergometrine maleate, 0.5 mg., was given intravenously with the birth of the anterior shoulder; the placenta, which followed immediately, was covered by a large, dark clot of 30 oz. (850 ml.) (supporting the theory that afibrinogenaemia occurs after placental separation). Five units of "pitocin" were added to the next pint (570 ml.) of blood, as there was a steady loss and the uterus tended to relax.

At 10 a.m. the fibrinogen was dissolved and ready for administration. By this time the patient had received 4 pints (2.2 litres) of blood and two bottles of triple-strength plasma, and 2.3 g. of fibrinogen in 200 ml. of water was given slowly.

At 11 a.m. the blood clotted normally. The patient's condition was fair, her blood pressure being 100/60 mm. Hg, and there was a slight trickle of blood per vaginam. The pulse was 90 and of good volume. Two more pints (1,140 ml.) of blood were given.

At 5 p.m. her condition was satisfactory; blood pressure 120/80 mm. Hg, pulse 86. The total loss was estimated at 120 oz. (3.4 litres), which had been replaced by 120 oz. (3.4 litres) of blood, and two bottles of triple-strength plasma. That the loss was underestimated was proved two days later, when the haemoglobin (which had been 73% on admission) had fallen to 57%.

The fibrinogen content of the blood was normal 26 hours after delivery, when the clotting-time was $4\frac{1}{2}$ minutes.

COMMENT

In this case the diagnosis of hypofibrinogenaemia was made within 15 minutes of admission. Fibrinogen replacement had begun 15 minutes later. Within 90 minutes the patient had received 6 g. of fibrinogen (in the form of concentrated plasma) and the blood showed signs of clotting. That, and the measures taken to prevent post-partum haemorrhage, made it possible for the patient to be discharged on the eleventh day, with a normal blood pressure, a trace of albumin in the urine, and a haemoglobin of 67%.

The reasons why we think this method, which is only a slight improvement on the clot-observation test, is worth reporting are: because it is simple and does not need help from a laboratory, because it is applied routinely, and because the diagnosis can be made by an inexperienced house-surgeon soon after admission. Early diagnosis is of prime importance in the treatment of hypofibrinogenaemia.

We thank Mr. K. A. K. Hudson and Mr. A. W. Purdie for permission to report cases under their care.

Reviews

MEDICINE AND THE NAVY

Medicine and the Navy, 1200-1900. By J. J. Keevil. Volume II—1649-1714. (Pp. 331+ix; illustrated. 40s.) Edinburgh and London: E. and S. Livingstone, Ltd. 1958.

It is indeed fortunate that Surgeon Commander Keevil lived long enough to complete the essentials of his second volume of *Medicine and the Navy*. This volume follows the pattern of the first, presenting a most entertaining and readable account of the development of medicine in England with a naturally naval bias. The theme running through this collection of historical facts might well be founded on the dictum of Lowell that "Tis man's worst deed to let things that have been run to waste and in the unmeaning present sink the past," for it is a somewhat pathetic story of the obscurantism of the age which could not or would not profit by lessons learnt. The prevention of scurvy among sailors, admittedly empirical, had been found, but 200 years later the medical profession was still unable to connect cause and effect. It may also be salutary for those who decry the National Health Service to realize that it took high on 200 years to produce the money to build a naval hospital. History as recounted in this volume undoubtedly repeats itself, for there is a strange, if somewhat ominous, similarity between the frequent "Commissions for Sick and Wounded" of the seventeenth and eighteenth centuries and our modern Commission on the Medical Services of the Crown. The basic reason for these commissions—an attempt to produce the effect of a financial quart out of the Treasury pint pot—is always the same, and it would appear that the results are equally alike.

This volume brings the story up to 1714. It is tragic to realize that Surgeon Commander Keevil, a historian of such outstanding capacity, cannot himself bring the history up to date. We can only trust that the Naval Medical Service will find another "Keevil" to carry on the work of this very gifted and painstaking biographer of the naval surgeons of the past, so that their persistence and perseverance in moulding the evolution of the Naval Medical Service into the highly efficient service of the present day may receive the credit they so richly deserve.

J. C. DOWSE.

ADVANCED PAEDIATRIC SURGERY

Pediatric Surgery. By Orvar Swenson. (Pp. 740; illustrated. \$20.) New York: Appleton-Century-Crofts, Inc. 1958.

This book is the work of one who worthily carries on the great traditions of the Boston school of paediatric surgery. His solving of the problem of Hirschsprung's disease is the most important work to come from it since Ladd's classical study of the congenital malrotations of the intestine.

It is significant that in the last few years three detailed, highly instructive, beautifully produced, and very expensive textbooks have appeared on the subject of the advanced surgery of the infant and young child—those of Gross, of Boston; Grob, of Zurich; and now this one of Swenson's. The demand responsible for the appearance of these books springs from a growing realization that many babies and young children are being allowed to die unnecessarily because of the remarkable lack of teaching on this subject in medical education. (Though the Scottish schools, in particular Glasgow, treat it far better than the English.) The whole subject has changed vastly in quite recent times: it is not so long ago that a work on paediatric surgery (Brenner, 1938) began with the words, "The immature organism is predominantly unstable, and this incompetence forbids heroic surgery."

Taking the adjective heroic to mean extensive, we see in all these books that this timidity is entirely unjustified: given the necessary technique, the most drastic and extensive operations can be successfully performed on the youngest and frailest of infants. And it is with technique

that Dr. Swenson is particularly concerned; in this respect his book is the most instructive of the three. Because of his own efficiency in this regard he favours immediate end-to-end anastomosis when bowel has to be resected for atresia, or for necrosis in such conditions as intussusception; and it is probably for the same reason that, like other great American surgeons, he dislikes paying the price of added risk for the ease of operating given by muscle relaxants.

He makes the stimulating suggestion that congenital dilatations of the ureters and bladder are caused by defects of the parasympathetic system. Whether or not this is accepted, his method of replacing an inefficient ureter by a segment of surgically narrowed bowel illustrates his technical ingenuity and powers. I am personally flattered by his recommendation of my technique for hypospadias; not surprised by his flat statement that hormone therapy has no place in the treatment of the undescended testicle; and hope that on experiment and reflection he will give up the belief that the cremaster can pull this organ into the inguinal canal.

Like all human works the book has gaps and inequalities of treatment. There is no mention of tonsils and adenoids, nor of spina bifida; the section on hare-lip and cleft palate is poor; and paediatric surgeons in the States have so far been unable to break into the tightly closed shop of the orthopaedists, where it is possible that new advances might result from the approach that has been so successful elsewhere. But the book is a most valuable one for the magnificent treatment of the infant's abdomen and chest, in particular for the section in which the author describes his unequalled experience of Hirschsprung's disease.

DENIS BROWNE.

METABOLISM OF BONE

The Chemical Dynamics of Bone Mineral. By William F. Neuman and Margaret W. Neuman. (Pp. 209+xi; illustrated. 37s. 6d.) Chicago: University of Chicago Press. London: Cambridge University Press. 1958.

There can be fewer subjects in medicine which leave teachers and taught in such an uneasy frame of mind as that of bone metabolism. The original fertile ideas as to calcification processes—such as the calcium and phosphorus product of the plasma, phosphatase and the local factor—have been barely extended since they were originated, and they have subsequently been accepted and developed so glibly by clinicians as to reach the realm of fantasy. This book aims to correct this situation. Its first chapters deal in physico-chemical terms with the modern views of solution chemistry, solubility of bone mineral, crystal structures, and surface chemistry. Heavy going, but an essential corrective in the circumstances. From here on things become more easily digestible by doctors, and the chapters on skeletal dynamics and on physiological regulatory mechanisms are thrilling from the way the authors have developed the basic arguments along more clinical directions. The key factor here is the local citrate concentration and its influence on the product of the ionic activities of Ca^{++} and HPO_4^{--} . Both parathyroid hormone and vitamin D can now be plausibly linked with different stages in citrate metabolism, and thus act independently but in the long run synergistically. The final chapter deals critically with the authors' current concept of the calcification mechanism. They firmly reject the generally held view that the local stimulus is due to an increase in calcium and phosphorus product mediated by phosphatase, and prefer to suggest the existence of a local crystal seeding mechanism (epitaxy) probably induced by the organic constituents.

It may appear unfortunate that I cannot withhold a protest against the frequent misspelling in the figures of the standard abbreviations for common terms such as gram and milligram. This slovenliness appears to be increasing in the medical literature of the English-speaking countries, which seems a pity when our spelling conventions have

been internationally agreed to by the entire scientific world, Russia and China included.

The book fills a long-felt gap in the medical literature. Its clear and forthright style makes it easy to read and remarkably stimulating to one's thought processes.

C. E. DENT.

ADVANCES IN VIRUS RESEARCH

Advances in Virus Research. Volume V. Edited by Kenneth M. Smith and Max A. Lauffer. (Pp. 376+x; illustrated. \$9.50.) London: Academic Books, Ltd. New York: Academic Press, Inc. 1958.

This is the fifth in a series of annual reviews of advances in virus research. The striking feature of this book is the apt choice of a fundamental subject from each field of virology and the completeness with which each subject is discussed. The first essay, by J. B. Brooksby, on "The Virus of Foot and Mouth Disease," is an up-to-date and full account of the virology of this infection. Mention is made of the geographical distribution of the virus types, but little is said about its epidemiology. Herbert Werner's contribution, "Psittacosis-Lymphogranuloma Group of Viruses," gives a comprehensive account from both the epidemiological and laboratory aspects. Most usefully he emphasizes the large numbers of animal diseases caused by this group and the relation of these animal viruses to human disease. There are two contributions on bacterial viruses. The first, by G. S. Stent, entitled "Mating in the Reproduction of Bacterial Viruses," is a well-studied and extremely interesting theoretical essay based on work on the action of ultra-violet light, radioactive phosphorus, and x rays on phages and their host bacteria. The interpretation of Watson and Crick's classical work on the molecular structure of deoxyribose nucleic acid is modified to explain his observations. Using four phages as models, G. Bertani gives a lucid and factual account of lysogeny. A lengthy discourse is given by Ph. L'Heritier on the "Hereditary Virus of *Drosophila*," with special emphasis on the action of CO₂ on the infected insects and the transmission of this virus. There has been an outstanding requirement for a review on the measurement of complement-fixation by viruses. This has been amply fulfilled by Forrest Fulton's article. Each component of the test has been fully dealt with, and their application in three dimensions as antigen, antiserum, and complement contours described. The author has tackled a difficult subject and has attempted to clarify it by a mathematical approach. The last contribution, "The Mechanism of Hemagglutination by Influenza Virus," is by A. Buzzell and M. Hanig. This is a detailed review of the subject; nothing important has been omitted, and it is written so concisely and clearly that all who work with influenza will find it invaluable.

P. S. GARDNER.

THE DISCOVERER OF STREPTOMYCIN

My Life with the Microbes. By Selman A. Waksman. (Pp. 320. 21s.) London: Robert Hale Ltd. 1958.

Although it is true that the great discovery comes to the mind prepared, it is also true that there are many different ways of preparing the mind. Fleming's mind was trained to appreciate the value of the chance observation, but Dr. Waksman had prepared himself for the discovery of streptomycin by knowing more about soil bacteriology, and particularly the influence of the members of this teeming microbiological population upon each other, than anyone else in the world. His researches conducted for 20 years had shown, as early as 1936, that actinomycetes were able to exert a considerable influence on the growth and activities of fungi and bacteria in the soil. The discovery of streptomycin in 1943, therefore, following the discovery of penicillin by Fleming, was no more than the climax of these researches, for it was prepared from an organism, *Actinomyces griseus*, first isolated by himself and a collaborator in 1915.

Dr. Waksman emigrated from Russia to the United States in 1910, and has been since 1918 on the staff of the College of Agriculture at Rutgers University in New Jersey. The

University had made an agreement with Merck and Co. in 1939 that all patentable processes should be assigned to this firm in exchange for a royalty of 2½% and for considerable scientific help provided by Merck's. After the discovery of streptomycin Merck's agreed that other interested organizations should be allowed to manufacture it under arrangement similar to that made with themselves.

Some of the interest of Dr. Waksman's excellent autobiography is to be found in his story of the complicated relationships that crowd upon the discoverer in the modern world—relations not only with his employing university and with manufacturers, but also with the press and the public, with patients both gratified and disappointed, and even with his assistants. A former student instituted a legal suit for a share of the large profits; he was paid 125,000 dollars for the assignment of all foreign patent rights and 3% of the royalties. Whereupon Dr. Waksman, whose judgment and good will were not submerged by these legal complications, decided that half his share in the royalties—namely, the 10% which he had returned to the Rutgers Research and Endowment Foundation—should be distributed among the 26 of his former students and assistants who had helped in the development of the antibiotics programme. The law is now prepared, not only to assess the financial value of an erring wife, but also to judge the contribution made to a great discovery by the laboratory assistant who prepares the culture media. A friend of mine when receiving an award for his researches said, "The prestige I gladly share with my assistants; the money I will keep for myself"—a simple and old-fashioned solution of a problem which has now acquired a new look.

D. V. HUBBLE.

PERIPHERAL CIRCULATORY DISTURBANCES

Begutachtung Peripherer Durchblutungsstörungen. By H. W. Passler and H. Berghaus. (Pp. 272+xi; illustrated. DM.45.) Stuttgart: Georg Thieme Verlag. 1958.

This book on the examination of peripheral disturbances of the circulation is based on 100 well-documented cases. Investigation by serial angiography is found to be very important. There are a number of excellent photographs of the vessels of the legs obtained in this way. The author claims that it is absolutely safe. The campaign in Russia provided an enormous amount of material for the study of the effect of cold on the vascular system. The author had special opportunity to investigate these cases. The effect of cold is considered in both healthy and diseased arterial systems. Deficiency states are dealt with, and the effects of trauma. In another section the effects of peripheral disturbance of the venous circulation are considered. The numerous cases are well described and shortly presented. The illustrations are excellent. There is a full list of references. The print and index are clear and adequate. Altogether an up-to-date and efficient presentation of an important subject. The book can be heartily recommended. As the title implies, there is nothing about therapeutics.

TERENCE EAST.

Centenary of the General Medical Council, 1858-1958 (pp. 31 +2 plates, published by the Council, 3s. 6d.) gives an account of the history and present functions of the G.M.C. compiled by Mr. Walter Pyke-Lees, its present Registrar. After a brief note on the events leading up to the Medical Act of 1858, which brought the Council into being, Mr. Pyke-Lees describes the difficulties encountered in the preparation of the first *Medical Register* and *British Pharmacopoeia*. He also discusses the Council's efforts from time to time to promote legislation for the better discharge of its functions. The Council's duties in the field of medical education—not always appreciated—are shown to be one of its major concerns; it has devoted much time to examination and revision of the curriculum. Its disciplinary powers, it is pointed out, are not intended to be retributive, but are for the protection of the general public. In the words of Sir Donald MacAlister, an outstanding past-president, the Council's two great functions are "to prevent the unfit from gaining access to the Register, and . . . to remove the unworthy from it."

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY DECEMBER 13 1958

B.M.A. CLINICAL MEETING

The candid, and usually caustic, critic of the B.M.A. is never tired of saying that an organization which costs over a quarter of a million pounds a year to run spends too much of its energy on getting more money for doctors. Those who report the A.R.M. in the press sometimes accuse our spokesmen of talking money instead of medicine, of what they can get out of the country instead of what they can give it. Since 1948 the B.M.A., the critic says, has taken on too much of the colouring of a trade union—too much, at least, for the liking of many of its members. The worst consequence of the N.H.S. is that it has made doctors too self-conscious about money. And small wonder! The gay promise of the Spens Reports has not been fulfilled. What seemed a decent enough charter has been turned by politicians and the quibblings of civil servants into a dirty piece of paper. Not insensitive to all this, those responsible for the conduct of B.M.A. affairs have this year, and last week, instituted the first Annual Clinical Meeting. It was held in Southampton from December 4 to December 7. It was an annual meeting of the B.M.A. in which the words Spens, Danckwerts, capitation fee were neither uttered nor published. It was, refreshingly and hopefully, a meeting at which men and women spoke and thought solely of their work, of clinical medicine and scientific investigation. It was a meeting of doctors.

Panel discussions, general sessions, colour television, medical films, clinical demonstrations in the hospitals of Southampton, filled out the day, with short respites for lunch and tea. There was a big attendance of doctors from the neighbourhood and from further afield, and many distinguished physicians and surgeons came from as far north as Edinburgh to join in this feast of reason and good fellowship. A large audience saw a magnificent demonstration of a "live operation" for atrial septal defect colour-televised from Southampton General Hospital. The other *coup de théâtre* was the Transatlantic Clinical Conference between a British group in the Guildhall of Southampton and a team from the U.S.A., at the American Medical Association's Clinical Meeting in Minneapolis. There were

two cases for diagnosis, and only one member of each team knew the answer for his own side. It was, certainly, at least for the British, a dramatic occasion. Two to three hundred British doctors in Southampton Guildhall participated in a clinical conference between four British and three American doctors separated by four thousand miles. Medicine certainly is not dull, and no one who listened in will ever again see a case in which there is an excess of gammaglobulins in the blood without thinking of myxoma of the atrium.

The Southampton meeting was a success, and any fears its sponsors may have had on this score were soon laid to rest. Drs. R. S. Russell-Smith, J. G. McDowell, and R. P. W. Shackleton, who laboured so mightily in their home town to make the meeting what it was, must now feel justifiably content. And so must be the chairman of the Committee of Management, Dr. Ronald Gibson, untiring in his efforts to weld the B.M.A. into a unity of like-minded men and women whose common meeting-ground must always be the art and craft and science of a great and inspiring vocation. As Professor A. P. Thomson, the B.M.A.'s President said last week, the Southampton Clinical Meeting has set a standard and example for the future. The next meeting will be in Norwich a year from now. Maybe less time should be given to the set lecture in the general session and more to panel discussions and clinical demonstrations. What is surely needed is active participation, and it was curious how this was felt at the Transatlantic Clinical Conference. Everyone present was silently taking part and making his own diagnosis. The lecture, however, puts the listener too far back into the passive receptivity of the student furiously scribbling notes on a hard bench. But the pattern set at Southampton, if not perfect, was little short of excellent, so excellent that some hope that a spring and an autumn clinical meeting on the Southampton model might be separated from the Annual Representative Meeting, which itself could be held regularly in the summer in the Parliament of the B.M.A.—B.M.A. House, Tavistock Square.

PERIPHERAL NEUROPATHY AND THE LUNGS

Over the years a formidable list of causes of peripheral neuropathy has grown up. It includes chemical agents, metabolic disorders, and infective states. In many diseases the neuropathy is a well-established component or complication—for example, poisoning by heavy metals, diabetes mellitus, vitamin-B deficiency, and diphtheria. In others it occurs infrequently and is usually ascribed, for want of a better

explanation, to a "toxic" cause. Occasionally it develops in conjunction with respiratory disorders, and many attempts have been made to discover a specific relationship between the lungs and the peripheral nerves. These have not been entirely unsuccessful. For example, peripheral neuropathy and carcinoma of the bronchus would seem at first sight to make uneasy bedfellows, but their association has been proved to be real beyond doubt.¹ Of the infections, perhaps advanced tuberculosis is the best known, but transient neuropathies may complicate pneumonia and influenza, and two instances of rather severe chronic peripheral neuropathy have recently been recorded in bronchiectatics, the neurological features being relieved in each by effective treatment of pulmonary suppuration.²

In trying to relate the pulmonary condition to the neuropathy, the problems posed by carcinoma and the infections are different. The mechanism of the association with carcinoma remains a complete mystery, whereas the main issue with the infections is to decide whether neuropathy occurs more frequently with inflammation of the lungs than it does with inflammation elsewhere in the body. A consideration of the clinical aspects strongly suggests that such mechanisms as may be involved are dissimilar in the two pulmonary conditions.

The first manifestation of carcinoma may precede, coincide with, or follow the neurological signs. The tumour is often situated peripherally and its size bears no relation to the degree of neuropathy. The neuropathy runs a variable course, sometimes becoming arrested or remitting spontaneously and usually being unaffected by surgical removal of the growth. Hence any causative link seems to act in a haphazard way. In seeking an explanation, many suggestions have been made. Intoxication by arsenic springs to mind as an obvious common factor, but no evidence of excessive exposure to arsenic has ever been found in these cases. The possibility of a virus being responsible for both seems improbable, since it would be likely to act upon the nerves within a matter of weeks, whereas a carcinoma would take much longer to develop. Metabolic disorders are very difficult to assess because of their complexity, but vitamin therapy rarely if ever relieves the neuropathy; disturbances of pantothenic-acid metabolism or even the production of an anti-vitamin substance by the carcinoma cells have been mentioned.³ Nervous reflexes from the lungs might conceivably play a part.⁴ In other

words, we do not know, even to the extent of which system may provide the link.

Many acute infections are known sometimes to be associated with peripheral neuropathy—for example, septicaemia, puerperal sepsis, mumps, measles, smallpox, scarlet fever, gonorrhoea, syphilis, meningitis, typhoid, paratyphoid, dysentery, typhus, malaria, influenza, and pneumonia. The neurological features ordinarily develop during or shortly after the febrile phase, and no evidence exists suggesting that pulmonary involvement *per se* predisposes to peripheral neuropathy. The question whether chronic infections are more likely to do so if situated in the lungs rather than elsewhere is less certain. Peripheral neuropathy has been observed in advanced phthisis, chronic suppurative of the extremities,⁵ osteomyelitis,⁶ and bronchiectasis.² These are toxic and debilitating diseases which may easily disorganize metabolism to the extent of interfering with the nutrition of the peripheral nerves, possibly with amyloidosis in addition, but again no specific pulmonary mechanism seems to be acting. However, the recent publication of two cases of bronchiectasis with peripheral neuropathy and no evidence of cachexia or metabolic upset² is perhaps a straw in the wind; the publication of further similar cases must be awaited before a firm conclusion can be drawn.

INSULIN ANTIBODIES

Insulin resistance is a well-known phenomenon in diabetes mellitus. It may occur temporarily during infections or ketosis, and is a common finding in the obese diabetic and in the patient who has diabetes in association with acromegaly or Cushing's syndrome. Occasionally patients need enormous doses of insulin to control the disease. Several mechanisms have been suggested to explain this resistance. Antagonism of insulin by growth hormone, and particularly by adrenal steroids, might well be expected, but except in the endocrinopathies has not been proved. It is known that the liver contains an enzyme insulinase which destroys insulin, and that this enzyme in its turn is acted upon by insulinase inhibitors.¹ It is not yet clear, however, what part this complex plays in the diabetic syndrome. A third possibility is that certain patients develop antibodies to insulin. This has been suspected for some years.²

though their presence cannot always be detected by the usual immunological techniques. Nevertheless the presence of insulin antagonists in the serum of resistant patients can be shown by various indirect means, such as the protection afforded to animals receiving lethal doses of insulin and the effect on the uptake of glucose by the rat diaphragm.³

Renewed interest in the role of antibodies has been stimulated by recent studies of the fate of insulin labelled with radioactive iodine.⁴ It has been found that treated diabetics retain insulin-¹²⁵I in the circulation longer than those who have never received insulin, and that the radioactivity is concentrated in the globulin fraction of the plasma proteins. Such insulin binding, presumably in the form of an antigen-antibody complex, is an invariable response to repeated insulin injection, but its relation to the development of resistance is not at all clear. Thus, while some workers^{5, 6} have found much greater binding in insulin-resistant patients, others⁷ have been unable to show any connexion between the degree of insulin binding and the dosage and duration of treatment. N. Kalant and colleagues⁸ have concluded that neither retention of radioactive insulin in the serum nor the degree of binding affect the response to a given dose of insulin. Moreover, the serum of animals actively immunized to the hormone does not exhibit insulin-neutralizing activity, nor do such animals show any great diminution in responsiveness to insulin. They suggest that repeated injection of insulin leads first to a decrease in its rate of degradation, followed later by the appearance of circulating antibodies in the form of a loose complex which does not necessarily interfere with the action of insulin. A further factor which may partially explain why the presence of antibodies is not clearly linked to insulin resistance is the ability of serum from treated diabetics to inhibit insulinase.⁹

A full interpretation of the phenomenon of insulin binding must await further work on the metabolism of insulin, both in normal subjects and in diabetics. It is possible, for example, that a similar mechanism occurs in the serum of healthy people,¹⁰ and that the insulin-globulin complex is not an immunological response in the strict sense. The fact that it always appears in the treated diabetic suggests that it has little to do with insulin resistance. Similarly it seems unlikely that such a mechanism would influence the long-term insulin requirements of the average patient. Yet it is possible that the development of antibody would tend to increase the dose required for a given effect,⁷ and this would explain the resistance that occurs in patients receiving insulin-shock treatment.

MORBIDITY IN GENERAL PRACTICE

During the twelve months from May, 1955, to April, 1956, 171 general practitioners in more than 100 practices in England and Wales kept clinical records of all their Health Service consultations. This survey of the morbidity encountered in general practice was conducted jointly by the General Register Office and the College of General Practitioners, and the first volume of results has now been published.¹ Two more are promised. There are few comparable studies, though the rich rewards that can be won from careful observation in general practice have been brilliantly shown by Budd, Mackenzie, Pickles, and others. There was an obvious need for more information of this sort; an earlier pilot study from the General Register Office showed that it was well worth collecting^{2, 3}; and epidemiologists, public health officers, and general practitioners have been awaiting the results of this large study with the keenest expectation.

The survey is based on two items of information—the consultation between doctor and patient, and the diagnosis of the patient's complaint. More than half the book consists of tables presenting this basic information differentially by sex, age group, and geographical area. Two different types of rate have to be distinguished: the "consultation rate" measures the numbers of times a patient was seen by his doctor for a particular disease; the "patient-consulting rate" is the number of patients suffering from a disease, regardless of the number of consultations. It is unfortunate that the two names are so similar and are not self-explanatory so that it requires a little mental effort to hold them in mind while studying the tables. The patient-consulting rate is held to give a truer picture of the amount of sickness in the community because doctors will differ widely in the number of consultations which they give to a patient for a particular illness. Nearly 400,000 patients were seen by the doctors and the number of consultations reached nearly 1½ million.

The early chapters give details of the methods adopted to ensure completeness and uniformity in the data. Sometimes arbitrary decisions had to be made on how to deal with recurrent diseases; for example, whether each attack of asthma should be considered separately or as a continuation of a single disease. The devices for recording several diseases at a single consultation and for linking subsequent consultations with previous ones for the same disease are ingenious.

The book is so arranged that it will be invaluable to anyone planning similar investigations, and it is so complete that it would not be difficult to repeat the survey in every respect. The later volumes will show in more detail what inferences can be drawn from these tables, but the present volume gives certain interesting statistics. For example, only 30% of female patients did not consult their doctor during the year, whereas 37% of males kept away. One would have expected a larger discrepancy. The proportion of patients seen was

higher in the age group under 15 years, but the elderly patient tended to be seen twice as often as the average child or young adult. The number of patients consulting for malignant disease was 5.2 per thousand, suggesting a total of approximately 230,000 cases of cancer under treatment in the whole country. Those interested in psychoneurotic disorders will find that the patient-consulting rate for these was 45.7 per thousand, indicating a national total of 2,000,000 patients under the care of their doctor during that year, or one in twenty of the population. The common cold gave the highest patient-consulting rate for individual diseases, 81.1 per thousand, though it entailed fewer consultations than this rate would suggest, and it was bronchitis that most often required medical attention. With a consultation rate of 261.1 per thousand and a patient-consulting rate of 62.3 per thousand, bronchitis had the third highest patient-consulting rate, coming after arthritis-and-rheumatism with 64.9 per thousand. Surprisingly, influenza came fifth on this list, both for patient-consulting rate and for consultation rate, though there was no great influenza epidemic in that year.

High praise must go to Dr. W. P. D. Logan and his team at the General Register Office, to the general practitioners, their secretarial staffs and probably their wives, for the fine work which has produced this volume, and the care and skill with which it has been written. Still higher praise must go to those general practitioners who were able to offer an account of the occupation of all their patients. It requires much work to obtain the full statistics of sex and age for a general practice, and to add to this the occupation of the patient is a formidable undertaking. A sufficient number of general practitioners, nevertheless, did so to make possible an analysis of sickness in relation to occupation which is promised for a subsequent volume. The present work whets the appetite for what is to follow, and everybody interested in epidemiology and morbidity figures will want to collect the series.

IMAGE INTENSIFICATION AIDED BY TELEVISION

In diagnostic radiology an x-ray image is usually rendered visible by allowing it to fall on some material which converts x rays into light (a fluorescent screen) or on to a photographic film which, on processing, reveals the latent image; or a combination of these two methods may be used. Image intensification refers to any electronic method which enables the film or fluorescent image to be obtained with a reduced quantity of x rays. There are many reasons for wishing to reduce the dose of radiation, the potential hazards being in themselves a cogent one. The present methods of image intensification are first to convert the x-ray image into a light image with the use of a fluorescent screen and then to convert the light image into an electron

image. The energy of the electrons is then increased and the image may be focused with electron lenses and allowed to fall on another fluorescent screen yielding a considerably brighter image than the first one. Alternatively, the initial image may be scanned as in television, the resultant electric current being then amplified and viewed on a conventional television screen as an image with increased brightness. In either case the image may be photographed, but the television system has the advantage that contrast can be varied at will. The use of equipment of this type, which is available commercially in the U.S.A., has been described by R. H. Morgan and R. E. Sturm¹ and by R. Janker.² For medical purposes, however, the radiologist is primarily concerned with obtaining a brighter image with less radiation and without significant reduction of definition rather than with achieving merely increased brightness with the same doses of radiation as are used with conventional methods. Unfortunately, when the quantity of x rays required to give a fluoroscopic image is significantly reduced, the definition of the image falls because of statistical fluctuation of the x-ray quanta on these low levels.³ This means that, though it may be possible to intensify the image without increasing the dose of radiation, so far it has not been possible to maintain definition in the intensified image with doses of radiation much less than those used at present. It seems unlikely that further advances of major importance can be made in this field unless a more efficient means than the fluorescent screen is found for converting the primary x-ray image, for, though image intensifiers may have an intensification factor of hundreds, the radiologist can reduce the dose of radiation only by units. However, improvements sufficient to make the method useful in practice may result from comparatively small refinements in any of the components of the system. These problems are being investigated in several centres, including the department of instrument technology of the Imperial College of Science and Technology, London, and their solution will be eagerly awaited by radiologists.

QUALITY OF DRINKING-WATER

In this age of standardization it is not surprising that the quality of water for domestic consumption has been under consideration. Both in Great Britain¹ and in the U.S.A.² there have been standards for many years, but the first attempts to obtain international agreement were at the Congresses of the International Water Supply Association in Amsterdam in 1949 and in Paris in 1952. Little progress was made, and so the matter was taken up by the World Health Organization, which had long appreciated the need for some form of international agreement on the requirements for safe and potable water supplies. This problem has become more acute with the great increase in travel, especially air travel. "where common carriers must be watered at many points in the world, and the traveller must be furnished with acceptable drinking-water that will not produce unfavourable effects on his health."³ Groups of experts

each one representing a member state of the World Health Organization, studied these questions at a regional level between 1953 and 1956. The unanimity attained exceeded expectations, and a final study group therefore met in Geneva in the summer of 1956. It has put forward detailed recommendations applicable the world over.³ This report is intended primarily to refer to water as it is supplied to the public.

The introduction to this important publication states that "supplies of drinking-water should not only be safe and free from dangers to health, but should also be as aesthetically attractive as possible. Absence of turbidity, colour, and disagreeable or detectable tastes and odours is important in water supplies intended for domestic use." The requirements for providing water of this quality are set out in successive chapters discussing bacteriological, chemical, physical, biological, and radiological requirements. The standards of bacteriological quality recommended are not as strict as might be, but there are many areas in the world where the regular attainment of a standard of coliform organisms absent in 100-ml. volumes is not economically or technically practicable. Different standards are set down for treated and untreated supplies for present use throughout the world, with the hope that improvement in economic and technical resources will permit of stricter standards being adopted at a later date. Limits for toxic substances such as lead, arsenic, and cyanide in the water are given, and also for specific substances, such as fluoride and nitrate, which may affect health. Many other chemical substances affect the potability of water, but, owing to the wide variation in chemical composition of water in different parts of the world, rigid standards cannot be laid down. What has been done is to designate limits for such substances as iron, copper, zinc, sulphate, chloride, and so on which are "permissible"—that is, would be generally acceptable by consumer—and "excessive," values greater than which would eventually impair the potability of the water.

But this publication is not a mere list of standards. Many aspects of water quality are fully discussed and details of sampling procedure are set out in the appendices, together with approved methods of analysis. Moreover, since standards and analytical methods are not static, but must change with advances in knowledge, a list of subjects for future research is included. Finally, the frequency of sampling, particularly bacteriological, is worth mentioning. The report rightly attaches importance to this procedure and gives a sound guide for sampling before and after the water has entered the distribution system. To get water to the consumer without any deterioration in quality, a close watch has to be kept on the network of mains, pipes, and reservoirs—the "Achilles heel" of a water undertaking. Regular sampling and analysis is one way of checking the distri-

bution system, and the W.H.O. experts have proposed a practical programme of routine control to this end.

TREATMENT OF ASTHMA WITH HYDROCORTISONE POWDER

The success of steroid therapy in carefully chosen cases of chronic asthma, coupled with its undoubted and serious risks, has led investigators to try the effect of these drugs in smaller dosage when applied locally to the bronchial mucosa by means of some form of oral inhalation. W. S. Foulds¹ and his colleagues reported an uncontrolled trial of hydrocortisone snuff on 15 patients, of whom 12 improved. H. Herxheimer and M. McAllen² found that in 4 out of 10 patients with pollen asthma the symptoms disappeared after nasal insufflation of hydrocortisone snuff. R. M. Morris-Owen and S. C. Truelove³ made a similar observation. W. Brockbank and C. D. R. Pengelly,⁴ using a very small dosage, reported improvement in 17 out of 24 asthmatics with inhalations of hydrocortisone acetate powder, but when prednisolone was used there was no effect in 6 out of 7. W. H. Helm and F. Heyworth⁵ have recently conducted a short-term blind-controlled trial of inhalations of hydrocortisone acetate in 26 patients, prescribing up to 45 mg. a day. 14 out of 17 improved, but only 3 out of 9 showed benefit when an inert powder was given. They concluded that these inhalations were an effective form of short-term treatment in some cases of bronchial asthma. In a second paper⁶ they described the effect of treating 53 patients in a similar way, 81% showing improvement. But there was a strong tendency to relapse if treatment had to be maintained. Prolonged benefit was more likely to occur if the inhalations were given intermittently for recurring asthmatic attacks. They also determined that there was a wastage into the stomach of about 20% of the powder.

Herxheimer⁷ and his colleagues have described three trials of similar treatment in London, Cardiff, and Berlin, but do not state what salt of hydrocortisone was used. The dosage was one 15-mg. capsule administered daily, half in the morning and half in the evening. Although more than two-thirds of the patients benefited, the results need interpreting with caution. Some of them were a selected group and seemed likely to respond before treatment began, and did so. In contrast, the Cardiff study was of unselected cases, and there the number of failures (19) exceeded the number of successes (15). This treatment cannot therefore be expected to relieve the average chronic asthmatic, but only certain types. Herxheimer and his colleagues endeavoured to analyse the types that seemed to derive most benefit from the treatment. It is not surprising to find that those with excessive secretion failed to respond. The improvement occurred in patients with evidence of

allergic aetiology and those without hypersecretion. Cases of dry asthma responded dramatically. In Helm and Heyworth's⁶ study cases of recurrent acute asthma without significant bronchial infection responded best, while cases of wheezy bronchitis with significant infection and more than ¼ oz. (7 ml.) of sputum daily responded least. This important work is worth following up. It is an ideal piece of research for the busy general practitioner.

SEBORRHOEA

In the last two decades there has been much study of the structure and function of the skin, particularly of the epidermis and its appendages and the surface film, or "mantle of the skin." Much of this work has been done in the United States and has been summarized in the two important textbooks of S. Rothman¹ and W. Montagna.² The great importance of the skin in relation to general metabolism and the reflection of systemic disease in the skin steadily assume greater importance in medicine; it is, moreover, an organ that should be susceptible of more exact study than those hidden beneath the surface. The integrity of the skin is important as a barrier against injury from without, mechanical, chemical, climatic, or infective, and this integrity is in part dependent on humoral and endocrine influences. Emphasis is now placed on the equipotentiality of epidermal cells—the ability of any epidermal cell to produce any element of the surface epithelium or of its appendages.

Much has yet to be discovered about the process of cornification or keratinization, but much is known about the surface film. Marchionini long since stressed the variation in hydrogen-ion concentration of the surface film at different sites on the skin surface and under different conditions, and Rothman has shown that the character of skin fats in the film may vary with different diseases and may bear upon the causation of those diseases.

The surface film is dependent for its effectiveness not only on sebaceous and apocrine secretion but on the fats and waxes provided by the desquamating horn cells, and the whole is emulsified by the contribution of the sweat glands, which, for instance, carry sebum readily over the palms and soles where no sebaceous glands exist. The contribution of the sebaceous glands is enhanced by the advent of puberty when apocrine glands also begin to function, and throughout adult life endocrine influence is paramount. It is at puberty that the surface film spontaneously destroys the *Microsporum audouini* fungus on the scalp as a consequence of the increased secretion of the long-chain saturated fatty acids. But this is only one aspect of the seborrhoeic diathesis, itself a reflection of a physiological state dependent on genetic, emotional, and other factors besides the endocrine.

J. M. Beare and colleagues³ have recently studied the pH of the skin surface in infants suffering from seborrhoeic dermatitis, and believe that the difference from that of normal control subjects is sufficient to be of value in differential diagnosis in difficult cases. Their investigations have been carefully controlled statistically and show that in seborrhoeic dermatitis in infants the surface film is more alkaline than in the normal. The incidence of seborrhoeic dermatitis in infants varies considerably with geographical location and nutritional state, but it is a mild affection that clears readily with treatment, or spontaneously, unless it triggers off a constitutional eczema. The seborrhoeic state is not, in fact, natural to the human until puberty, and its occurrence in infancy—sometimes with a phase of acne vulgaris—is probably dependent on hormonal influences carried over from the mother which disappear in the course of the first few months of life.⁴ The findings are of interest because the active state of seborrhoea at puberty and the seborrhoeic diathesis in the adult are generally regarded as being associated with an abnormally acid secretion. These features are related to the bacterial and fungal activity on the skin surface, and further investigations on these lines would be welcome.

THE EDINBURGH MEETING

Next year's Annual Meeting of the British Medical Association looks like being an invigorating affair. For one thing it is to be a Joint Meeting with the Canadian Medical Association, and those who went to Toronto in 1955 know what a stimulating experience it is to forgather with our Canadian colleagues.⁵ For another thing the meeting is to be in Edinburgh, one of the few big cities in the world where history, culture, and learning still hold out against industry and commerce. The arrangements for the meeting are well in hand, and this week's *Supplement* contains the provisional programme. As can be seen, the scientific meetings cover a very extensive field, and the opportunity to hear the views of so many experts from both sides of the Atlantic is one that will seldom recur. Edinburgh being what it is, the social occasions are also likely to be memorable, and the wives and families of members will all be made welcome—in fact, special arrangements are being made for the entertainment of young people.

Both the British and Canadian Medical Associations will have Prince Philip, Duke of Edinburgh, as their President next year, and, though he will be in Canada with the Queen at the time when the Annual Meeting is taking place in Edinburgh, his acceptance of both Presidencies brings the two Associations into even closer harmony than before. The Joint Meeting will certainly attract great numbers of doctors and their families to Edinburgh next July. Therefore, since the holiday season will be well under way, members who are in a position to do so would be well advised to book their accommodation in Edinburgh now, and also to make their train reservations.

Drug Treatment of Disease

DISSEMINATED SCLEROSIS

BY

MICHAEL KREMER, M.D., B.Sc., F.R.C.P.

Physician, Department of Nervous Diseases, Middlesex Hospital;
Physician, National Hospital, Queen Square, London

It is still unfortunately true that there is no specific remedy in disseminated sclerosis, but it would be very wrong indeed for this reason to abandon these patients without treatment of any kind, for much can be done to give symptomatic relief. As important as anything else in the treatment of this condition is the attitude of the doctor. There is still some ignorance in the profession of the natural history of the disorder, and once the diagnosis is made a feeling of pessimism may overwhelm the practitioner, who feels he is faced with a hopeless patient soon to be reduced to a life of chronic incapacity and needing almost full-time care. That this is not the case is by no means sufficiently widely known.

The frequency of the disease in Great Britain is about one in 2,000 of the population; it varies in different counties. There are therefore a large number of sufferers, and it is clear at once that there are not that number of severely incapacitated patients in this country suffering from disseminated sclerosis. Many of these patients have long periods of remission often lasting many years. There are others whose disorder is mild, and, while they may have many abnormal signs in the nervous system, yet disorder of function and impairment of useful life are slight.

An explanation to the intelligent patient along these lines may be very helpful; it may prevent him from feeling that the doctors are abandoning him and stop him and his relations from wandering round seeking help which is not available.

Lines of Attack

Many treatments of the disease have been tried, but assessment of results is impossible except on a very long-term basis, as any therapy may coincide with a natural remission. The major lines of attack are as follows.

Vaccines.—The latest of these is the Shubladze-Margulis vaccine from the U.S.S.R. There is no evidence yet available that this has any effect on the disease and it is able that this has any effect on the disease and it is possible that the substance is dangerous. Bacterial vaccines, usually autogenous, have been tried, and these too have not been accepted as producing any relief.

Pyrexia.—Before the second world war there was a great vogue for pyrexial treatment. The pyrexia was induced by the use of killed organisms, such as T.A.B. vaccine, intravenously, and the patient was allowed to have up to six or even more bouts of fever. But in recent years this method of treatment has been used less and less. There is no doubt that it could initiate a remission for a time.

Vasodilators.—This is a useful method of treatment and may be of considerable help in bringing a relapse to an end rather sooner than would otherwise happen. Probably any vasodilator would be effective, but many have unpleasant side-effects. The least unpleasant is nicotinic acid given in flushing doses. This may be 50–100 mg. given three times daily before meals. The patient must be warned that in 15–30 minutes a feeling of flushing, paraesthesiae, unpleasant fullness in the head, and an odd taste will be produced. These symptoms rarely last more than 15–20 minutes. If no great flush is produced when the nicotinic acid is taken by mouth, it may be given in doses of 50–100

mg. either intravenously or intramuscularly once daily. It is useful to continue this treatment for four to six weeks and then to discontinue it for about the same period before starting again. Nicotinic-acid derivatives which do not produce vasodilatation are not so beneficial.

Histamine in rising dosage has also been given, but it causes headache and perhaps is not so easy to control. If it is used, then a starting dose such as 0.1 mg. intravenously begins the course, and it can be increased by 0.1 mg. daily or even twice daily.

Steroids.—Like vasodilators, steroids may be very helpful in initiating a remission, but if no obvious effect is being produced within two or three weeks then they should be tailed off fairly quickly; but, if benefit is obtained, the steroids may be continued for two or three months. The usual careful watch for toxic results must be maintained. A good starting dose is 10 mg. of prednisone three times a day, and it may usefully be combined with nicotinic acid. A.C.T.H. in doses of 50 units daily by injection has also been prescribed for three or four weeks and then gradually reduced to a maintenance dose of 10 units daily for several months. The good effects are unfortunately transient.

Arsenic.—The vogue of arsenic therapy seems to have diminished recently, though there are many neurologists who still use it quite extensively. The usual mode of administration is to combine both organic and inorganic arsenic. In each course neoarsphenamine is given intravenously once a week in doses of 0.15 g., 0.3 g., 0.45 g., and 0.45 g. This four-weeks course can be repeated every three to four months. If the veins are difficult to enter, then intramuscular sulpharsphenamine in corresponding doses is given. Between injections liq. arsenicalis, 3–5 minims (0.2–0.3 ml.), is given for three weeks each month. Careful watch must be kept for intolerance to arsenic.

Intrathecal Treatment.—It has been suggested at Oxford that P.P.D. (purified protein derivative of tuberculin) given intrathecally produces a specific response in the cerebrospinal fluid of Mantoux-positive patients and that there may also be a helpful therapeutic effect. It is too early to assess the merits of this procedure, which can be carried out only in hospital.

Whichever of these means of treatment is used, if the patient's mobility is affected, whether owing to disturbance of power, tone, co-ordination, or sensation, then re-education with the help of trained physiotherapists is an essential part of treatment. It is probable that at present this may well be the most important part of treatment, and it is clear that this calls for special training of physiotherapists and for their being part of a team engaged specially in helping such disorders of mobility and equilibrium. Unless the therapists know what they are trying to achieve and have adequate leadership, they may well share the hopelessness that is so frequently seen in those faced with these patients. It is remarkable how much an enthusiastic doctor or department can achieve in restoring really useful function, quite apart from the help that can be given by introducing mechanical aids in the kitchen, bathroom, and elsewhere in the house.

Symptomatic Treatment

In addition to treating the patient as a whole, some symptomatic treatment can give help.

Hypertonus and Spasms.—Occasionally hypertonicity is so great, especially in the hip adductors and plantar flexors,

that even with reasonable power walking is difficult. Some patients gain relief from meprobamate or mephenesin. The former can be started in 200-mg. doses three times a day after meals and the latter as mephenesin carbamate in 0.5-g. doses three times a day. Each can be pushed up to double or even treble these doses, provided the patient does not become too drowsy and there is no gastric irritation.

Extensor and flexor spasms may be very troublesome—disturbing rest and posture, and often being associated with a good deal of pain. Both meprobamate and mephenesin may help to diminish these contractions, but often so large a dose is necessary that the patient may be asleep the greater part of the day. In such a case it is probably better to give smaller doses such as 400 mg. of meprobamate three or four times a day and add small quantities of barbiturate such as phenobarbitone $\frac{1}{2}$ gr. (32 mg.) or amylo-barbitone $\frac{1}{2}$ gr. (32 mg.) to each dose.

Unfortunately there are many advanced cases in which no drug treatment has any effect on the spasms, and life is rendered almost intolerable by the continuous violent and painful contractions. In such patients the only reasonable treatment is selective surgical section of peripheral nerves or fractional knock-out of spinal anterior nerve roots by means of phenol. Both these techniques require expert performance by someone familiar with the hazards of the procedures, but offer the possibility of turning an impossible existence into a more comfortable though paraplegic life.

Vertigo.—This symptom, with associated disequilibrium and vomiting, is usually due to a brain-stem plaque damaging the central connexion from the vestibular labyrinths. The treatment is the same as that of any acute vertigo. While vomiting is going on the intramuscular injection of 50 mg. of promethazine, chlorpromazine, or promazine will often ease the acute disturbance. If the attack is very severe the injection may have to be repeated some six hours later. The drowsiness which results is welcomed by the patient. Once the acute vomiting has ceased, then the same substances can be given by mouth in 25-mg. doses two or three times a day, or prochlorperazine ("stemetil") in doses of 5–10 mg. twice a day can be substituted. This drug produces less drowsiness.

Sphincter Disturbances.—The function of the bladder is commonly disturbed and the patient suffers from frequency, urgency, and precipitancy of micturition. Later incontinence may occur, but this is often due to a combination of precipitancy with diminished mobility. Retention is unusual except in the acute paraplegias due to a transverse plaque.

It is difficult to control the rapidly emptying spastic bladder except by sedation, but occasionally the use of a pill containing ergot 1 gr. (65 mg.) and ext. belladonnae sicc. $\frac{1}{4}$ gr. (16 mg.) may be helpful. Frequently, however, and especially in women, the urinary disturbance is accentuated by infection. If there is any real risk of this it may be helpful to keep the patient on small doses of sulphonamide such as sulphathiazole 0.5 g. twice a day, or sulphamethizole ("urolocosil") 0.2 g. twice a day for some months. If an obvious acute infection supervenes, then treatment with the specific substance to which the organism is sensitive is clearly indicated. Several courses may have to be given before the urine becomes sterile. Occasionally the long-continued use of sulphonamides may be interrupted with a course of hexamine mandelate, 0.5 g. three times a day for two or three weeks.

Retention of urine is treated by administering the stable esters of acetylcholine, of which there are many preparations available, in doses of 0.25 mg. intramuscularly or 1 mg. by mouth, repeated if need be. When this fails catheterization will be necessary.

The bowel difficulty is usually constipation, and diarrhoea and rectal urgency are most often the result of incautious aperients. It is safer to give only mild laxatives and supplement these by glycerin suppositories or "dulcolax" (2-(4:4'-diacetoxydiphenylmethyl) pyridine) suppositories.

Enemas may be necessary, but it is essential to avoid irritating the bowel either from above or from below.

Pain.—This is a fairly frequent symptom in this disease. The pain may be associated with muscle spasms as already described, but other forms are as follows:

- (a) Lightning pains.
- (b) Root pain indistinguishable from a brachial neuralgia or sciatica or a trigeminal neuralgia.
- (c) Headache due to plaques causing narrowing of the aqueduct of Sylvius and oedema, or interfering with the root entry zones of sensory nerves.
- (d) Central pains due to involvement of the spinothalamic tract or the thalamus. Here the pain is of an intense burning and gnawing character, often with a profound affective reaction.
- (e) Painful paraesthesiae.

The treatment of all forms of pain in this condition is to use the analgesics such as compounds of aspirin, phenacetin, and codeine in full doses unless gastric irritation and constipation are troublesome. Their efficiency is often greatly enhanced by adding small quantities of sedative such as amylobarbitone in doses of $\frac{1}{2}$ –1 gr. (32–65 mg.), and during the earlier part of the day by adding also an analeptic such as dexamphetamine 5 mg. This is particularly helpful for central pain and painful paraesthesiae.

Pressure Sores.—Once the patient is confined to a chair or bed the risk of pressure sores is great. This is particularly so if there is sensory impairment and urinary overflow.

They can be avoided only by scrupulous attention to the nursing care of the skin at the points of pressure, by changes of posture, and by the use of smooth bed linen or special seats. There is no drug which will help more than the efficient use of soap, spirit, and occasionally a silicone skin cream. The healing of pressure sores is so slow and the risk of spread in the paraplegic so great that treatment must be preventive. Once pressure sores are present, the only really effective treatment is prevention of weight bearing by the sore area. Necrotic tissue must be removed, and antiseptic creams may help to some extent.

Morale

It must be clear now that a great deal can be done for these patients to provide some symptomatic relief, but it is equally clear that the essential part of treatment is the maintenance of morale in the patient and the relatives at as high a level as is possible. Patients can be helped by using all the benefits provided by the Health Service, in particular the provision of wheel-chairs, perhaps even motorized chairs, commodes, gadgets, and other appliances, but the most essential contribution to keeping up morale is the attitude of the medical staff of every kind who come into contact with the patient.

Reporting on legal proceedings taken in 1957, the City Analyst for Birmingham writes in his Annual Report: "Only twice was it necessary to use the 'big stick' of prosecution, and on both occasions farmers were the culprits; the use of this weapon against food and drug retailers has to all intents and purposes been abandoned. A very different picture is presented in the first annual report made by me as city analyst in 1929; in that year 12 farmers were prosecuted in respect of 49 samples, and fines were imposed in 45 cases. Two of these farmers were each fined £100 for adulteration on the grand scale, which it was calculated resulted in both cases in the sale of 100 gallons of water per week as milk. In addition, summonses were issued in respect of four other foods and drugs. The total fines paid by offenders amounted to £328: this figure is practically ten times as great as the corresponding one for 1957, and this reduction of 90% is an indication both of a greater sense of responsibility on the part of manufacturers and of a changed attitude on the part of local authorities."

FIRST B.M.A. ANNUAL CLINICAL MEETING SOUTHAMPTON, DECEMBER 4-7

When Professor A. P. THOMSON, President of the British Medical Association, formally declared open the Association's First Annual Clinical Meeting, in the Guildhall at Southampton at 10.30 a.m. on Friday, December 5, the meeting was in fact already well under way. Some two hundred doctors, many from far beyond the Southampton region, had attended with their wives and guests a civic reception the previous evening; and two panel discussions—on "Hand Injuries" and on "The Treatment and Prevention of Deafness"—had already taken place.

A Change of Emphasis

The President, after expressing the meeting's gratitude to the Mayor and Corporation of Southampton for putting their fine Guildhall at the Association's disposal, referred to a remark made by the chairman of the Southampton Division the night before. Dr. R. S. Russell-Smith had said that they in Southampton had spent a great deal of time in preparing for this first Annual Clinical Meeting of the B.M.A. with but one hope in mind: that the meeting might prove a serious contribution to a change of emphasis in the Association's work. It had been feared in Southampton, said the President, that in the meetings organized by the B.M.A. the cultivation of professional excellence had been neglected in the press of political events. With Southampton's hope that the emphasis on professional work would be restored Professor Thomson said he wished to identify himself completely. He hoped that this first Clinical Meeting would be the first of many.

At the reception the previous evening in the Guildhall, given by the Mayor and Corporation, the Mayor, Alderman R. R. H. HAMMOND, in his welcome to the delegates said that Southampton was proud to have been chosen for the first B.M.A. Annual Clinical Meeting. Dr. R. S. RUSSELL-SMITH likened the occasion to the birth of a baby—always an exciting event. The B.M.A. was not just a medico-political organization, he said. The meeting showed that the Association had a real interest in clinical medicine. He thanked particularly Dr. J. G. McDowell and Dr. R. P. W. Shackleton, respectively honorary general secretary and honorary science secretary, for their untiring work in preparing for the meeting.

PANEL DISCUSSIONS

Friday, December 5, 9.30 a.m.

Hand Injuries

Between 50 and 70 people attended each of the two simultaneous panel discussions held at 9.30 a.m. on Friday morning. In the one on "Hand Injuries," with Mr. J. N. BARRON (Salisbury) in the chair, Mr. L. W. PLEWES, of Luton, and Mr. R. G. PULVERTAFT, of Derby, answered questions on many aspects of this subject—which, as the chairman stressed, is of such great importance to the general practitioner. The panel first considered the organization of a hospital department for dealing with hand infections. Mr. PLEWES said only one thing counted: "to have a person who is interested in hand infection and to let him have his head—one permanent member of the staff, not a bird of passage."

Treatment of Infections

The whole treatment of hand infections had changed with the advent of antibiotics, said Mr. PULVERTAFT. "We don't see the pulp infection that we did; it is more often the minor hand infections we see now; the major ones are scotched very rapidly." Dr. N. B. EASTWOOD (Oulton Broad, Suffolk) said treatment was made more difficult by patients going on working until it was too late. Mr. PLEWES, however, took up Mr. Pulvertaft's remark about

antibiotics. He believed that we used them too much. There were only two indications for antibiotics in hand infections, he said—cellulitis or a spreading lymphangitis. Penicillin should not be given for pulp infections, paronychia, and so on. Challenged by Dr. W. R. S. CAMPBELL (Oxford) for his reasons for saying this, Mr. PLEWES said, first, there was the presence of increasing numbers of insensitive staphylococci; in some hospitals the incidence was now in the region of 80%. There was no logic in giving these patients penicillin—"after all, it is the only safe antibiotic we have got, isn't it?" Secondly, one should rely on the most effective treatment, which in his view was not antibiotics. 98% of infections in the hand were due to *Staph. aureus*, which caused its damage by its exotoxins producing tissue necrosis. "Operate on these patients and remove the necrotic tissue; that is the only thing that is important." The incision should be made directly over the pus, not by the standard incisions, under either general or local anaesthesia. The main thing was to have a tourniquet and an assistant. Dr. J. A. SADLER (Cambridge) objected that in general practice patients expected penicillin as a routine. The treatment was by immobilization of the hand and antibiotics. "We don't find so many resistant staphylococci as you talk about in hospital." The patients did very well indeed. Mr. PLEWES endorsed the importance of immobilization and mentioned that in his view any form of heat was harmful. Dressings for hand injuries could be minimal if the slough had been removed at operation: not a lot of gauze and wool which crippled the patient, but just a small strip dressing to keep the skin edges together. "We do a lot of damage to our patients by wrapping them up in cotton-wool. We ought to aim at getting our pulp infections back to work within one and a half days, acute paronychia back to work in 24 hours, acute suppurative tenosynovitis within three days." There was no place for operative treatment in acute suppurative tenosynovitis, where there was a lovely closed space capable of holding a hundred times enough penicillin to kill any organism. All that was needed was to put a needle into the space, aspirate the few drops of pus which were there, inject 500 units of penicillin, the patient was cured.

Cut Tendons and Mallet Finger

The problem of severed tendons was discussed by Mr. PULVERTAFT. Dealing first with the extensor tendons, he described the treatment of lesions at various levels. Lesions over the proximal phalanx would recover if the finger was splinted in full extension. At the back of the hand primary suture was necessary. Division of the flexor profundus beyond the level of the sublimis attachment at wrist and palm level might be treated by primary suture; but if the tendons were divided between the distal palm-creases and the insertion of sublimis, where there was a rigid fibrous sheath, primary suture was unwise. The correct treatment then was suture of the skin only, so that later the tendons could be replaced by a free tendon graft taken from some other part of the body. Mr. J. S. ELLIS (Southampton) asked if there was any place for secondary suture in the no-man's-land of fibrous tissue. As a general policy, Mr. PULVERTAFT thought there was not. Replying to Dr. M. B. CARSON (Southampton), he said that a finger would work almost as well with a profundus tendon alone as with both profundus and sublimis tendons.

Mr. PLEWES expressed definite views on mallet fingers. Instead of the disabling plasters with the finger held in the flexed position, he used a tiny splint of "perspex" over the distal two-thirds of the finger, leaving the proximal joint free. The patient could return to work wearing the splint, which he kept on for six weeks, thereafter wearing it only

at night. There was no place for surgery in this condition. Mr. PULVERTAFT used a "pin" beneath the skin, but confessed to less than 90% cure. Sometimes he performed open surgery on these cases. Mr. J. B. SHIELD (Fordingbridge, Hants) found that patients often came for advice three or four weeks after injury, and he felt that it was asking too much to expect a response to splinting alone in such cases, but Mr. PLEWES claimed 45% cures in patients seen after six weeks.

Fractures and Crush Injuries

Mr. PULVERTAFT felt that there should be a complete reorientation of our ideas on hand fractures. Many of these would do better by mobilization and pinning at an open operation. He admitted that this required most careful and time-consuming surgery, but, if this was the best way of treating them, it should be done. Mr. PLEWES agreed that some fractures must be operated upon. He did not agree with the statement in two recent textbooks that there was no reason for splinting fractures of the hand. One fracture—the impacted neck of the fifth metacarpal—could be left without splinting. "If we don't do something to our patients to relieve the pain they are not going to use the hand." In answer to Mr. ELLIS, who put in a plea for the functional treatment of fractures of the metacarpals, Mr. PLEWES thought that these were often over-treated. He thought 14 days was usually long enough in plaster.

Mr. BARRON remarked that all injuries except burns were caused by cuts or crushes. In severe crush injuries, Mr. PLEWES said, only one thing mattered, and that was the prevention of further injury by oedema to the structures that had already been damaged. He recommended delayed treatment with refrigeration and elevation. Mr. PULVERTAFT agreed that the prevention of oedema was most important, but believed that elevation was the best method of treatment. In reply to a question from the floor, he said that the correct first aid for a dirty crush-injury was to do nothing to the hand: "Put a dressing on, but don't clean it, don't put on antiseptics; let the hospital deal with the cleaning under anaesthesia." The best cleaning of a wound was by washing, washing, and washing.

Treatment and Prevention of Deafness

The importance of careful clinical observation in the diagnosis of deafness, both in the very young and in the elderly, was emphasized by the panel, consisting of Miss EDITH WHETNALL (London) and Mr. F. MCGUCKIN (Newcastle upon Tyne), which discussed "The Treatment and Prevention of Deafness," under the chairmanship of Mr. N. W. MACKEITH (Southampton). Replying to a question from Dr. R. S. RUSSELL-SMITH (Southampton), Miss WHETNALL stressed the importance of diagnosing deafness in children very early. Usually by three months a child could suppress undesirable noises and would react appropriately to meaningful sounds, and by six months he should begin to imitate his mother's voice. Deafness might be detected by observing the failure of a child to react like this, although other causes such as prematurity, mental deficiency, or simple neglect must be considered. To test the diagnosis sound must be brought to the baby by means of a hearing-aid—even very small babies could wear an aid. A deaf baby must wear its aid continuously so that he could learn to appreciate sounds in the same way as would a normal baby. The longer he was deprived of sounds, the more difficult would it be for him to learn to hear and later to talk. Thus early diagnosis was the keystone of successful treatment. The management of these children must of course be carried out through the mother, and it was important to explain to her that dramatic and immediate results could not be expected. Mr. MCGUCKIN made the point that surgical treatment was available only for middle-ear types of deafness, which were uncommon in the very young.

Dr. D. M. T. GAIRDNER (Cambridge) asked the panel what the lesion was in deafness following purulent meningitis and what was known of the pathology of congenital deafness.

Mr. MCGUCKIN pointed out that the perilymph was continuous with the subarachnoid fluid, and that, unless it became sealed off early in the disease, infection from the meninges might spread to the inner ear, causing deafness and vestibular symptoms. If only one inner ear was damaged the deafness was unlikely to be detected in early childhood. Miss WHETNALL divided cases of congenital deafness into those arising from hereditary factors, those associated with maternal illness in pregnancy, and those resulting from disorders during or immediately after birth. There might be any degree of involvement, from the complete absence of the cochlea to the loss of only a few of the organs of Corti. In those cases due to maternal rubella it was only the organs of Corti that were affected. These children were often extremely intolerant of noise, and this fact might render the wearing of an unsuitable aid most uncomfortable.

Dr. MARY CAPES (Southampton) asked the panel whether they thought that cases of partial deafness in children were being missed, thus giving rise to educational difficulties when the child arrived at school, where the true reason might not be appreciated. How far was screening advisable? Mr. MCGUCKIN replied that an audiogram was no more valuable than an x-ray; it was merely part of the clinical investigation. The patient's performance on testing would depend on many factors, including the speed of onset of the deafness. "Machines can go wrong," he said, and the shrewd clinician should be able to predict the audiogram result. Miss WHETNALL agreed, and thought that we were becoming too reliant on machines. Careful clinical assessment was every bit as scientific as audiology. The CHAIRMAN summed up by saying that it seemed that the audiogram was a good servant but a bad master.

Deafness in the Elderly

Dr. JOHN L. STRUTHERS (Southampton) asked the panel what the indications were for referring older patients with increasing deafness to a specialist. Mr. MCGUCKIN said that they came to a doctor because they or their relatives felt they were losing contact with others. The common cause of deafness over the age of 55 or 60 was cochlear degeneration. These patients had difficulty in hearing consonants. As well as the straightforward difficulty in hearing sounds, the normal damping effect on undesirable noise was lost and the patient tended to get words jumbled up, particularly if speech was fast. The provision of a hearing-aid of limited output, combined with instructions to the household to speak slowly and distinctly, was all that was required. The CHAIRMAN, while agreeing, thought that without a trial it was very difficult to tell how much a hearing-aid would help. The old-fashioned speaking-tube was often very useful, he added.

In reply to a question from Dr. W. H. N. ANGUS (Southampton) on modern surgical techniques for the relief of deafness, Mr. MCGUCKIN said that only middle-ear deafness was amenable. There were two main problems—otosclerosis and the late effects of otitis media. In the former condition the underlying lesion was the ossification of the elastic membrane around the oval window. In a few cases it was possible to fracture this new bony tissue during the inactive stage, thus mobilizing the stapes with excellent results. In the fenestration operation the oval window and the ossicles were abandoned and a new hole was made into the external semicircular canal. This would give the patient an adequate degree of hearing. In chronic otitis media the contents of the middle ear except for the stapes had been lost. Various operations had been devised to re-form the middle-ear chamber by skin-grafting, the essential requirement being the presence of some healthy mucous membrane in the region of the round window. The results of these operations could be very satisfactory, with a hearing loss of only ten to fifteen decibels. In answer to a question about their percentage success, Mr. MCGUCKIN stated that he preferred to regard them as salvage operations. In his opinion about half the patients could be so salvaged.

Dr. RUSSELL-SMITH (Southampton) asked the panel for their opinion on the dangers of treating acute otitis media with penicillin or sulphonamides. The CHAIRMAN felt that this was a matter of fine clinical judgment. If there was an appreciable amount of pus in the middle ear, then the drum should be incised, but early cases could be safely treated by medical means alone. Both the other members of the panel agreed.

FIRST GENERAL SESSION

Friday, December 5, 10.45 a.m.

Operative Treatment of Duodenal Ulcer

Dr. H. C. MAURICE WILLIAMS (Southampton) was chairman for the first general session, which he introduced. Professor JOHN BRUCE (Edinburgh), P.R.C.S.Ed., spoke on the choice of operation for duodenal ulcer. He emphasized that the surgeon could now approach his patient with a view to providing the most suitable type of operation, and this should be assessed beforehand by a maximal histamine test meal (Kay's), in order that the hazards of further ulceration could be avoided. Professor Bruce described the two forms of operation in vogue as being those attacking the gastric secretion by interruption of the nervous pathway accompanied by some form of "drainage operation," and those that reduced the degree of acidity by removal of secreting gastric tissue. He demonstrated that the reduction might be measured by Kay's test and also from an academic point of view by counting the acid-secreting cells. He showed that there was a correlation between their number and the concentration of acid as measured.

He divided the cases into three groups as determined by their capacity to produce various concentrations of acid. One-third would show less than 30 mEq, and these should therefore respond to gastro-enterostomy with vagotomy. The second group was those with medium secretion of acid, and these should be treated by partial gastrectomy of standard type. There remained some 17% who were high acid-secretors, above 50 mEq, and these would need a radical gastrectomy with vagotomy.

The results of these operations could be predicted, especially if the maximal histamine test meal was repeated. Only those showing a high acidity at the post-operative test would be liable to further ulceration, either of the suture line or of the jejunum. He concluded by answering many questions.

Prevention of Reactions to Antibiotics

Professor L. P. GARROD (London) discussed reactions to antibiotics, dividing these into three types—those causing sensitivity reactions or direct toxicity to various organs and those associated with superinfection. He pointed out that direct toxicity usually was related only to a few specialized tissues such as the kidneys, marrow, and the eighth nerve.

Chloramphenicol was a drug which should be reserved for serious indications—namely, whooping-cough in infancy, typhoid fever, and certain virus infections. Penicillin was apt to cause sensitivity reactions, and these might be severe and of the anaphylactic type, or more akin to serum sickness. He pointed out the doubtful value of skin tests, especially as a precaution against the more serious forms of reaction. The occurrence and significance of antibodies to penicillin in the blood needed further study.

The tetracycline group, or combinations of antibiotics with a similar "broad" effect, were apt to result in superinfection of the mouth, gastro-intestinal tract, or bronchi with yeasts or the overgrowth of resistant coliform, *Proteus*, and *Pseudomonas* species. He also stressed the more serious invasion by antibiotic-resistant staphylococci, especially after gastro-intestinal surgery. He thought the use of tetracycline preparations unwise after partial gastrectomy in cases where the gastro-intestinal flora might previously have been disturbed by long-acting sulphonamides, with suppression of the normal flora.

Sudden Death in Infancy

Dr. D. M. T. GAIRDNER (Cambridge) concluded the session with a discussion on sudden death in infancy, his figures being based on the first 81 cases from an inquiry by a combined team in Cambridge and London. If their figures were applied to England and Wales some 1,600 such deaths might be occurring annually. Sudden and unexpected death accounted for one-quarter of all deaths in the age group 2 weeks to 2 years. Most babies died in the colder months, and this ratio was similar in Australia. There was also a differential between the sexes, and infections, however trivial, appeared to be involved. Dr. Gairdner showed histological sections demonstrating that infections of the respiratory tract were especially important. Although full post-mortem examinations had been made on all their cases, there was a large number where no satisfactory medical cause for death was found. Post-mortem evidence did, however, show that many of these cases were not due to asphyxia.

SECOND GENERAL SESSION

Friday, December 5, 2.15 p.m.

The chairman at the afternoon general session was Dr. S. WAND (Birmingham), and the three invited speakers were Dr. A. RAE GILCHRIST, P.R.C.P.Ed., Professor A. M. CLAYE, P.R.C.O.G., and Dr. NEVILLE OSWALD.

Diagnosis of Acute Myocardial Infarction

Dr. A. RAE GILCHRIST (Edinburgh) said that the typical classical picture of acute myocardial infarction was often over-emphasized. Clinically the condition might present in various ways. There were (a) the painful syndromes which were associated with shock and collapse; (b) the cases in which the sudden onset of dyspnoea predominated; (c) those in which weakness, collapse, or even coma was the presenting symptom, or in which a sudden unexplained cerebrovascular incident occurred, or where the patient failed to improve as expected after surgery or an acute haematemesis; (d) sudden embolic phenomena which should suggest the possibility of an infarction; (e) changes of rhythm, notably auricular fibrillation and heart block in the middle-aged and elderly; and, lastly, (f) restlessness in an elderly patient without obvious cause.

In making the clinical diagnosis, more weight should be put on the abruptness of the onset rather than the duration or the severity of the illness. The diagnosis was established by the rapid development of signs of tissue destruction—leucocytosis, fever, elevated serum transaminase—and subsequently by an increased sedimentation rate. An E.C.G. was 95% accurate, given good interpretation, and was also valuable in assessing healing.

Comparing the accuracy of clinical as against post-mortem diagnosis, Dr. Gilchrist said that in a hospital series the diagnosis was almost as often wrong (37%) as right (43%), while in 20% the diagnosis was overlooked and only revealed post mortem. The errors of diagnosis included gross coronary atheroma with occasional local occlusions without infarction, pulmonary embolism, pneumonia, and post-operative collapse. The last occurring within three or four days of operation should always suggest acute myocardial infarction. Correct diagnosis was important, as it might make it possible to prevent embolic phenomena, the increase of shock, or congestive failure.

After his address Dr. Gilchrist answered questions. In reply to one on the value of the serum transaminase estimation, he said it could be of considerable use in the first three or four days. It reached a maximum within 48 hours, immediately preceding the rise in E.S.R. Though not as good as skilled reading of an E.C.G., it could be helpful. Asked about the indications for anticoagulant therapy, he said it was indicated in virtually all cases except those with advanced liver disease, renal insufficiency, a recent history of peptic ulcer, or severe anaemia. Were anticoagulants going out of fashion? They should be out

of fashion, said Dr. Gilchrist, if there was no reliable laboratory control. Anticoagulant therapy protected patients against embolic phenomena, particularly pulmonary emboli; any patient who had a pulmonary embolism within two or three weeks of coronary infarction was in very grave danger.

Asked if the E.C.G. was sometimes negative soon after infarction and positive a few days later, Dr. Gilchrist said the time when it became positive varied. In most people it became positive in 12-24 hours, in others it might take 10-72 days. In doubtful cases a series of E.C.G.s should be taken at two- to three-day intervals. Replying to a question about the value of corn-oil emulsion, he pointed out that it was a vegetable oil which in fact did reduce the blood cholesterol. The blood cholesterol was high in the younger age groups, but no one had shown that its reduction reduced the degree of atheroma.

Prevention of Severe Pregnancy Toxaemia

In the last 25 years, said Professor A. M. CLAYE (Leeds), the causes of maternal mortality had altered greatly in their order of frequency. "Eclampsia and other toxaemias" had now replaced puerperal sepsis as the commonest cause. He quoted mortality figures for 1955 in which 112 deaths had been due to toxaemia, 68 to abortion, and 41 to post-partum haemorrhage. In about half the deaths from toxaemia the antenatal supervision had been inadequate, the responsibility for this being divided between patients and their attendants. Patients who frequently defaulted from antenatal clinics had an increased incidence of toxaemia.

Dixon Hughes, of Sydney, had said that, if the mother did not gain more than 8 lb. (3.6 kg.) between the 20th and 30th weeks, she was unlikely to get toxaemia; if more than 8 lb. then it was much more possible. Toxaemia was commonest in first pregnancies. In those who had previously had toxaemia the chances were fifty-fifty, but once a woman had had toxaemia she should attend hospital for her subsequent pregnancies. The patients who were prone to develop toxaemia were those with twins, diabetics, and those in whom the blood pressure was more than 140/90 at least twice before the 20th week. Where there was no previous essential hypertension, 1.8% developed toxaemia, but in those with a previous history 35.5% developed it. In about half the women with essential hypertension the blood pressure fell to normal in the second trimester, and therefore the condition might be missed if they first attended during that time. Professor Claye described how to get a clean specimen of urine uncontaminated by vaginal discharge, and reminded his hearers that albuminuria might be due to urinary infection or chronic nephritis. When albumin was found in pre-eclamptic toxaemia it was a late sign, while headache, vomiting, and epigastric pain were very late signs.

The patient with toxaemia might lose her baby, develop eclampsia, or have an accidental haemorrhage. Describing the routine hospital treatment of toxaemia, Professor Claye said that the use of diuretics and hypotensive drugs was not yet established. Once albuminuria had appeared it rarely cleared up until after parturition, and even then it might continue for up to two years. The response of the blood pressure varied considerably. Regarding termination of pregnancy, there was little hesitation after 36 weeks; between 32 and 36 weeks he tried to tide the patient over unless her condition was deteriorating. If severe toxaemia developed before the 32nd week, the baby had little chance of survival either way. Caesarean section might have to be performed in a fulminating case.

Professor Claye then answered some questions.

Management of the Pulmonary Complications of Influenza

Dr. NEVILLE OSWALD (London) described the pulmonary complications seen during the Asian influenza epidemic in October, 1957. He said that reports showed that 5% of the cases developed pneumonia or other complications. He deprecated the routine use of antibiotics for influenza; most of the pneumonias had been straightforward. The influenzal

virus was apt to pave the way for bacterial infection of the respiratory tract which might lead to tracheobronchitis, oedema, pneumonia, or toxæmia. The tracheobronchitis might lead to severe obstruction with stridor and indrawing of the soft tissues of the neck during inspiration. If antibiotics failed to overcome the obstruction rapidly, intrabronchial intubation might be life-saving. Tracheotomy with suction was the method of choice, but bronchoscopy was permissible in extreme cases. In the lungs, oedema might be widespread before pneumonia developed; it could be relieved to some extent by aspiration through a tracheotomy tube.

The bacteriology of pneumonia complicating influenza did not differ materially from that of ordinary pneumonia, except that perhaps staphylococcal superinfection might be rather commoner. The great majority of pneumonias responded to adequate doses of penicillin or one of the tetracycline group. About half the staphylococcal cases responded equally well to these drugs, but the remainder were caused by resistant strains. Hence sensitivity tests, which took 24 hours to perform, were most important in staphylococcal pneumonia. If the results of the tests could not be awaited, intravenous erythromycin was most likely to be effective, given in doses of up to 1 g. four-hourly for the first day or so. The severe toxæmia might lead to peripheral circulatory failure, which might be fatal in a few hours. Intravenous hydrocortisone, 100 mg. six-hourly, in a drip, together with antibiotics, might prevent the fatal collapse. Lung abscess was seen as a late complication, and it responded well to antibiotics.

Asked if staphylococcal and convalescent sera were of any use in these overwhelming cases, Dr. Oswald replied that, though they were used, it was difficult to assess their value, as so many drugs were employed with them. "If you have it, use it," he said. If oxygen was needed, a tent was best for a young child and a mask or spectacles for adults. He advised a rate of 5-6 litres a minute.

TELEVISION AND FILMS

For many, one of the major attractions of the meeting, because unrealizable with the resources at the disposal of most local medical societies, were the two "live" colour television programmes of operations from the Southampton General Hospital and the "Transatlantic Clinical Conference." These admirable contributions were sponsored by Smith Kline & French Laboratories, who for the colour television were using their own experimental mobile van and equipment.

Voices Across the Atlantic

The British and the American Medical Associations joined together for an hour's clinico-pathological conference on Friday afternoon, at which two cardio-pulmonary cases were discussed blind by picked teams on either side of the Atlantic. The link was by transatlantic cable, and the voices of the speakers were transmitted by loudspeakers to each audience. This medical brains trust—which certainly enthralled the large audience in Southampton Guildhall—went as follows: Each side had beforehand been given a written case history summarizing the clinical findings, investigations, and course of the case to be diagnosed, together with slides of relevant x-ray films, E.C.G.s, etc. The highlights of the case were then recapitulated over the transatlantic telephone by the physician presenting it, after which he answered questions from the opposing panel, whose task it was to make a diagnosis. Finally, he gave the answer, as found at necropsy, over the telephone cable for all to hear.

The British team in the Guildhall at Southampton were Dr. W. D. BRINTON (Winchester), the moderator and organizer of the programme, Professor JOHN McMICAL (London), Dr. J. G. SCADDING (London), and Mr. T. HOLMES SELLORS (London). Opposing, at the A.M.A. Clinical Meeting in Minneapolis, were Dr. JAMES R. FOX (Minneapolis), as moderator, with Dr. JOHN BRIGGS (Saint Paul) and Colonel JAMES A. WEIR (FitzSimmons Army Hospital). For the

benefit of the two audiences watching the programme enormous photographs of the members of the opposing team were mounted on the stage, and when one of them spoke a red light went on over his picture.

The British team bowled first, and the ball they sent the Americans most certainly was a "fizzer." Professor McMICAL described the case of a man in his fifties with a progressive and eventually fatal pulmonary hypertension who had first presented some three years earlier with a mild febrile illness, loss of energy, a normochromic anaemia, and an E.S.R. of 85 mm. After a remittent but progressive course during which there developed a transient attack of blindness, dizziness, and an idiopathic hyperglobulinaemia, the patient died in right heart failure. The answer, which not surprisingly floored both the teams, was a myxoma of the left atrium obstructing the blood flow. The American case, ably presented by Dr. Fox, though involving a triple diagnosis, was by comparison straightforward. The correct diagnosis of silicosis, pulmonary tuberculosis, and as the final event a bronchial carcinoma with widespread pulmonary metastases was successfully made for the British team by Dr. SCADDING.

There was no doubt that the British audience found this first transatlantic clinico-pathological conference between B.M.A. and A.M.A. teams very good fun and highly instructive. The American team's voices reached the Guildhall perfectly clearly.

Colour Television

Those who have attended recent B.M.A. Annual Meetings will be familiar with the pattern of the Smith Kline & French Laboratories' colour television demonstrations of surgical operations. The cameras divide their attention between the operation itself, which is telecast as it proceeds, and a panel of experts in a temporary studio at the hospital who demonstrate charts, x-ray pictures, etc., and answer questions relayed from the audience in the meeting hall. On both Friday and Saturday, operations from the Southampton General Hospital were televised during the lunch hour to the audience in the Guildhall. The moderator on both days was Mr. H. H. LANGSTON (Winchester).

On Friday two operations were shown. The first was the repair of an atrial septal defect under hypothermia, in which the surgeon was Mr. E. F. CHIN and the anaesthetist Dr. E. S. MACHELL. The studio panel who answered questions on the case were Dr. R. V. GIBSON (London), Dr. D. J. PEARCE (Southampton), and Mr. I. K. R. McMILLAN (Southampton). The second was an operation for lymphoedema, where the surgeon was Mr. J. E. LAING and the anaesthetist Dr. P. J. HORSEY. Mr. J. N. BARRON (Salisbury) answered questions in the studio. On Saturday the first operation was a partial thyroidectomy for a "cold" nodule by Mr. G. ST. J. HALLETT (anaesthetist, Dr. H. C. J. BALL), and in the studio were Mr. T. ROWNTREE and Dr. H. K. MELLER (both of Southampton). Next was shown an arthrodesis of the knee for advanced osteoarthritis by Mr. D. E. MACRAE (anaesthetist, Dr. C. B. PICKEN), with Mr. J. S. ELLIS and Dr. J. PRESTON, of Southampton, answering questions. Finally Mr. L. A. RICHARDSON performed a stripping operation for varicose veins (anaesthetist, Dr. W. L. M. BIGBY), with Mr. ROWNTREE in the studio.

Medical Films

Dr. R. P. LISTON, chairman of the B.M.A. Film Committee, compered the showing of three films from the B.M.A. Film Library, for an hour on Friday evening. All were in colour and sound. The first on "The Jugular Venous Pulse," made by the Wellcome Film Unit, had as its commentator Dr. PAUL WOOD. It illustrated modern instrumental techniques for analysing the jugular pulse. In the second film, "The Management of Twins in Pregnancy and Labour," produced by the Wellcome Foundation Ltd., the medical authority was Professor W. C. W. NIXON. The last film was on "The Treatment of Cardiac Arrest." It had been made by the Department of Medical Illustration, Guy's Hospital Medical School, under Sir RUSSELL BROCK'S

direction. The film showed emergency exposure of the heart and cardiac massage in a case of cardiac arrest, and also demonstrated the use of the defibrillator.

DINNER AND RECEPTION

On the Saturday evening a dinner, attended by nearly 200, was held in the Royal Pier Pavilion. Speeches were made by the BISHOP OF SOUTHAMPTON, who proposed the toast of the British Medical Association, to which the President, Professor A. P. THOMSON, replied. "The Guests" was proposed by Dr. D. P. STEVENSON, Secretary of the Association, and the Vice-Chancellor of Southampton, Dr. D. G. JAMES, replied. Professor THOMSON said that since becoming President of the B.M.A. he had put to himself anxiously the question, What were the Association's purposes? Medicine had passed through three revolutions and it was still in process of adjusting itself to the last of them, which, stemming from the philosophies of men such as Herbert Spencer, held that the doctor had a duty not only to the individual but to society as a whole. That accounted for the perhaps undue concern over politics in the recent past, and he therefore welcomed a meeting devoted entirely to clinical medicine. It was a return to the original idea that what really mattered in medicine was the quality of the people practising it. The other two revolutions medicine had experienced in the past, and only slowly digested, had been the Hippocratic revolution through which medicine became rational and the ethical concept was introduced, and the scientific revolution beginning in the sixteenth century which had established experiment as the test of truth—and the implications of this latter revolution had taken over 300 years to be fully absorbed.

The night before, the Southampton Division of the B.M.A. gave a most successful informal reception at the Palm Court Restaurant, at which Dr. and Mrs. R. S. RUSSELL-SMITH received the guests.

In all, 325 doctors registered for this first B.M.A. Annual Clinical Meeting. On all sides it was accounted to have been a great success. Reports of the panel discussions, the final general session, and the visits to local hospitals for clinical demonstrations on the Saturday, and of the Sunday morning outings, will be given next week.

Nova et Vetera

RICHARD BRIGHT

Reference was made in the *Journal* last week (pp. 1402, 1422) to the commemoration of the centenary of Richard Bright's death, which occurred on December 16, 1858. Today he is remembered chiefly for his description of the disease to which his name has been given, and through the passage of time his many contributions on other subjects and his wide interests and accomplishments have been largely forgotten.

Bright was born in Bristol on September 28, 1789, and in 1808 began the study of medicine at Edinburgh. Two years later, while still a student, he accompanied Sir George Steuart Mackenzie and (Sir) Henry Holland on a two months' tour of Iceland, and contributed chapters on botany and zoology to Mackenzie's account of the expedition (*Travels in Iceland*, 1811).

On his return, Bright studied for a time at the united hospitals of Guy's and St. Thomas's, and graduated M.D. Edinburgh in 1813. In the summer of 1814 he embarked on a lengthy Continental tour, which included Belgium, Holland, Germany (where he spent some time at the Charité in Berlin), and Austria. In the spring of 1815 he travelled through lower Hungary and published an excellent description of the social and economic life of that country (*Travels from Vienna through Lower Hungary*, 1818). Some account of this little-known volume of over 700 pages was given in this *Journal* by R. T. Williamson over thirty years

ago. It exemplified "Bright's wonderful power of observation and description, his wide reading, his accuracy, as is shown by the tables, maps and appendices, and his artistic ability, for it is illustrated by beautiful engravings from sketches by himself."²

Returning to London, Bright was appointed assistant physician to Guy's Hospital in 1820, and full physician in

1824, resigning in 1843. He was elected F.R.C.P. in 1832, and, on the accession of Queen Victoria in 1837, was appointed her Physician Extraordinary. His first description of chronic nephritis was given in vol. 1 of his *Reports of Medical Cases*, 1827, and a more extensive account appeared in *Guy's Hospital Reports* in 1836. Sir William Hale-White³ has published a description

of these writings, including a condensed version of the 1836 paper; they have also been reprinted under the editorship of A. A. Osman.⁴ Vol. 2 of the *Reports of Medical Cases* appeared in two parts in 1831. It is devoted to diseases of the brain and nervous system.

Hale-White³ has also reminded us of Bright's important writings on subjects other than renal disease. These include spastic paraplegia, epilepsy, localization of cerebral function, aphasia, glycosuria and pancreatic disease, cirrhosis of the liver, acute yellow atrophy, diaphragmatic hernia, chronic peritonitis, Addison's disease, appendicitis, the administration of oxygen, heart block, and the lungs in whooping-cough. His description of unilateral (Jacksonian) epilepsy preceded the more important account given by Hughlings Jackson in 1863. He was the first to describe Addison's disease, but he did not connect the symptoms with disease of the adrenals. In 1836-9 he collaborated with Thomas Addison in writing *Elements of the Practice of Medicine*, vol. 1. No second volume appeared, and the first, now a rarity, contains what is probably the first accurate account of appendicitis.

Bright's death, which occurred at his house in Savile Row, was due to aortic disease. He was twice married. His first wife was the daughter of William Babington, M.D., another illustrious physician of Guy's Hospital.

The portrait of Bright was supplied by the Wellcome Historical Medical Library.

The 43rd Annual Report of St. Dunstan's for the year ended March 31, 1958, is entitled "Wars end—but blindness remains. . . ." The report is divided into three sections, "Learning to be blind," "Out into the world," and "Their future is bright." The oldest member of St. Dunstan's is now 90 years old; he lost his sight during an incendiary bomb raid in the second world war. "Since the last shot was fired in World War II," says the report, "we have received no less than a further 500 young men. Some were certainly casualties in Korea, Kenya, and Malaya, but the majority have been men whose sight for one reason or another failed from old wounds, the results of privation and hardship suffered in P.O.W. camps, jungle fever and tuberculosis, or from illnesses contracted on war service."

Reports of Societies

RESULTS OF LEUCOTOMY

[FROM A SPECIAL CORRESPONDENT]

The Section of Neurology of the Royal Society of Medicine took a look, on November 6, at the results of leucotomy in the light of recent long-term follow-up studies. In addition two neurosurgeons described, respectively, their experience of a modified rostral leucotomy and of orbital undercutting.

In Depression

Dr. ALICK ELITHORN said he had followed up, by clinical assessment and questionnaire to patient and relative, some 105 patients under Dr. Eliot Slater's care who underwent leucotomy at Queen Square before 1954. He had paid particular attention to the effects of the operation in depressive illness, and his findings supported the thesis, recently rejected by Garmany,^{*} that there are two distinctive types of depressive illness, one a reactive depression determined by environmental factors and the other the so-called endogenous depression which is determined at least partly by one or two genes of large effect. Using the customary criteria, Dr. Elithorn had separated the possible "endogenous depressions" from the other types and compared them in terms of response to leucotomy. It was clear that the results were very much better with the endogenous patients and that these patients were much more enthusiastic about the operation than were those with reactive depression: of the endogenous depressives, 84% were glad to have had the operation and only 1 out of 32 regretted it; while, of the reactive depressives, 51% were glad to have had the operation and 8 out of 35 regretted it. These results were not attributable to the type of operation carried out: in the series 50 had the standard and 55 the modified procedure.

Within the group of reactive depressions the outcome varied according to the kind of environmental determinant. Thus the results were very much worse where the illness was a reaction to some definite physical factor—e.g., severe and prolonged pain—rather than to purely psychological events. This effect was evident no matter what type of operation was employed, although it was slightly more marked with the modified technique. It followed, therefore, that, if "endogenous depression" was simply a type of reactive depression in which there was minimal environmental cause for distress, then the results of leucotomy should be best in those cases where there was least evidence of an external cause—that is, in the truly cyclical or manic depressive cases. This had not been the experience in this series. Leucotomy appeared not to affect the enduring physical basis of cyclical depressive illnesses; the periodicity of the attacks was unaltered, although the intensity or elaboration of the depressive spell was diminished. Dr. Elithorn concluded that some endogenous depressions were prognostically and aetiologically distinct from most reactive depressions, and that leucotomy had a specific but only transient effect on the mechanisms underlying endogenous depression.

Ten-year Follow-up of Standard Prefrontal Operation

Dr. MAURICE PARTRIDGE presented the long-term results in 96 patients upon whom Mr. Wylie McKissock had performed a standard prefrontal leucotomy some 10 to 12 years earlier and who had recently been followed up again. (They were the first 96 of the 300 reported on by the speaker in 1950†.) The incidence of epilepsy in these cases had increased in the intervening years from the 10% originally reported to 15%. Of the schizophrenics, those with affective colouring or who had had remissions prior to the operation

To-day's Drugs

With the help of expert contributors we publish below notes on a selection of drugs in current use.

Marcoumar (Roche Products Ltd.).

Marevan (Evans Medical Supplies Ltd.).

These are preparations of warfarin sodium, which is the sodium salt of 3-(α -acetylbenzyl)-4-hydroxycoumarin, and is chemically closely related to dicoumarol. Like dicoumarol, warfarin in an anticoagulant which exerts its effect by interfering with the hepatic synthesis of prothrombin.

There are now a number of anticoagulants, most of them closely related chemically, that are available for clinical use. These include the earlier preparations, dicoumarol and ethyl biscoumacetate, and the more recent one, phenindione. Warfarin exerts its full therapeutic effect earlier and more constantly than dicoumarol and ethyl biscoumacetate. Fremont and Jagendorf¹ have claimed that marevan is superior also to phenindione in this respect, producing an initial effect within 18 hours and exerting its full therapeutic effect by 36 hours. Warfarin also appears to be a stable and predictable form of maintenance therapy, and frequent alteration of the dosage has been found unnecessary.

Toxic reactions are similar to those produced by other anticoagulants, but so far complications from haemorrhage have not been serious and respond quickly to vitamin K₁. The indications and contraindications are the same as for other anticoagulants.

The initial dose is commonly between 35 and 50 mg., depending on the weight of the patient. Maintenance dosage depends on the results of prothrombin estimations, which are necessary for satisfactory control of the therapeutic effect and prevention of complications.

N.H.S. basic price: marcoumar, 25 3-mg. tabs., 5s.; marevan, 100 3-mg. tabs., 32s. 6d.

REFERENCE

- ¹ Fremont, R. E., and Jagendorf, B., *J. Amer. med. Ass.*, 1957, 165, 1381.

Actal (Bayer Products Ltd.).—Each tablet contains sodium polyhydroxyaluminium monocarbonate-hexitol complex in tablets of 360 mg. This is an elegant preparation of aluminium hydroxide. The tablet has a pleasant taste, dissolves readily in the mouth, and, being an antacid rather than an alkali, will not cause alkalosis. Like all preparations of aluminium hydroxide it is somewhat constipating. There is no published work on this preparation; it is therefore impossible to say whether any advantage it may possess over the ordinary B.P. tablet of aluminium hydroxide is sufficient to justify the disparity in price between them.

N.H.S. basic price: 48 tabs., 4s. 3d.

(Continued from preceding column)

constant psychiatric help) 35 fully recovered and a further 14 improved enough to carry on without psychiatric help, in spite of slight symptoms; of 44 "socially incapacitated" (out of hospital but not working) 31 fully recovered and 8 improved; and of the remaining 70 cases who were "totally disabled" (in mental hospitals) 43 fully recovered and 19 improved. In the whole group there were two deaths, both hypertensive cases, and six patients developed epilepsy. The highest recovery rate (75%) was obtained in the group with anxiety and tension states, followed by those with depression (66%), obsessional states (61%), and lastly schizophrenia (44%). The operation relieved cases of agitation and depression in which all other forms of treatment had failed and where the illness had been present for 10 years or more. This suggested that there might be a case for its earlier employment in some of these cases.

did best and those with a progressive course before the operation least well. About one-third of these schizophrenic patients remained out of hospital, although some lived in sheltered circumstances. Cases of affective disorder did better, but continued to have recurrences, though these were milder. Seven previously incapacitated obsessional had been able to live an approximately normal life without relapse. Seven of the 96 had died from causes unconnected with the operation; of the 89 survivors, 46 had been able to remain continuously out of hospital for 10 to 12 years.

Rostral Leucotomy

Mr. WYLIE MCKISOCK then described his more recent experience with rostral leucotomies. When it was recognized that the earlier types of prefrontal leucotomy often produced undesirable personality changes, modifications of technique had aimed at producing a smaller and more accurately localized lesion, he said. Since 1948 he had carried out rostral leucotomy in increasing numbers. In 1957, for instance, of 144 leucotomies he had performed 125 were rostral and only 19 a standard Freeman Watts. After Pippard's report of some personality changes of undesirable kind in the rostral (G) operation he had modified his technique, taking a more forward line of section, now directed towards the midpoint of the orbital plate. He called this operation rostral (P).

There had been a distinct change in the type of case referred for operation—fewer old schizophrenics and more cases of tension, agitation, or depression. In his series of 490 rostral leucotomies, the mortality of less than 1% emphasized the safety of the procedure. Nor did the operation require any specialized apparatus or equipment. In a series of 60 rostral leucotomies he had performed at one hospital there was a recovery rate of 60%, while a further 30% had been discharged from hospital although not working. These figures could be compared with recovery and discharge rates of 39.6% and 13.5%, respectively, in a series of 111 prefrontal leucotomies performed in the same institution. When the cases submitted to rostral leucotomy were separated into those with depressive and those with other psychotic illness it appeared that the best results were obtained with the depressives. Thus 25 of 38 depressed patients were discharged and working and a further 11 were discharged but not working. For the other psychotic states, the corresponding figures were 6 out of 17 discharged and working, and a further 7 discharged and not working. These differences were also seen in the prefrontal series. Of 5 cases of obsessive compulsive states, all were discharged and working. Rostral leucotomy had proved itself to be a form of treatment with a very low risk to life and to have remarkably few side-effects. If used in properly selected cases, it offered a high rate of recovery.

Orbital Undercutting

Mr. GEOFFREY KNIGHT said that, influenced by the results of animal experiments and Rylander's observation that lesions in the orbital aspects of the brain would produce tranquillity and loss of fear, he had followed in a modified way since 1949 Scoville's method of orbital undercutting. He used a more limited incision so as to disturb as little as possible the more lateral fibres subserving emotional appreciation and intellectual processes. The operation, although a long one taking up to two hours, was worth while because it resulted in the absence of all undesirable side-effects such as grossly increased appetite, adiposity, and incontinence. There was no intellectual blunting, the patients felt relaxed, and remained warm individuals with normal emotional reactions. In three cases a second operation at the same site, by extending the lesion, resulted in success.

Mr. Knight then analysed the results in the first 167 cases he had followed up out of a total of 250 treated in this way. Of 53 cases classified as "psychiatrically disabled" (in the sense that although out of hospital they were in need of

Medicine on Television

SIR,—A change of role to that of patient prevented me from hearing Mrs. Mary Adams and Mr. Dickson Wright discussing "Medicine on Television" (*Journal*, November 29, p. 1351), but Professor Roger Warwick's letter (p. 1354) has brought some of the flavour of it to me. My long interest in non-medical sound broadcasting and television, sadly and unprofitably restricted by the fact that these are not the most suitable spare-time occupations even for full-time doctors, has provided me with enough experience of several of the B.B.C.'s services to realize that a revolution is taking place in adult education. The desire of what we choose to call "backward peoples" to know about the world in which they live and how it works, and to hear what others have thought about it, makes most of our programmes seem extremely frivolous. Some small countries demand continual talks of a kind which would only be tolerated here by the few and would have to be put on at the most inconvenient times.

Television is an even more astonishingly influential means to adult education which has burst upon us all unprepared. There is a particular demand for public education in medicine. It is not clear why we should call a growing desire to understand what goes on in nuclear physics as enlightenment and the same inquiry in medicine as morbid curiosity. Since we are going to have medical television programmes whether we like them or not, we do well to consider the principles which might govern their presentation. For my part I think that first and foremost they should be entertaining. I consider that the B.B.C. started well long ago at Alexandra Palace when Mrs. Mary Adams and Andrew Miller Jones had a policy. Then they presented an account of how things worked, some simple demonstrations in physics or physiology, and related this to a simple human story. In later programmes the influence of advisers has been seen, results have been presented without previous explanation, and some have even sunk to exhortation and propaganda. The old programmes were entertaining and educational, the newer (with a few fine exceptions) have too often been peeps behind the scenes with the nasty bits glossed over or inexcusably dull.

To finish on a controversial note, my pet aversion on the television screen is the anonymous doctor. To me he appears as a superior expert whose credentials I cannot check, who sets himself apart from ordinary folk by a secrecy which enhances that personal mystique which is at the heart of most of what is phony in medicine.—I am, etc.,

Knockholt, Kent.

D. W. SMITHERS.

Cause of Post-vagotomy Diarrhoea

SIR,—In an earlier paper this year Burge and Pick¹ stated that the cause of diarrhoea following vagotomy and gastro-enterostomy for chronic duodenal ulcer was not known. It was mentioned in this paper that this problem was being investigated in the Medical School of the West London Hospital. This symptom has been generally thought to arise from intestinal infection due either to reduction in gastric acid or to post-operative gastric stasis.

As a result of our work we have evidence that this symptom is caused by pancreatic insufficiency resulting from vagal denervation which must follow division of the main posterior vagal trunk. This work will be reported in detail in the near future. Meanwhile, surgeons who use this operation are urged to preserve the coeliac division of the posterior vagus while dividing all its gastric branches. This is easily done by dividing the small omentum completely

from the pyloric antrum. The left gastric artery and vein are divided close to the stomach. In this region the main gastric division of the nerve is easily seen and divided, leaving the coeliac division passing posteriorly to the coeliac plexus.—We are, etc.,

HAROLD BURGE.
PETER CLARK.
LESLIE CHAPMAN.

The Art of Consultation

SIR,—May I send you a brief note to express my appreciation of Dr. G. F. Abercrombie's excellent James Mackenzie lecture on "The Art of Consultation" (*Journal*, November 29, p. 1349)? In a way I find myself fortunate, for I was for some years a general practitioner before taking up surgery as a specialty. I am thus able to see from both sides the problem which he presents. In my later years as a consultant I cannot tell how much I owed to the many excellent general practitioners of Northern Ireland. Especially would I like to pay tribute to the late Dr. John Taggart, who strangely enough was an assistant to Dr. James Mackenzie when he was a general practitioner in Burnley before going to London, and the latter never forgot what he owed to the years he spent in general practice.

Dr. Abercrombie draws a clear distinction between a consultation and a second opinion. This is, I think, a vital problem to-day. Surely the failure of consultants to meet G.P.s, and vice versa, is one of the tragic defects in the present N.H.S. (at least in Northern Ireland). In former times those meetings were the very bread-and-butter of consultants. To-day I understand many part-time consultants and all those on full time never want to see a general practitioner. Why is this? Do they foolishly think that the G.P. has nothing to contribute to the average consultation?—I am, etc.,

Belfast.

S. I. IRWIN.

Poliomyelitis Vaccine

SIR,—Your leading article and the articles on live poliomyelitis vaccine (*Journal*, November 15) are valuable contributions on this important but controversial subject. However, it would appear that some clarification of the technical policy of the World Health Organization in this connexion is necessary in order to avoid possible misunderstanding. All Expert Committee Reports carry on their cover the statement that "this report contains the collective views of an international group of experts and does not necessarily represent the decisions or stated policy of the World Health Organization." In this instance the policy of the Organization is in substantial agreement with the recommendations of the Committee, although it may be that there are differences in the interpretation of certain recommendations.

The statement quoted in the leading article (p. 1210) to the effect that "tests on hundreds of thousands of people will be necessary to establish whether the theoretical expectations of safety can be confirmed in actual practice" is, in its context, a statement of fact and not a recommendation that such tests be carried out now. Since it is not known what the currently used tests on monkeys mean in terms of safety for man, it is obvious that only actual tests on man on a sufficiently large scale will finally prove the innocuity of a strain. These large-scale tests should not be carried out until there is good presumptive evidence of safety and stability, based both on laboratory and on small-scale human studies. The Expert Committee insisted most strongly on the need for a cautious extension of strictly controlled human trials under the most careful supervision. The criteria which should be fulfilled were specified in some detail. So far W.H.O. has not given direct support to any trial of live poliovirus vaccine, and, contrary to some reports, the "test" in the Belgian Congo was not supported by W.H.O. The Organization has of course

followed closely the scientifically conducted studies which are in progress in several countries, and it is clear that a great deal of new information will become available in the coming months on which future policy may be based.

The Director-General made the present position of W.H.O. clear in a statement to the Eleventh World Health Assembly in May, 1958, in which he said that W.H.O. was not satisfied with the evidence for the stability of the available strains and did not support large-scale trials of this vaccine at the present time. He emphasized the need for caution, pointing out that the availability of a safe and effective inactivated vaccine greatly reduced the urgency of developing the live virus vaccine.

With respect to the statement by Professor G. W. A. Dick and Dr. D. S. Dane (p. 1184) that the Expert Committee virtually ignored the problem of spread of the vaccine virus, I can assure them that the problem was carefully discussed and that it was one of the important reasons behind the strong recommendation for the most careful supervision of field trials by someone experienced in investigations involving poliovirus, who would therefore be fully aware of the danger of spread. I have myself repeatedly called attention to this problem, both in publications and in communications to those proposing to use the vaccine. Some carefully designed trials to throw light on this important problem are in progress and the results may be expected in a few months.—I am, etc.,

World Health Organization,
Geneva.

A. M.-M. PAYNE,
Secretary to the Expert Committee
on Poliomyelitis.

Pharmaceutical Houses and the Doctor

SIR,—It would be a great pity if Dr. Mary Rayner's letter (*Journal*, November 22, p. 1291), or any replies to it, were allowed to imperil the good relations which exist between the pharmaceutical industry and the profession.

We in the industry are aware that some members of the profession are at times critical of us, but I can assure you, Sir, that we take note of such criticisms, taking care to put it into perspective, to determine the validity, and to take whatever action is necessary. Our job is to provide the tools of clinical medicine. To do so we must bring the results of our efforts to the clinician as quickly as possible.

The alternatives to co-operation and understanding are acrimony and prejudice; as we are indispensable to one another let us pursue the first course.—I am, etc.,

London, W.C.1.

T. H. M. KERFOOT,
President,
The Association of British Pharmaceutical Industry.

SIR,—I agree entirely with Dr. Mary M. Rayner and Dr. Charles S. Thompson (*Journal*, November 22, p. 1291). Neither of them, however, mentioned a new form of advertising which appears to have crept in. I refer to the discussion in the doctors' columns of newspapers and women's magazines of drugs, mentioned by name, and in certain cases with the maker's name and cost, and the implication that the reader may well ask his doctor for these drugs.

I do not suggest that the drug houses are responsible for this. Nevertheless, I feel that drugs so mentioned have moved into the class of the publicly advertised aspirin derivatives, and I wonder whether one should continue to prescribe them, good though some of them may be. To whom are those who write these articles responsible, and is there no way of restraining them?—I am, etc.,

Salford, 6.

R. HEWITT.

SIR,—I was most interested in the letter of Dr. Mary M. Rayner (*Journal*, November 22, p. 1291) and find myself in agreement with many of her views.

I wonder how many of my colleagues recently received a sample of antacid tablets in a wedding cake presentation box. At my home it was opened with pleasurable anticipation, and we were well and truly "taken in." My first impulse was to return a similar package containing

senna pods to the managing director of the firm responsible, but second thoughts prevailed. Instead I wrote to him saying that this kind of salesmanship was not appreciated and to cross us off the mailing list. I should have known better. In reply I received a long letter which, using military language, may be divided into three parts. Firstly, the retreat; with the expression of sorrow that their efforts to present their products in a humorous and rather different style, etc., had not been appreciated. Secondly, the marshalling of the forces; with an exposition of the merits of the firm. Finally, the attack; with a final paragraph turning the knife in the wound by describing in detail the efficacy of the first-mentioned antacid tablets.

"What kind of a people do they think we are?"—I am, etc.,

Bearwood, Smethwick.

H. S. SPILLER.

SIR,—Reading through the correspondence columns in the *British Medical Journal* recently, I have been struck by the attack on the pharmaceutical houses. It appears to me that much of this is unwarranted and that insufficient credit is given where credit is due. It is common knowledge that, as a result of money invested by them in research, they have given to the medical profession a number of very valuable drugs which have provided the doctor with powerful weapons in his fight against disease. Of course the pharmaceutical houses are profit-making concerns which must advertise and sell their products, but the criticism often levelled against them, that their prices are excessive, has not been substantiated. Indeed, on looking through a recent official publication giving the cost of proprietary and official equivalents,¹ I was impressed by the large number of cases in which the cost of the proprietary preparation was no greater than that of the official, and in a few cases was even less. Moreover, there were a large number of drugs which were considered to be of such value as to be included in the *British National Formulary*, but which are available only in proprietary form. These are evidently the result of original research on the part of the pharmaceutical houses.

But the chief concern of correspondents seems to be the manner in which the pharmaceutical houses keep us informed of their products and their efforts to urge us to prescribe them. This is done by advertisements in the journals, by mailed literature, and by visits from representatives. Personally, I peruse the advertisements, sort the mailed literature, discarding the more sensational and filing the more informative, and enjoy a short discussion with representatives. But surely those who are not so inclined can deal appropriately with the postal advertising; and, after all, we who are accustomed to handling all manner of patients can surely deal with representatives in, I hope, a courteous manner.

As a former practising pharmacist, I was interested to read Dr. Mary M. Rayner's comment (*Journal*, November 22, p. 1291) on extemporaneous oral penicillin preparations, and I would very much like to see her prescription for a stable, elegant, and palatable preparation of oral penicillin, comparable to the proprietary products. Finally, if we are unable critically to appraise the literature sent to us and evaluate the pharmaceutical preparations for ourselves, then we have no right to be prescribing for our patients. And if, as Dr. Rayner suggests, we are treated as a band of immoral morons, then we have only ourselves to blame.—I am, etc.,

London, S.E.4.

JOHN E. PEARSON.

SIR,—Dr. Mary M. Rayner (*Journal*, November 22, p. 1291) and other correspondents are concerned about the propaganda methods of the drug houses. I would like to make a few comments.

The practice of consigning advertising matter to the waste-paper basket seems to me deplorable. We all use a proportion of proprietary drugs, and it is surely our duty

SIR,—I was interested to read Dr. A. H. Luscombe's letter (*Journal*, November 15, p. 1226), referring to the use of continuous antibiotic therapy for adult chronic bronchitis. Dr. Luscombe's letter exposes the unfairness of the present method of criticizing a doctor's prescribing costs without taking into consideration the possible savings which these effect by shortening the duration of the patient's illness. Dr. Luscombe is quite right when he says that the Ministry of Health is not interested in these savings, nor in the fact that a patient continues working throughout the winter. However, at a time when productivity in industry is of paramount importance, is it not time that the Ministry of Health did take these factors into account?

Dr. Luscombe asks for guidance in his problem; I would suggest he might utilize the method described by Elmes *et al.*¹ This method consists in giving bronchitic patients a supply of antibiotic tablets and an instruction to commence using these at the first sign of an onset of an exacerbation. In their paper Elmes *et al.* stated that between June, 1953, and June, 1954, male insured workers in Great Britain lost nearly 15 million days' work owing to sickness diagnosed as "bronchitis," and estimated that the cost to the community that year was about £30m. They stated that the simple measures they adopted would greatly reduce this figure, but advised that the method should be used only with patients intelligent enough to understand the instructions.

Using the latest figures available from the Ministry of Health the total cost of such a treatment (including chemist's profit, dispensing fee, etc.) is less than £3 10s., so that with, say, four exacerbations per year the total annual cost would be £14. The cost of keeping a patient in hospital for one week is over £23 in the provinces and £29 in London.

This factor, added to the benefits the patient and nation receive, is, I consider, a valuable argument if the Government is interested in the overall cost of bronchitis to the nation.—I am, etc.,

Folkestone.

W. J. KEATING.

Medical Education

SIR,—Having been educated in the United Kingdom, having lived in the United States, and now living and practising in Canada, I found your annotation on medical examinations (*Journal*, October 4, p. 842) most disturbing. There is a remarkable tendency these days for apparently thoughtful people in the United Kingdom to accept American methods uncritically, while at the same time they are prepared to jettison methods which have been well tried and proved in their own country for many generations. This is not to plead for the maintenance of the *status quo*. There is always room for progress, and medical education can be improved in many ways. But please think twice before accepting an American system of education, which succeeds in producing "well-adjusted morons" (an American criticism) from the schools by virtue of just some of the principles advocated in your columns: I mean "credit" advances from grade to grade, multiple choice examinations, and not permitting the poor student to fail, in case he should suffer some psychological shock. Heaven knows the Americans themselves are undergoing agonizing reappraisals of these matters since the days of Sputnik, and it is the more difficult for them as "democratic education" is deeply ingrained in the national thought, even though it leads to proceeding at the pace of the least intelligent and to a deep suspicion of all truly educated men (egg-heads).

I recall a conversation struck up with the representative of a large business organization, who had been visiting one of the largest and best-known U.S. Mid-Western Universities to interview recent graduates from the commerce faculty. These men were all wanted by industry, and had the pick of many openings at that time. "Of course," added my acquaintance, "after we get them we have to teach them to read and write." These skilled university graduates, with good technical education, had progressed through multiple-choice examinations and were virtually incapable of expressing themselves either verbally or on paper, because they had never been taught to do so. Multiple-answer examinations do have the virtue of being easy to mark. They are easy for the examiner. They do test the student's knowledge of the books. But they are not a test of a man's true calibre. Ask a man to write for three hours on one subject, and you will have a much better idea.

The credit system has defects too, and these have been discovered. For example, the percentage of passes may be seen as a reflection on the teacher's ability. You men of integrity may doubt the importance of this. We who have seen the system in action have become more cynical in this respect.

All tests of skill and knowledge are open to objections. Some able men do not do themselves justice under any system you choose to adopt. This should not obscure the broad pattern.

Men of initiative and brain are on the whole stimulated by a challenge, and all of us are the more tempted to work if idleness is penalized. "When a man knows he is to be hanged in a fortnight," said Johnson, "it concentrates his mind wonderfully."

Those who decry British education may derive consolation from the fact that British speakers are renowned throughout the New World because they are so much more polished, regardless of the scientific content of their talks, and it is a fact that the standard of discussion at any medical meeting in the United Kingdom is far higher for exactly the same reason. We can certainly learn from America in many ways. Their postgraduate training is often greatly in advance of what is offered in the United Kingdom. We can learn, in fact, from their successes and their failures.—I am, etc.,

Victoria, British Columbia.

KEMBLE GREENWOOD.

Munchausen Syndrome

SIR,—I was interested in the medical memorandum on the Munchausen syndrome by Dr. J. C. Barker and Dr. T. G. Grygier (*Journal*, November 22, p. 1274).

When I was a general practitioner in London, some years ago, a lady consulted me complaining of abdominal pains, for which she requested a prescription for pethidine. She had innumerable laparotomy scars all over the abdomen; their very number, and varied sites, aroused my suspicions; also she demanded a phenomenal quantity of pethidine tablets. Discreet inquiries revealed that she was a known pethidine addict. At that time I was unfamiliar with the syndrome, although I had met the "chronic hospital patient." Unfortunately, she was more interested in seeking pethidine *ad lib.* than in obtaining treatment for her addiction, so she never consulted me again.

I was left wondering whether the addiction was the result of innumerable surgical operations, or whether the laparotomies were sought merely in order to obtain pethidine.—I am, etc.,

Hale, Cheshire.

AUDREY ROBERTS.

Charges of Indecency

SIR,—In his article on the Disciplinary Committee of the G.M.C. (*Journal*, November 22, p. 1257) Mr. C. P. Harvey, Q.C., gives an instance of how a doctor may be charged by the police with "committing acts of indecency." He appears to imply that, merely because this doctor walked home from a party through a London park at night, he was seized upon and had this charge made against him. I gather Mr. Harvey to mean that he is not suggesting that the doctor committed any indecent act in reality.

I know such things have happened—a friend of mine was charged more or less in this way and was found not guilty by the court—but is Mr. Harvey really trying to tell us that one person in every so many will be charged with indecent acts merely because he walks home through a London park at night? He does definitely make the point that the story is staged in London, and I am happy to be able to share with him the view that this would be rather unlikely to happen anywhere else.—I am, etc.,

Birmingham, 31.

DAVID T. MACLAY.

Premonition of Death

SIR,—I should like to support Dr. A. A. Lewis (*Journal*, November 8, p. 1165) in his view that we are more apt to remember those occasions when a premonition of death has proved accurate, and to forget the "false alarm." Shortly after I qualified, I was staying with my grandmother, who was then 85, and was called to her at 5 a.m. one morning as she thought she was about to die. She was thanking her two faithful maids for all their care of her, and had literally turned her face to the wall. To my inexpert eye she did not appear to be dying, and in fact she lived for another ten years, and might have completed her century if it had not been for a fracture of the neck of the femur.—I am, etc.,

Cambridge.

JANET BOTTOMLEY.

* * This correspondence is now closed.—ED., *B.M.J.*

Obituary

J. A. CRAIG, M.D., F.R.C.S.

Mr. James Craig, well known as an ophthalmic surgeon, died in Belfast after a short illness in his 87th year. He was consulting ophthalmic surgeon to the Royal Victoria Hospital, Belfast.

James Andrew Craig was born on March 20, 1872, in Ballymoney, Co. Antrim, which was also the birthplace a year or two later of another eminent doctor who has recently died—namely, Sir John Megaw. Educated at the Coleraine Academical Institution and at the former Queen's College, Belfast, he obtained first-class honours in the final examinations for the M.B., B.Ch., B.A.O. of the Royal University of Ireland in 1895. For the next three years he held resident appointments at the Royal Southern Hospital, Liverpool, and then went to Vienna to study eye and ear diseases. Returning to Belfast, he was appointed demonstrator of anatomy at Queen's in 1899. Two years later he was elected honorary assistant in the eye, ear, and throat department of the Royal Victoria Hospital, and in 1902 he

obtained the F.R.C.S. of England. One of his first publications appeared in this *Journal* in 1906: it was on the subject of the operative treatment of detachment of the retina. Mr. Craig served the Royal Victoria Hospital faithfully until his retirement in 1937 at the age of 65. But in 1939 he returned to his old hospital post in order to release his junior colleagues for war service. He finally ceased to practise only a few years ago when he went to live in Cultra, in Co. Down.

Mr. Craig also gave unstinted service to Queen's University from the time he was appointed lecturer in ophthalmology and otology in 1913. In 1951 his distinguished work was recognized by the award of the M.D., *honoris causa*. In presenting him for this degree Professor Biggart said that Mr. Craig had been a generous benefactor to the university, and, stimulated by his gifts, Queen's would promote research in his own subject of ophthalmology. In his own specialty Mr. Craig quickly made a name for himself. He acted as one of the honorary secretaries of the Section of Ophthalmology when the B.M.A. held its Annual Meeting in Belfast in 1909, and when the B.M.A. met again in Belfast, in 1937, he was president of the same section. At one time a member of the council of the Ophthalmological Society of the United Kingdom and of the editorial committee of the *British Journal of Ophthalmology*, he was a past-president of the Irish Ophthalmological Society and of the Ulster Medical Society.

Mr. Craig was one of the early enthusiasts for skiing, and he was also a keen golfer, being a past captain of the Royal Co. Down Golf Club. His wife, formerly Miss Blanche Waldron, died in 1952, and he is survived by two sons, one of whom is on the staff of the ancient monuments inspectorate of the Ministry of Works and is also a writer and poet. Two of his nephews have been active in B.M.A. affairs—Dr. J. A. Moody, of Ilford, a member of Council, and Mr. J. C. McMaster, of Yeovil.

R. M. writes: In his early days, and for long afterwards, the specialties of ophthalmology and oto-rhino-laryngology were not divided, and James Craig quickly made himself a master of both of them. As the years passed his reputation

and his practice grew in gratifying symbiosis. His diagnostic acumen was such that his opinion was accepted without question, and his skill as an operator reflected his passion for perfection. This was, in turn, easily seen in his love of beautiful things and his appreciation of "good fare, good fellowship, and good company." Of him it may be said that he became "a legend in his lifetime." His former students all over the world will long recall the clarity of his teaching, his devotion to his hospital, and his quick wit, always lively but never wounding. He did not always suffer fools gladly, but those who sought his aid will remember his patience, his skill, and his kindness.

Sir ALDINGTON CURPHEY, C.B.E., M.C., M.D.

The Hon. Sir Aldington Curphey, president of the Legislative Council of Jamaica, and for many years a general medical practitioner in the island, died in Liverpool last month while on holiday. He was 78 years of age.

Aldington George Curphey was born in Jamaica on August 24, 1880, the son of Mr. T. J. Curphey, who came from the Isle of Man. From Wolmer's School, Jamaica, he entered Queen's University, Kingston, Ontario, as a medical student, and graduated M.D., C.M. in 1907. From then on until 1912 he held various appointments in Ontario, including those of assistant physician, assistant surgeon, and full surgeon at St. Joseph's Hospital, Hamilton, and coroner for Wentworth County. During this period he obtained, in 1909, the Scottish triple qualification. In 1912 he returned to Jamaica and became government medical officer and medical officer of health at St. Ann. From 1915 to 1919, during the first world war, he served with the 2nd British West Indies regiment as captain in the R.A.M.C. in Egypt, Palestine, and Syria. He was awarded the Military Cross in 1919 for distinguished services in connexion with the military operations in Egypt, and was also mentioned in dispatches. After the war he returned to St. Ann and settled in private practice. From 1936 to 1944 he was a member of the St. Ann parish council, eventually becoming its chairman. Nominated a member of the Legislative Council in 1945, he was appointed president of the council in 1952. For his services as major in the Jamaica Medical Corps he was appointed M.B.E. (Military Division) in 1944, and in 1952 C.B.E. (Civil Division) for public services in Jamaica. He was created a knight in this year's Birthday Honours. A member of the British Medical Association for 37 years, he was president of the Jamaica Branch in 1937–8. He became Scout Commissioner for Jamaica in 1939, and was welfare officer to the Caribbean Forces and chairman of the Jamaica Legion. During the second world war he served as surgeon-major to the Jamaica local forces, and later as honorary colonel of the Jamaica regiment. His death has deprived Jamaica of a kindly and experienced doctor and of a public-spirited citizen.

P. N. B. ODGERS, D.M., M.Ch., F.R.C.S.

Mr. P. N. Blake Odgers, consultant surgeon to the Northampton General Hospital and formerly reader in human anatomy in the University of Oxford, died in London on November 30. He was 81 years of age.

Paul Norman Blake Odgers was born on July 3, 1877, and was brought up in Oxford. He took first-class honours in the school of natural science at Oxford and went on to Guy's Hospital with a senior scholarship in science. Qualifying in 1902, he took the F.R.C.S. in the following year, graduated B.M., B.Ch., and proceeded to the M.Ch. in 1904. At Guy's he was a demonstrator of anatomy, and he held numerous house appointments and then went down to Plymouth to be senior house-surgeon at the South Devon and East Cornwall Hospital. Interested in children's diseases, he held clinical assistantships at the Evelina Hospital and at Great Ormond Street. In 1913 he served as vice-president of the Section of Diseases of Children, including Orthopaedics, at the Annual Meeting of the

B.M.A. in Brighton. A few years before this he had been elected to the staff of the Northampton General Hospital as an assistant surgeon, and he remained in that town until 1925, when he gave up clinical practice for an academic career in Oxford. During the first world war he had served in the R.A.M.C. as a temporary major. Among his clinical papers he contributed two to this *Journal*, one on retropharyngeal fibroma (1906) and another on a case of vegetable gastrolith (1912).

Mr. Blake Odgers retired from his readership in the department of human anatomy at Oxford in 1945 and came to live in London. He leaves a widow, two sons, and a daughter.

Professor W. E. LE GROS CLARK, F.R.S., writes: Blake Odgers will best be remembered by past students and others for his long period of devoted service to the department of human anatomy at Oxford. He was appointed a senior demonstrator in 1925, and in 1931 he was promoted to the readership in human anatomy. This latter post he occupied till his retirement in 1945. As a teacher, Odgers was particularly effective because his previous surgical experience gave him the appropriate orientation for the instruction of medical students. But his success in teaching was perhaps even more the result of the scrupulous care and patience with which he dealt with the individual problems of his pupils, and the conscientious manner in which he sought to cover the whole field of topographical anatomy in his lectures and demonstrations. His earlier research work was concerned with problems of anatomical topography and applied anatomy—for example, his careful analysis of certain markings on the neck of the femur (1931), his study of the lumbo-sacral joints (1933), and his report on a case of non-rotation of the gut (1933). But his interest became more and more focused on embryological problems, and no doubt his best work was represented by his patient studies (by means of reconstruction models) of the development of the venous valves of the human heart (1935), of the pars membranacea septi (1938), and of the atrio-ventricular valves (1939), as well as by his systematic descriptions of an early human ovum *in situ* (1937) and of a presumptive human embryo (1941). In 1944 he published a small *Class Book of Embryology*, which has proved of great use for routine practical classes. But, apart from his academic career, Odgers will be remembered for the kindness and the delightful courtesy with which he maintained such affectionate relations with his colleagues and his students. The department of human anatomy at Oxford owes a great debt of gratitude for his contributions to organization, teaching, and research over a period of 20 years.

H. I. MARRINER, F.R.C.S.Ed., D.L.O.

Mr. H. I. Marriner, surgeon to the ear, nose, and throat department of the Royal Victoria and West Hants Hospital, Bournemouth, and formerly chief assistant in the ear department at St. Thomas's Hospital, died suddenly at his home in Bournemouth on November 26. He was 66.

Humphrey Ingilby Marriner was born on August 12, 1892, the son of a Bournemouth doctor who specialized in ear, nose, and throat work. Educated at Cheltenham College and St. Thomas's Hospital, he qualified in 1919. After holding the posts of casualty officer and house-surgeon at St. Thomas's he worked for two years as house-surgeon in the E.N.T. department there, taking the F.R.C.S. of Edinburgh in 1922 and the D.L.O. two years later. He followed his father into ear, nose, and throat practice in Bournemouth, but he by no means severed his connexion with his teaching hospital, for, having been appointed chief assistant in the ear department in 1924, he came regularly to London to work in the out-patient department at St. Thomas's for a good many years. He was also at one time throat and nose surgeon to the North-eastern Fever Hospital in London. He joined the staff of the Royal Victoria and West Hants Hospital in 1923, and in later years

he was ear, nose, and throat surgeon at Blandford Cottage Hospital and laryngologist to the Royal National Sanatorium at Bournemouth.

Humphrey Marriner was one of those quiet and reserved doctors who nevertheless cannot help making the pleasantest of impressions on patients and colleagues. The reverse of pushing, he had a large private and hospital practice which kept him busy for many years. Those who got to know him well, including his theatre staff, regarded him with the greatest of affection. So far as public life went he kept in the background, though he once served as honorary secretary of the Section of Oto-rhino-laryngology at an Annual Meeting of the B.M.A. But his work for young people was outstanding, for he had a deep sympathy for children who had to face life without the advantage of a normal home background. An Officer of the Order of St. John, he was county cadet officer of the St. John Ambulance Brigade.

C. E. G.-S. writes: As a surgeon Humphrey Marriner was conscientious, careful, and rather conservative. He never followed the various surgical fashions which appeared and disappeared so constantly during the 40 years he was in practice. On the contrary, he followed throughout his professional life certain surgical principles which he had learnt in his parent hospital and which, from his experience, he considered sound. So long as his results were satisfactory he saw no reason to change his ways.

As a man he was the kindest person imaginable, retiring to a fault, and devoid of all personal ambition. He had, however, strong views and strong convictions which he preferred to keep to himself or share only with his intimate friends. It is certain that he never realized how great was his influence both on his professional colleagues and on all those with whom he came into close contact. His sound common sense and obvious integrity commanded universal respect and affection.

He had a profound understanding of the needs of young people and was able to put this to practical use in his work for the cadets of the St. John Ambulance Brigade and even more so in his magnificent work in connexion with the Talbot Homes for Boys. Throughout the years he was in the habit of taking a succession of boys from this institution into his home and giving them guidance and training to fit them for taking a useful place in the community. There are many men to-day both at home and in the Commonwealth who owe a great debt to Humphrey Marriner.

After the death of his beloved sister and his retirement from the active staff of the hospital, he must have felt rather lonely, but he found company and pleasure in his church community and among his friends at the E.N.T. and Eye Hospitals, where he was always assured of a welcome.

Marriner was a bachelor and the last of his line.

DOROTHY M. JAMES, M.D., D.P.H., T.D.D.

Dr. Dorothy M. James, an assistant county medical officer of health in Lancashire, died at Liverpool on October 15, aged 54.

Dorothy Mary James was born on July 1, 1904, the elder daughter of the late Mr. Arthur James and Mrs. James, of Penarth, Glamorgan. A distinguished student at the Welsh National School of Medicine, she graduated M.B., B.Ch. from the University of Wales in 1928, gaining a gold medal in both medicine and surgery. After holding house appointments at the Cardiff Royal Infirmary, Booth Hall Children's Hospital, Manchester, and Alder Hey Children's Hospital, Liverpool, she returned to Cardiff to take up a Cecil Prosser research scholarship in the tuberculosis department of the medical school, where she carried out some valuable original work on tuberculin. She took the D.P.H. in 1932, the Tuberculous Diseases Diploma in 1935, and proceeded M.D. in 1937.

Dr. ENID M. ROGERS writes: Most of us who were Dorothy James's contemporaries at the Cardiff medical school or were her colleagues in her later professional life are sad at her passing. She set up in practice in her home

town of Penarth for a period of three years until 1942, and was a very much loved, conscientious, and competent general practitioner. In spite of her great happiness in general practice, circumstances forced her in 1942 to make a career for herself in public health, and she became an assistant medical officer to the Lancashire health authority, with which she served until the time of her death. No account of Dorothy James's life would be adequate without a note on her personal qualities. Her integrity and quiet sense of humour were outstanding. She was a practising Roman Catholic, and in her fatal illness the spiritual strength derived from her religion stood her in good stead. To her mother and sister, all who knew Dorothy will wish to extend their sympathy.

W. V. CRUDEN, M.B., B.S.

Dr. W. V. Cruden, who was in general practice at Brighton, died at his home at Hove on October 31 after a long illness. He was 55 years of age.

William Victor Cruden was born at Muswell Hill, London, on February 5, 1903. From Tollington School he went on to St. Bartholomew's Hospital, qualifying M.R.C.S. L.R.C.P. in 1927, later graduating M.B., B.S. at London University. After holding several resident appointments, including that of house-physician to the late Lord Horder at St. Bartholomew's Hospital, he eventually settled in a partnership at Brighton, where he became a much respected family doctor. During the second world war he served in the R.A.M.C. in the Middle East and Italy, attaining the rank of lieutenant-colonel. In 1956 his health became seriously affected and in the following year he had to give up general practice. During his long illness he displayed an extraordinary fortitude and found it possible to contribute to *St. Bartholomew's Hospital Journal* articles on cough, smell, and even on the subjective effects of a treatment he was receiving. He was a loyal colleague whose quiet manner and clinical acumen gave to his patients that confidence and friendliness which endeared him to them. To his widow and to his brother, also a doctor, we offer our sincere sympathy.

—J. V. B.

J. A. GUNN, C.B.E., M.D., D.Sc., F.R.C.P.

The obituary of Professor J. A. Gunn was printed in the *Journal* of November 1 (p. 1107).

Dr. R. E. M. COKE HARVEY writes: I think Professor J. A. Gunn's own account of how his *Introduction to Pharmacology and Therapeutics* came to be written may be of interest. Some 20 years ago Professor Gunn told me (his own words are reproduced as closely as my memory allows): "I was in Edinburgh turning over books in a second-hand bookshop when I came upon a bound copy of a student's notes on my lectures on pharmacology, priced 10s. 6d. Being a Scotsman, it at once struck me that if a student's notes were worth half-a-guinea, how much more profitable should a book prove to the author himself." I remember he laughed happily as he told me the story.

T. N. WILTHEW, L.R.C.P.&S.Ed.

Dr. T. N. Wilthew, who was in general practice in the county of Durham for many years, died suddenly on November 10 at the age of 83.

Thomas Nicholson Wilthew was born at Hexham, Northumberland, on July 31, 1875. He took the Scottish triple qualification in 1912, and then set up in general practice at Sunnyside, Co. Durham. During the first world war he served first in the R.A.M.C., and then went out to the Middle East as a medical officer in the R.A.F. In 1921 he returned home to build up another practice at Dunston, near Gateshead. He was proud of the fact that he started both his practices by "putting up his plate," and his patients always came first with him. He ceased to practise in 1942, but found complete retirement too quiet, so became medical referee to several insurance companies—work which he con-

tinued until 1955. A member of the British Medical Association for 40 years, he was chairman of the Gateshead Division in 1930-1. In his younger days Dr. Wilthew was a keen games player and athlete, with a particular interest in running. Later he developed a fondness for tennis, playing the game until he was almost 60 years of age. He had the misfortune to lose his wife in 1914, and is survived by his son, who is in medical practice at Low Fell, Gateshead.

R. F. EMINSON, D.S.O., M.B., B.S., L.M.S.S.A.

Dr. R. F. Eminson, who practised in Scunthorpe, died at his home there on November 19, aged 69.

Ralph Franklin Eminson was born at Scotter in Lincolnshire on May 10, 1889, the son of Dr. T. B. F. Eminson. Educated at the Leys School, Cambridge, and Epsom College, he went on to study medicine at Charing Cross Hospital, graduating M.B., B.S. in 1911 and winning the gold medal in surgery. After holding resident posts at his teaching hospital, he joined his father in the large country practice in which he was brought up. Later he practised with his son in the steel town of Scunthorpe.

J. R. B. writes: With the death of Dr. Ralph Franklin Eminson the people of this corner of North Lincolnshire lose a good doctor and a very fine man. It must be rare to find in one locality grandfather, father, three brothers, then one son and two nephews, all of whom have been or now are medical men. Dr. Ralph was of the line of Eminson, well known round these parts for their high tradition of sound doctoring. The gentle, kind, thoughtful practitioner did not in his later years readily suggest the rugged enthusiast of hospital days, the R.A.M.C. officer whose D.S.O. and mentions in dispatches in the first world war were awarded for devotion to duty and rescue work in Flanders. His somewhat hesitant speech tended to obscure, to those who knew him little, the real value of his contributions to committee work and of his questions and comments at scientific meetings. He was a member of the local panel committee, the local medical committee, and the executive council for the County of Lindsey. A staunch supporter of the B.M.A., he was a wise and helpful member of the Scunthorpe Division and was its chairman in 1937-8. He played his part too in other local affairs and in his church, and the esteem in which he was held was shown by the mourners from all walks of life. His fortitude and calm acceptance of his long illness, which he knew must bring his life to a too early close, was an example to all associated with him. His fellow practitioners showed by their numbers at the funeral service the respect and affection they had for the doyen of the local medical profession. His wife, who died while still in early middle age, was a dearly loved and respected member of the local community, playing her part on the bench and in her church and other social spheres. To their two daughters and son, and indeed to all his close relations and to his patients, to whom Dr. Ralph Eminson was such a friend, we offer our sympathy.

FRANK KING, M.B., Ch.B.

Dr. Frank King, general practitioner, author, and playwright, died at the Royal Halifax Infirmary on December 3 at the age of 66.

Frank King was born at Causeway Foot, near Halifax, on February 12, 1892, and was educated at Rishworth and Bradford. A medical student at Leeds University, he graduated M.B., Ch.B. in 1914, and then practised in Leeds for a time, in partnership with Dr. J. J. Anning, before entering the R.A.M.C. for service in the first world war. Soon after his return to civilian life he settled in practice at Halifax, where he remained for the rest of his life. He gave up medical practice in 1936 and thenceforward devoted his whole time to writing. Before retiring he had already written a number of successful crime stories and thrillers. His favourite creation, "The Dormouse," came later, and appeared in several of his books, the latest of which was published only last month, while another is due out early

next year. Alone, and with the Rev. L. J. Hines, Dr. King also wrote a number of plays for stage and radio, and he was closely associated with the Halifax Thespians. When the Crime Writers' Association was formed in 1953 he became a member. The authorship of over thirty books gave him great satisfaction, for he regarded writing as a recreation. He leaves a widow.

H. M. WILSON, O.B.E., M.B., B.Chir., F.R.A.C.S.

Mr. ALAN SMALL writes: When I read Dr. Harry Wilson's obituary in the *Journal* of November 29 (p. 1360) I felt quite sad to think that the miniature of such a grand life should be so chronologically accurate and yet so unrevealing. For Harry Wilson was an interesting man both in himself and as an outstanding example of a disappearing Colonial type—a man of very great capacity, integrity, and a gift for leadership who chose quite deliberately to exert his influence and live his life in a small community in which he had his roots and for which he retained his love. His natural capacity was broadened by his training at Cambridge and St. Mary's (of whose XV he was an inspiring captain). His service to his community was fortified by the balance and integrity of his character, and by his very great skill as a doctor/surgeon. In these days of specialization we are apt to forget and even belittle the services rendered by those superior men who had added exceptional technical skill and knowledge to a basic desire to serve among people they knew. Harry Wilson was such a man. He made few mistakes and none from lack of thoroughness and care. New methods and new learning will help his successors to better his results, but there will be few to make better use of the knowledge which it is their privilege to use.

Sir JOHN MEGAW, K.C.I.E., D.Sc., M.B., B.Ch.

The obituary of Sir John Megaw was printed in the *Journal* of November 8 (p. 1166).

Major-General HUGH STOTT, I.M.S. (ret.), writes: The death of our old friend, Sir John Megaw, leaves a lasting memory of a great gentleman of distinguished and youthful appearance and a kindly gentleness combined with a penetrating scientific mind which was so essentially practical. I first met Megaw close on half a century ago, shortly after he, Leonard Rogers, and others in Calcutta had become engrossed in the relationship between epidemic dropsy and beriberi. The Mohammedan recruits of the regiment in Southern India to which I was attached became heavily affected with symptoms indistinguishable from epidemic dropsy, which in some cases cleared leaving a residue of dry paretic beriberi. The Hindu recruits remained entirely healthy. The complete records were sent to Captain Megaw, who, with characteristic enthusiasm, asked me to stay with him, arranging for unforgettable discussions with the Calcutta Medical College physicians and with Major (as he then was) Leonard Rogers, professor of pathology. This, in 1911, was the beginning of a long friendship.

The then recently established King George V Medical College at Lucknow was indeed fortunate in having Megaw posted as its professor of pathology and principal and one of its three clinical physicians in succession to Colonel Selby, D.S.O., I.M.S. During the long war years, with his calm manner, winning smile, and devoted efficiency, Megaw built up that fine spirit which became a characteristic of the Indian staff and students of the college, and so prepared the way for the handing over of its control from the local government to that of the Indian administration of the Lucknow University. This was the first experiment of such a medical transfer in All-India. After the first world war it became my lot to succeed Megaw at the Lucknow Medical College. Manifold evidence of the fruition of his work during six years there existed on every hand, and of the extension of that harmony which already existed in the college to his colleagues in the other faculties and to the Indian administrative officials of the University. His bungalow and garden were bequeathed to me, together

with his love of plants and flowers, which were, perhaps, mainly the offspring of the labours of his charming wife, who was so happy a support to him in all his social and professional work. At this time Megaw continually stressed the advantages of modern air-conditioning, then almost unknown in India, for better work-output in hot climates. Nor was he satisfied until I had personally adopted it and realized the advance it was. At frequent intervals Megaw returned as external examiner in pathology to the medical college for which he had done so much. At those visits the post-war progress of the college in all its diverse ways and the welfare of its students were always a first concern to him.

Apart from his wide clinical, scientific, and administrative abilities, it is surely for his generous humanitarianism that Megaw will be remembered. And it is certain that in present-day India his numerous old students and friends will read his obituary with affectionate remembrances and with appreciation of one of the very greatest of those officers of the Indian Medical Service who served the land of their adoption so faithfully and so well.

F. F. STROTHER SMITH, M.D.

Colonel F. F. Strother Smith, who served in the Indian Medical Service for most of his professional life, died at Bromley, Kent, on June 21. He was 74 years of age.

Fleet Floyd Strother Smith was born on July 30, 1883. From Campbell College, Belfast, he entered Edinburgh University as a medical student, and graduated M.B., Ch.B. in 1907. He proceeded to the M.D. in 1912. Passing into the Indian Medical Service in 1908, he served at Gallipoli and in Salonika in the first world war, and was decorated with the Order of St. Sava by the Serbians. Between the two world wars he served in India in many capacities, and was appointed Honorary Surgeon to the King and also to the Viceroy. He retired from the I.M.S. in 1940, but was re-employed, and served in the second world war as a surgical and as an ophthalmic specialist in several military hospitals. Colonel Strother Smith was a nephew of the famous "Jullundur" Smith, and, using his uncle's technique for the intracapsular extraction of cataract, performed during his service very many operations, probably hundreds. He was a great lover and judge of dogs, and was at one time president of the Bull Terrier Club of India, and, latterly, chairman of the Indian Kennel Club, and a constant attendant at gun-dog trials. To his widow and family we extend our sympathy.—A. R.-G.

Medico-Legal

INDECENT ASSAULT UNDER PRETENCE OF MEDICAL EXAMINATION

[FROM OUR LEGAL CORRESPONDENT]

A curious but classic expedient of those whose foible is indecent assault on women is the pretence of being a medical man conducting a clinical examination requiring removal of the clothing. An example of this was recently before the courts.

A man, aged 52, pleaded guilty at Blackburn Quarter Sessions recently to two charges of indecent assault on girls, and asked for a third similar offence to be taken into consideration. His technique was to advertise in a newspaper for a magician's assistant. When a girl went for interview in answer to the advertisement he would explain that as the job entailed going abroad a physical check-up would be necessary, and he said that he was a medical man as well as a magician and was prepared to do the examination. When the girl, believing an examination to be necessary to get the job, agreed to be examined by him, he improperly assaulted her in the course of the examination.

The man, who was married to a good wife and had a family and a well-kept home, was sentenced to nine months' imprisonment.

Medical Notes in Parliament

Booster Doses of Polio Vaccine

Mr. SOMERVILLE HASTINGS (Barking, Lab.) asked for what proportion of children under 15 years of age, who had had two injections of poliomyelitis vaccine, the parents had agreed to a third some months later; what proportion of children had already had a third injection; and what steps were being taken to urge parents to agree to this boosting dose. Mr. WALKER-SMITH replied on December 1 that third injections started only this autumn, and by the end of October nearly 250,000 had been carried out. This represented about a tenth of the children who had had their second injection seven months or more before that date. He had so far had no evidence of parents refusing to allow their children to have third injections when their turn came. Appropriate references to the value of the boosting dose would, however, continue to be made in the publicity about the vaccination scheme.

Medical Care Abroad

Miss ALICE BACON (Leeds, South-east, Lab.) asked with which countries the Ministry of Health had reciprocal arrangements for hospital treatment. Mr. WALKER-SMITH stated on December 1 that the Government had reciprocal social security agreements containing health service provisions which were open to all British residents in Sweden, Norway, and Yugoslavia, including tourists, and to limited classes of British nationals in Belgium, France, Luxembourg, and the Netherlands. In all cases hospital treatment was available for the persons covered. He added that discussions were in progress for a social security agreement with Federal Germany, but it was unlikely to provide medical benefit for British nationals other than pensioners resident there, and British workers.

Milk Consumption.—Consumption of liquid milk in the United Kingdom in the first ten months of this year amounted to 1,264 million gallons—about 12½ million gallons more than in the corresponding period in 1957.

Marriage Guidance.—The Home Secretary attaches great importance to the work of the National Marriage Guidance Council and the other organizations engaged in marriage guidance, and intends to propose to Parliament in due course that the grants shall be increased by 50% in the financial year 1959-60.

Chiropodists.—The registration of chiropodists is provided for in the draft scheme for the statutory registration of professions supplementary to medicine, which is under consideration.

Hearing-aids.—If there are no unexpected production difficulties, it is hoped to begin issues to adults towards the end of 1959 of transistor hearing-aids.

Universities and Colleges

UNIVERSITY OF EDINBURGH

At a meeting of the University Court on October 20 the title of honorary senior lecturer in the department of radiodiagnosis was conferred on Dr. Eric Samuel, and that of honorary assistant in the department of medicine on Dr. Jerome Rotstein, of the New York College of Medicine. Dr. Katherine M. Levy was appointed assistant in the department of public health and social medicine. The resignations of Mr. H. A. F. Dudley (lecturer in clinical surgery) and Dr. J. W. Galloway (lecturer in dentistry) were received.

UNIVERSITY OF LONDON

The following degrees were awarded during September:

M.D.—L. S. Sackler, E. Parry-Jones.
M.S.—M. A. Birnstingh.

The following candidates have been approved at the examinations indicated:

ACADEMIC POSTGRADUATE DIPLOMA IN CLINICAL PATHOLOGY.—Fatima S. Ahmed, M. Y. Ali, E. F. Bowers, R. Carroll, Betty M. Clark, C. H. Coetzee.

Vital Statistics

Industrial Accidents and Diseases

The number of workpeople (other than seamen) in the United Kingdom whose deaths from accidents in the course of their employment were reported in October was 73, compared with 102 in the previous month and 107 in October, 1957.

The numbers of cases of industrial diseases in the United Kingdom reported during October, 1958, were as follows: lead poisoning 10, phosphorus poisoning 2, epitheliomatous ulceration 16, chrome ulceration 14; total 42. There were 2 deaths from epitheliomatous ulceration due to mineral oil.—*Ministry of Labour Gazette*, November, 1958.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the years 1949-57 are shown thus - - - - -, the figures for 1958 thus ———. Except for the curves showing notifications in 1958, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Week Ending November 29

The largest fluctuations in the number of notifications of infectious diseases in England and Wales during the week ending November 29 were increases of 798 for measles, from 6,112 to 6,910, 351 for dysentery, from 747 to 1,098, 76 for scarlet fever, from 1,088 to 1,164, 38 for acute pneumonia, from 369 to 407, and the only decrease of any size was 33 for whooping-cough, from 757 to 724.

The largest rises in the notifications of measles were 189 in Middlesex, from 250 to 439 (Brentford and Chiswick U.D. 65); 154 in Cheshire, from 349 to 503 (Stockport C.B. 87); 68 in Lincolnshire, from 246 to 314 (Scunthorpe M.B. 158); 65 in Glamorganshire, from 77 to 142 (Cardiff C.B. 100); 62 in Hertfordshire, from 79 to 141 (Elstree R.D. 85); 52 in Derbyshire, from 111 to 163 (Shardlow R.D. 66); and the only large exception to an increasing incidence was a fall of 65 in Essex, from 252 to 187. The largest fall in the number of notifications of whooping-cough was 23 in Staffordshire, from 32 to 9. No large changes were recorded in the local returns for scarlet fever. 7 cases of diphtheria were notified, being 2 fewer than in the preceding week. 3 of these cases were notified in Birmingham C.B., and a further 2 cases occurred in the outbreak in Finsbury, London.

The notifications of acute poliomyelitis numbered 69—3 more for paralytic and 6 fewer for non-paralytic cases than in the preceding week. The largest returns were Lancashire 14 (Manchester C.B. 6, Liverpool C.B. 3, Chadderton U.D. 2); Yorkshire West Riding 13 (Leeds C.B. 10); Hampshire 11 (Southampton C.B. 10); Derbyshire 5 (Shardlow R.D. 3); Durham 5 (Darlington C.B. 2).

The largest rises in the number of notifications of dysentery were 78 in Yorkshire West Riding, 76 in Glamorganshire, and 43 in Essex. The largest centres of infection during the week were Yorkshire West Riding 176 (Leeds C.B. 90, Thorne R.D. 28), Lancashire 130 (Liverpool C.B. 38, Eccles M.B. 25, Fleetwood M.B. 25, Manchester C.B. 11), Glamorganshire 124 (Cardiff C.B. 93, Rhondda M.B. 16), Warwickshire 116 (Coventry C.B. 88, Bedworth U.D. 15, Birmingham C.B. 10); London 95 (Wandsworth U.D. 15, Lambeth 15), Essex 75 (East Ham C.B. 42, Epping and Ongar R.D. 16), Middlesex 51 (Hendon M.B. 33), Kent 43 (Royal Tunbridge Wells M.B. 33), Northumberland (Ashington U.D. 17), Nottinghamshire 31, Bedfordshire 26 (Amphill R.D. 25); Cumberland 22 (Carlisle C.B. 15), and Lincolnshire 20 (Grimsby C.B. 12).

INFECTIOUS DISEASES AND VITAL STATISTICS
Summary for British Isles for week ending November 22 (No. 47) and corresponding week 1957

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the whole of England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available.

The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES	1958					1957

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenza pneumonia.
‡ Includes puerperal pyrexia.

Medical News

Nuffield Committee for the Advancement of Medicine.—A decree reconstituting the Nuffield Committee for the Advancement of Medicine was approved last week by the Congregation of Oxford University. The object of the change is to meet Lord Nuffield's wishes that the income (about £110,000 per annum) from the trust fund given by Lord Nuffield in 1936 to finance medical research at Oxford University shall be restricted to expenditure on research, including expenditure on the training of postgraduate students in methods of research. The new committee for the advancement of medicine will be composed as before, but its duties will be to formulate policy and to prepare an annual report and accounts for submission to the trustees. The decree adds: "In making such annual reports the committee shall be required to satisfy the trustees that the time spent by the Nuffield professors of clinical medicine, surgery, obstetrics and gynaecology, anaesthetics, and orthopaedic surgery, and by the director of the Nuffield Institute for Medical Research in the instruction for students reading for the degree of B.M., shall not be such as to impair their prosecution of research and of the training of postgraduate students in methods of research." Explaining the new decree in Congregation, Mr. J. C. MASTERMAN said that a smaller special committee would be set up which would have the single function of administering the funds of the benefaction (*Daily Telegraph*, December 3). The proposals have been accepted by the United Oxford Hospitals and by the board of the faculty of medicine at Oxford.

Travelling Scholarship for G.P.s.—Details of a travelling scholarship offered by the trustees of the Claire Wand Fund are printed in the Association Notices this week (*Supplement*, p. 254). The purpose of the scholarship is to enable a general practitioner to study what is done for the further education of general practitioners in Canada and the U.S.A. The last date for the submission of applications is January 31.

Iron in the Home.—The danger of iron preparations to children in the home is again evident from figures published by the *Pharmaceutical Journal* (November 29, 1958). They refer to England and Wales in 1956 and were specially extracted by the General Register Office. Out of 15 children aged under 5 who died of accidental poisoning, 7 were poisoned by preparations containing iron. By contrast, among the remaining 341 cases of poisoning of persons aged 5 and over none was caused by an iron preparation.

Mr. H. J. Seddon, director of studies at the Institute of Orthopaedics, has been elected an honorary member of the Société Française d'Orthopédie and of the Société de Chirurgie de Lyon, having been a corresponding member of both societies for some years.

NEW ISSUES

The journals listed below are obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

Journal of Neurology, Neurosurgery and Psychiatry.—Issued four times a year (£3 annually). The new issue, Vol. 21, No. 4, includes:

FURTHER OBSERVATIONS ON SUBARACHNOID HAEMORRHAGE. Wylie McKissock, Kenneth Paine, and Lawrence Walsh.
LEUCOTOMY FOR PAIN. Alick Elithorn, Eric Gliether, and Eliot Slater.
A CONTROLLED STUDY OF THE EFFECTS OF LEUCOTOMY. A. A. Robin.
THYROTOXIC MYOPATHY. Ragnar Hed, Lennart Kirslein, and Curt Lundmark.
INDIVIDUAL VARIATION IN THE SIZE OF THE TENTORIAL OPENING. J. A. N. Corbelli.
ARTERIES OF THE SPINAL CORD IN THE CAT. Peter Bradshaw.
ACCOMMODATION IN THE HOLMES-ADIE SYNDROME. G. F. M. Russell.
THE EFFECT OF RESERPINE ON THE DURATION OF MANIC ATTACKS. David C. Watt.
A CONTROLLED TRIAL OF MEPROBAMATE IN ANXIOUS OUT-PATIENTS. John M. Hinton.
MYELOID CELLS IN CEREBROSPINAL FLUID. A. I. Spierres.
TWO HUNDRED AND ONE CASES OF INTRACRANIAL TUBERCULOMA TREATED SURGICALLY. C. Afsari.

Journal of Clinical Pathology.—Issued six times a year (£4 4s. annually). The new issue, Vol. 11, No. 6, includes:

SYMPOSIUM IN HONOUR OF THE CENTENARY OF VIRCHOW'S "CELLULAR PATHOLOGY" (1858-1958):
1858. Sir Roy Cameron.
DIAGNOSIS FROM CELLS. J. Bamforth and G. R. Osborn.
THE BACTERIAL CELL. Robert Cruickshank.
THE CELL IN CULTURE. Honor B. Fell.
CYTOCHONDRIAL ASPECTS OF CELLULAR PATHOLOGY. John W. Harman.
TWO BIOCHEMICAL ASPECTS OF CELL NECROSIS. N. H. Martin.
EXTENSION OF THE LIMITS OF CELLULAR PATHOLOGY: THE ROLE OF ENZYME HISTOCHEMISTRY. A. G. Everson Pearce.
THE EFFECT OF REDUCED OXYGEN TENSION ON PLATELET FORMATION IN VITRO. R. J. V. Pulveritt.
THE ANTIBODY CONTENT OF SINGLE CELLS. M. C. Berenbaum.
THE CHAIRMAN'S SUMMING-UP. G. J. Cunningham.

Medical and Biological Illustration.—Issued four times a year (£3 annually). The new issue, Vol. 8, No. 4, includes:

MYXOEDEMA. J. H. Briggs.
MAX BRÜDEL, 1879-1941. Sylvia Treadgold.
THE ILLUSTRATION OF BRAIN SECTIONS FOR REPRODUCTION. W. Hewitt.
SILHOUETTES. C. E. Engel.
A METHOD OF PRODUCING MODELS OF HOLLOW ORGANS. J. A. E. Gleave.
FLASH PHOTOMICROGRAPHY OF LIVING ORGANISMS. B. A. Jarrett.

Abstracts of World Medicine.—Issued in the first week of each month, this journal contains abstracts of important papers selected from the current medical literature of the world. Annual subscription £4 4s.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, December 15

● GUY'S HOSPITAL.—At Anatomy Lecture Theatre, 5.15 p.m., lecture: demonstration in endocrinology by Dr. P. M. F. Bishop: Anomalies of Sex Differentiation. Guest speaker, Dr. P. E. Polani. A clinical exhibition will be on view before the lecture.
● HUNTERIAN SOCIETY.—At Talbot Restaurant, London Wall, E.C.4, 7 for 7.30 p.m., dinner meeting, 8.30 p.m., discussion: Human Endurance. To be opened by Sir Vivian Fuchs and Dr. O. G. Edholm.
MANCHESTER MEDICAL SOCIETY: SECTION OF GENERAL PRACTICE.—At Clinica! Sciences Building, York Place, 8.30 for 9 p.m., medical film programme.

Tuesday, December 16

ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Dr. J. G. Scadding: Sarcoidosis—Diagnostic Aspects.
ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH.—5 p.m., Sydney Watson Smith Lecture by Professor R. Platt: Some Consequences of Renal Inadequacy.
SOUTH-WEST LONDON MEDICAL SOCIETY.—At Bolingbroke Hospital, 8.30 p.m., Mr. R. S. Lawrie: Some Surgical Cases.
WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Mr. L. C. Oliver: Contributions of Surgery to the Treatment and Understanding of Parkinsonism.

Wednesday, December 17

BIRMINGHAM MEDICAL INSTITUTE: SECTION OF PSYCHIATRY.—8 p.m., Sir John Wolfenden, Kt.: Homosexuality and the Law.
BRITISH PSYCHOLOGICAL SOCIETY: MEDICAL SECTION.—At Medical Society of London, 8.30 p.m., papers by Dr. S. I. Abrahams, Dr. V. J. Marmery, Dr. H. S. Pasmore, and Dr. M. Balint: The Integrating Role of the General Practitioner.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Guest lecture by Dr. J. M. Barnes: Experimental Study of Toxic Substances.
INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Mr. J. G. Sandrey: Epididymitis.

Friday, December 19

ROYAL MEDICO-CHIRURGICAL SOCIETY OF GLASGOW.—At Royal Faculty of Physicians and Surgeons of Glasgow, 8.30 p.m., Professor P. Alexander: Hamlet and the Psychoanalyst.

APPOINTMENTS

HOSPITAL FOR SICK CHILDREN, Great Ormond Street, London, W.C.1.—Rosalie E. B. Eastwood, M.B., Ch.B., House-physician; V. Ratner, M.B., B.S., Resident Officer to Neurological and Neurosurgical Department; E. P. Berwick, M.B., B.Ch., D.A., Resident Anaesthetist, Tadworth.
LIVERPOOL REGIONAL HOSPITAL BOARD.—Cynthia J. Discombe, M.D., part-time Consultant Pathologist giving six sessions per week to Ormskirk and District Hospital Management Committee group.
WOLLEN, W., M.B.E., Med.Dip., D.P.H., D.P.M., consultant psychiatrist and deputy physician superintendent, Darent Park Hospital.

BIRTHS, MARRIAGES, AND DEATHS

DEATHS

MacLean.—On November 10, 1958, at Arichat, Nova Scotia, Iain Malcolm MacLean, M.R.C.S., L.R.C.P., formerly of Isle of Skye, and Sierra Leone, aged 41.
Male.—On November 20, 1958, at Dorchester, Dorset, Maurice Taylor Male, M.B., D.P.H., Surgeon Commander, R.N., retired, of Upwey House, near Weymouth, Dorset, aged 83.
Robb.—On November 19, 1958, at Western General Hospital, Edinburgh, John Robert Beith Robb, M.D., F.R.F.P.S., B.L., J.P., of Torkillie House, by Carnoustie, Angus, formerly of Lenzie, Dunbartonshire.
Vlasto.—On November 17, 1958, at "Sherwoods," Hartley Wintney, Hants, John Alexander Vlasto, M.C., M.B.
Withey.—On November 10, 1958, Thomas Nicholson Withey, L.R.C.P., F.S.Ed., L.R.F.P.S., of Low Fell, Gateshead, Co. Durham, aged 83.
Witherspoon.—On November 15, 1958, at Bow End House, Betley, near Crewe, Cheshire, Allan Witherspoon, M.B., Ch.B., D.P.H., late of Stoke-on-Trent, Staffs, aged 68.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Treatment of Diphtheria

Q.—Has diphtheria antitoxin any place in the treatment of diphtheria? How should the general practitioner deal with a suspected case of diphtheria?

A.—Diphtheria antitoxin remains the only specific treatment for diphtheria: antibiotics have little if any place in the treatment. No doctor should take any risks with a suspected case of diphtheria. If the child is croupy he should be sent to hospital, as he needs expert treatment whether the croup proves diphtheritic or not. If a throat swab has been reported positive for diphtheria bacilli the patient should be sent to hospital: if there is membrane in the throat he will be treated urgently as a case of diphtheria; if there are few clinical signs, he will be isolated for several days until the results of a virulence test are known. If the patient has exudate on the throat which the general practitioner thinks might be diphtheritic, he should try to get the advice of a consultant from an infectious diseases hospital—the only person likely these days to have clinical experience of diphtheria. If admission to hospital is not arranged, a throat swab for organisms and blood for white cell count and Paul-Bunnell test should be sent to the laboratory. Infectious mononucleosis is the commonest cause of membrane in the throat resembling diphtheria. If the degree of suspicion is high enough to suggest giving antitoxin, then not less than 20,000 units should be given—this is an adequate therapeutic dose for a mild case of faucial diphtheria. But if antitoxin seems necessary, admission to hospital is even more necessary.

Cushing's Syndrome

Q.—How can one differentiate between the pituitary and adrenal types of Cushing's syndrome?

A.—The clinical features of these conditions are described by some as Cushing's disease and Cushing's syndrome, respectively, to denote the so-called pituitary and adrenal types. More generally the term Cushing's syndrome is used in the description of the whole group. It seems certain that in all instances there is increased formation of cortisol by the adrenals, and this is of the greatest importance in the production of the clinical features. The adrenals may be of normal size or, more usually, hyperplastic and occasionally the site of an adenoma or carcinoma. A patient with a tumour may occasionally be distinguished clinically by the additional presence of signs of virilization.

It is widely assumed that all the non-tumorous adrenals are stimulated by excess of secretion of corticotrophin by the anterior pituitary, but this has been shown to be true in only some and not all of the few cases examined. Sometimes small basophil adenomas are present in the pituitary but are not large enough to be detectable by clinical means. Rarely, larger basophilic or chromophobe tumours are found, sufficient to produce local radiological abnormalities or even an occurrence of visual changes due to chiasmal pressure. If such changes are present the pituitary can definitely be incriminated. More usually the problem resolves itself into an attempt to demonstrate the presence of an adrenal tumour, and this may be based on some or all of the following observations: (1) Abnormal renal position shown by I.V.P. (2) Outline of tumour by presacral air insufflation. (3) Excess excretion of adrenal corticoids with notable increase of 17-ketosteroids. (4) Poor response of corticoids to corticotrophin stimulation together with absence of significant diminution after the administration of suppressing steroids such as 9 α -fluorohydrocortisone. (5) The

presence of secondary growths (although here care must be taken to distinguish those occasional cases of Cushing's syndrome associated with bronchogenic carcinoma). (6) Operative demonstration of a tumour.

The practical importance of making the questioner's differentiation is that tumours of the adrenal should always be removed if this is possible. In some cases where it is thought that the pituitary is excessively stimulating the adrenal, it may be desirable to treat by local application of β radiation, proton bombardment, x-irradiation, or possibly by hypophysectomy, rather than choose the alternative of subtotal or total bilateral adrenalectomy.

Nystagmus

Q.—In the absence of organic disease, can nystagmus be present in a person who is not under the influence of drink or drugs?

A.—Congenital nystagmus can occur in the absence of any demonstrable lesion of the visual system or of the vestibular nerves and their central connexions. It is usually a rapid, pendular movement, sometimes associated with movements of the head. The condition may be present in several members of the same family. Hysterical nystagmus is said to occur, but the writer has never seen it. The tale is told of a medical student who was able to astonish his teachers by the voluntary production of nystagmus.

NOTES AND COMMENTS

Barbiturate Chemistry.—Mr. H. H. ARMSTRONG, F.R.I.C. (Stockport), writes: May I draw your attention to an error of chemical nomenclature (*Journal*, November 29, p. 1347)? Barbituric acid is classified as a diuretic, whereas it is, in fact, a cyclic monoureide. It is further suggested that the reaction for the formation of barbituric acid should show the working conditions—i.e., phosphorus oxychloride and 100° C.

Disclaimer.—Mr. B. W. RYCKOFF writes: My attention has been drawn to an article which was published in a Sunday newspaper on November 9, in which my name and those of my staff were mentioned. Would you please be kind enough to inform our profession, through your columns, that this article was published entirely without my knowledge, approval, or consent, and that no information was supplied to the newspaper by any member of my staff.

Corrections.—In the article on "Onset Enuresis" by Drs. J. D. Paulett and E. Tuckman (November 22, p. 1266) the word "unreasonably" appeared instead of "unreasoningly" in the sixth line of the right-hand column on p. 1267.

In the article on "Drugs in Treatment of Epilepsy," by Dr. D. Williams (*Journal*, November 8, p. 1155) the long-acting phenobarbitone should have been described as in "spanule" form, not "enseal."

Collected Articles from the "British Medical Journal"

CORONARY HEART DISEASE AND PHYSICAL ACTIVITY OF WORK

EVIDENCE OF A NATIONAL NECROPSY SURVEY*

BY

J. N. MORRIS, F.R.C.P., D.P.H.

AND

MARGARET D. CRAWFORD, M.D.

Social Medicine Research Unit of the Medical Research Council, London Hospital

It has previously been shown that the drivers of London's double-decker buses are more likely to die suddenly from "coronary thrombosis" than the conductors, and that Government clerks suffer more often from rapidly fatal cardiac infarction than do postmen.^{1,2} On the basis of these and similar observations a hypothesis has been stated that *men in physically active jobs have a lower incidence of coronary (ischaemic) heart disease in middle-age than men in physically inactive jobs. More important, the disease is not so severe in physically active workers, tending to present in them in relatively benign forms.*

It is a principle of epidemiological research of this type to seek evidence from as many, as various, and as independent sources as possible.¹⁰ The present report deals with the frequency, in relation to occupation, of ischaemic myocardial fibrosis in men dying from causes other than coronary heart disease itself. These myocardial scars are often evidence of early coronary heart disease and of less severe, or at any rate non-lethal, ischaemia. Thus the present study provides a picture of coronary heart disease in one of its simpler forms, and this may help in elucidating social connexions. At the same time another test of the hypothesis is made, using quite different data from the previous inquiries and upon quite another aspect of the condition. The inquiry it was hoped would provide some information on the pathological mechanisms of any differences with physical activity of work that were found: and in particular we sought to learn something about the relationships of occupation to coronary artery disease. In brief, Can the hearts of men be seen to vary with the kind of work they have done? At what phases in the complex of coronary-myocardial disease as a whole can this particular "cause"—physical activity/inactivity—be seen to operate? More generally the inquiry was intended to provide a statistical account of the coronary arteries of the middle-aged British male population, 1954-6.¹²

Method

Through the universities and regional hospital boards we appealed personally to all pathologists in the National Health Service who might regularly be in

*Part of this report was included in the Ernestine Henry Lecture delivered by one of us (J.N.M.) before the Royal College of Physicians of London on June 10, 1958.

charge of post-mortem examinations to co-operate in the inquiry, and the pathologists of 206 hospitals or hospital groups—between 85% and 90% of the "possibles"—very kindly agreed. We cannot be more precise about this fraction, because it is not known whether some of those who did not reply at all to our letters were in fact regularly responsible for appreciable numbers of necropsies.

Each pathologist was invited to provide particulars on a standard form of 25 consecutive unselected necropsies on men aged 45-70 years, no matter what the cause of death or how the case came to necropsy. 5,000 reports were sent to us: trial runs with records from 1944 to 1951 in the Pathological Institute of the London Hospital^{19, 60} had encouraged the hope that with such numbers stable group patterns would emerge. In all cases *macroscopic details* were requested of *disease in the coronary arteries*, its nature, amount, and distribution, with descriptions of any stenosis; and of *fibrosis of the myocardium of the left ventricle and interventricular septum*, using lesions of 1 cm. in any dimension as markers; and the *heart weight*. Particulars were also asked about the main causes of death and other important clinical and pathological findings such as valvular heart disease, including especially aortic stenosis. By appealing for detailed descriptions of lesions seen, discouraging evaluations such as "slight" or "much," and giving guidance on terminology if not on technique, we hoped to reduce the variability of such procedures. It was postulated, moreover, that the variability in observation and recording over so many departments of pathology would be "random" in relation to the main factor with which pathology was to be correlated—physical activity of work.

The pathological data on each record relating to disease in the coronary arteries and fibrosis of the myocardium were graded, agreed, and coded by at least two and often three physicians in the unit. It took many months to define appropriate scales; but finally scales emerged that made pathological sense, were simple in use, having no more than five points, and the gradings on which proved highly reproducible by ourselves and by others.

Pathologists were also invited to give details of the *last occupation* of the deceased, but in many cases this information had to be obtained by the unit from the

General Register Office. The last stated occupation, apart from other difficulties,³⁷ is unlikely to be an exact indicator of men's jobs during their middle-age. The present inquiry, however, is concerned only with *type of job* in terms of its characteristic *physical activity*. Some special categories apart, the last job is probably by and large an adequate indicator of this. (Occupational histories of their national series kindly made available to us by Doll and Hill^{11, 13} showed on analysis that among 152 fatal cases of lung cancer in men aged 55-64, 80% had been in the same job for more than their last 10 years and a further 10% had changed jobs during the last 10 years of life but remained in the same physical activity category. These proportions over 15 years were 70% and 14% respectively; over 20 years, 61% and 17%.)

The 1,700 different descriptions of occupations included in the 5,000 returns of the present inquiry were classified, in terms of the physical activity habitually involved, by two experts in industrial medicine who first graded all the jobs independently and then presented the unit with an agreed coding. They used a three-point scale: typically "light" jobs (for example, schoolmaster, bus-driver, clerk of any description); "active" jobs (for example, postman, carpenter); or "heavy" jobs (for example, boilermaker, dock labourer). Light jobs, that is, include sedentary; heavy include the heaviest.

The technical problems involved in such studies as the present have already been considered,^{37, 40, 42} and further comments are included in this and will be given in subsequent papers. There are many imperfections in the data on both biological and social sides of the equations to be attempted. The method used, like any other, and more than most, has its limitations as well as its possibilities. In particular, detailed occupational histories could not be obtained, which may be a considerable loss, and more than occupation-wise, since related economic/nutritional standards varied far more widely in the 1930s than in the 1950s.^{13, 36, 51} Moreover, considered agreement on pathological techniques, not to say uniformity, has been sacrificed for numbers. The crucial issue was that of range of occupation: only a countrywide and comprehensive survey gathering large numbers of cases from many different centres could include enough men in the diminishing categories of truly "heavy" workers—coal hewers, farm labourers, men in heavy engineering, and the like. The interest of the questions that can be asked only from the present kind of study will, it is hoped, compensate for what has had to be forgone—and suggest what might next be done.⁴¹

Material

Necropsy material may be classified for our present purposes as follows^{39, 42}:

Group A.—Deaths due to coronary heart disease: coronary heart disease itself; or with hypertension, and/or other pathology; and including slow, congestive cardiac failure as well as the more numerous sudden deaths. There were about 1,200 altogether in Group A.

Group B.—Deaths from conditions associated with a specially high prevalence or severity of coronary artery disease—for example, deaths from hypertension and its complications; deaths from vascular disease in sites other than the coronary arteries, with or without hypertension; ("senile") aortic stenosis; deaths from destructive renal disease; the cases of diabetes. In addition to such well-recognized associations it was noticed that deaths from

peptic ulcer in the present material showed a significant excess of occlusive coronary artery disease, and these deaths were therefore included in Group B. This group of 1,000 cases was called the *high coronary artery disease group*.

Group C.—Deaths from other conditions, the remainder and majority of necropsies, including injuries, infections, cancers. No disease or disease-group with 100 cases or over included in Group C showed significantly more or significantly less coronary artery disease at the 5% level than the remainder, as judged by the prevalence and amount of mural disease and the frequency of lumen narrowing of 50% or more in a major artery. This group is therefore called the *basal group* as regards coronary artery disease. There were 2,800 cases in it.

The present report deals with the 3,800 cases in Groups B and C. Brief reference is also made to Group A, but these cases will be fully considered on another occasion.

Ischaemic Myocardial Fibrosis

In some 500 of the 3,800 non-coronary deaths fibrosis was reported in the myocardium of the left ventricle and/or septum. All these records were scrutinized, and any subjects with rheumatic heart disease or other possible cause of myocardial fibrosis, the collagen-vascular diseases, for example, or ostial syphilis, were excluded: cases with generalized, "diffuse" fibrosis not otherwise described were also discarded. ("Myocarditis" was rarely mentioned by the pathologists; no microscopical examination was requested.) This left close on 400 cases with scars, commonly in the lower, antero-lateral walls of the left ventricle, in the front of the septum, or high on the posterior wall, which are presumptively ischaemic, will henceforth be regarded as *ischaemic myocardial fibrosis*, and have alone been analysed. In most of these 400 cases there was much coronary artery disease and a report of topical coronary narrowing.* The few scars in the right ventricle were ignored.

Scars were classified on two axes, whether they were single or multiple and large or small. Two main types of ischaemic myocardial fibrosis soon identified themselves, and provided a quick first answer to one of the main questions of the inquiry:

Type 1.—The *large, discrete patch* of fibrosis, over 1.5 cm. in one dimension, and often solitary. These patches were commonly transmural, and they are presumably the healed end-result of major and maybe acute infarction—"large healed infarcts"—or sometimes of confluent lesser infarcts. They were usually associated with occlusion or near-occlusion in the related main coronary artery, often high in it, rather than with lesser coronary narrowing. All aneurysmal dilatations have been included here, and also some large areas of fibrosis which were not clearly circumscribed.

Type 2.—*Small, multiple scars*, in the left ventricular wall, the septum, or papillary muscles which were usually thinner and less defined than type 1 and were associated in this material mostly with minor degrees of focal narrowing, low in a main coronary artery, for example, or in smaller branches. These scars are commonly regarded as the product of lesser and more slowly developing coronary insufficiency and myocardial ischaemia. However, some of this "focal myocardial fibrosis" may well be the result of very small infarcts.

It was soon apparent that the occurrence of a large patch was strongly related to physical activity/inactivity of occupation, the occurrence of the small multiple scars less so. Discrete patches of 0.5-1.5 cm. in diameter, and some very small scars also regarded as ischaemic, were all found to behave much more like type 2 in relation to occupation, to coronary narrowing (and, as seen later, to hypertension).

*In the minority of scars in which there was no record of topical coronary narrowing the same relationships with physical activity of occupation were observed as among the majority with a record of obstructive arterial disease. Only one tabulation is therefore presented.

than the large healed infarcts of type 1, and they have therefore been classified to type 2. All type 2 scars will, for convenience, be called "focal myocardial fibrosis." Mixed cases with both types of fibrosis were included with type 1.

Results

As stated, this report deals mainly with the (presumptively) ischaemic myocardial fibrosis found in a national sample of 3,800 non-coronary deaths in middle-aged men. Table I sets out the findings, first for the 2,800 miscellaneous deaths from injuries, infections, cancers, etc., and, below, for the 1,000 deaths from hypertensive and other vascular disorders, the deaths in diabetics, etc. Throughout, in each line of Table I, the rate among the "light" workers (e.g., 2.0% in the first line) is substantially higher than in the "heavy" (0.3% in the first line). The "active" rates mostly fall between, but occasionally are below the "heavy" (as in the second line of the Table). This trend was repeated time after time in the analysis of Group C, Group B, and various pathological, medical, and social subdivisions of these; it was found in Scotland, Wales, Greater London, and the rest of England, separately; in London teaching hospitals, other teaching hospitals, and non-teaching hospitals when these were distinguished; and it was also the main finding of the trial study of the 1944-51 Woods and Russell London Hospital cases.

The results in Table I can be summarized thus:

1. Disregarding age, cause of death category, and type of scarring (last line of the Table) there is twice as much

ischaemic myocardial fibrosis in the "light" workers as in the "heavy"—13.4% compared with 6.8%.

2. There is a stronger gradient with physical activity of occupation in the cases with large fibrous patches—three-fold overall, 3.5% to 1.2%—than in those with the smaller/multiple scars—9.9% to 5.7% (second and third last lines of Table I).

3. This excess of large healed infarcts among the "light" workers is more evident in the younger age group than at 60-70 years. At 45-60 years, in Groups B and C combined, there are four to five times as many of these scars in "light" workers as in "heavy"; at 60-70, two to three times as many (Table II).

Numbers are often small, but it seemed preferable to set out all the data instead of amalgamating the active and heavy occupations and comparing these with the light, which was the alternative the data indicated. Table I emphasizes that even among the heavy occupations there is a good deal of ischaemic myocardial fibrosis; though, in fact, large healed infarcts were as common in light workers aged 45-54 (2.0%) as in heavy aged 65-70 (1.9%).

TABLE II.—Large Healed Myocardial Infarcts. 3,800 Non-coronary Deaths. Men

Ages	Occupation		
	Light	Active	Heavy
45-60	2.3%	1.3%	(0.49%)
60-70	4.7%	2.6%	1.8%

TABLE I.—Proportions with Ischaemic Myocardial Fibrosis by Physical Activity of Occupation ("Light," "Active," "Heavy"). 3,800 Non-coronary Deaths. Males Aged 45-70

Age	Ischaemic Myocardial Fibrosis	Occupation			
		Light	Active	Heavy	
Deaths from Conditions in "Basal" Group

	Rate %	13.4%	8.7%	6.8%	

National Necropsy Survey, Scotland, England and Wales, 1954-6. Data from 206 hospitals or hospital groups. The number of non-coronary deaths that were analysed varied slightly around 3,800, depending on the availability of data. Forty-six cases have been omitted from this and all subsequent tables because information was inadequate, or it was impossible to classify a main cause of death to Groups A, B, or C (e.g., 12 cases of polyarteritis nodosa). In addition 114 non-coronary deaths have been omitted from tables dealing with the physical activity of occupation because the last job was unknown or could not be classified. Occupations were classified by Dr. R. Murray and Dr. D. Turner. Throughout these tables rates of ischaemic myocardial fibrosis are printed in italic. Rates based on a numerator of less than 5 cases are bracketed (). 45-60 years incl. 45-59 years 60-70 years incl. 60-69 years 45-70 years incl. 45-70 years. Because of the similarity of age distributions crude rates have been used throughout the analysis and tables in amalgamations of 45-70 years inclusive. Tests of Significance.—The test used in this table (and throughout this paper where relevant) is the test for linear trends in proportions (P. Armitage, *Biometrics*, 1955, 11, 375). A significant value of p indicates that the trend in the proportions (percentages) from "light" through "active" to "heavy" occupations is unlikely to be due to chance. The p values in separate subgroups—e.g., age groups 45-60 and 60-70—have usually been combined in the total groups—e.g., aged 45-70—the method of combination allowing for the fact that the trend was in the same direction in each subgroup. Third last line, p < 0.001; 2nd last line, p < 0.001; last line, p < 0.001.

Hypertension

Pathologists were asked to report any clinical or pathological evidence of hypertension, and much detailed information was provided for us. Using one at least of these criteria—(a) a clinical history of hypertension with record of diastolic pressure over 110; often there were particulars of treatment; (b) "concentric" left ventricular hypertrophy; or (c) in younger cases particularly, left ventricular hypertrophy not otherwise described or explained, together with nephrosclerosis—it was possible to distinguish those with "record or evidence of hypertension" from the "others." Close on 10% of the "basal" Group C had incidental hypertension as so defined. In almost half the cases of the "high coronary artery disease" Group B hypertension was present, and considered usually to be a principal factor in the death—for example, in many of the deaths from cerebrovascular disease.

The prevalence of ischaemic myocardial fibrosis in relation to hypertension is summarized in Table III, which shows no difference in the large fibrous patches (large healed infarcts) but substantially more of the smaller/multiple scars (focal myocardial fibrosis) among the hypertensive

($p < 0.001$). This latter excess, it may be noted, held for each of the subtypes of small scars and multiple scars included in type 2; whence the use of the term "focal myocardial fibrosis" for all of type 2 scars.

Table IV continues this analysis by occupation, and includes all the cases in Groups B and C—that is, all the non-coronary deaths. There is nothing of interest in the large fibrous patches, both the hypertensive (e.g., 4th line, in italics, left half of the table) and the "others" (e.g., first line in italics, right half of the table) showing the expected

6	0.01 > p > 0.001	0.02 > p > 0.01

This table amalgamates the "basal" and "high" coronary artery disease Groups C and B, and corresponds with Table I. 0 and 0% = No cases with ischaemic myocardial fibrosis. Tests were for trends in percentages from "light" through "active" to "heavy" occupations (cf. footnote to Table I). * Trend not significant—i.e., $p > 0.05$.

TABLE V.—Coronary Artery Disease by Physical Activity of Occupation. 3,800 Non-coronary Deaths. Males Aged 45–70

Coronary Artery Disease	No. of cases	"Basal" Group			"High" Coronary Artery Disease Group			All Non-Coronary Deaths		
		Occupation			Occupation			Occupation		
		Light	Active	Heavy	Light	Active	Heavy	Light	Active	Heavy
(1) Coronary atherosclerosis present	Rate %	85	82	82	91	90	86	87	84	83
(2) Much coronary atherosclerosis with focal obstruction ("severe disease")	Rate %	10	9	10	24	17	22	14	11	13
(3) Much coronary atherosclerosis without focal obstruction	Rate %	5.7	6.0	4.6	9.0	8.4	9.3	6.7	6.6	5.7
(4) Calcification present	Rate %	19	18	18	32	26	31	23	20	21
(5) Focal obstruction present including	Rate %	21	16	19	34	28	32	25	19	22
(6) Complete or near-complete occlusion of a main coronary artery	Rate %	3.7	3.0	2.5	10.3	7.3	5.7	5.8*	4.2	3.2

The figures in the last panel cannot be used directly as indicators, however crude, of the overall prevalence of coronary artery disease, and of its various manifestations, in the whole middle-aged male population of Britain. Even if the dead can be taken at all to represent the situation in the living, it must be remembered that deaths from clinical coronary heart disease (Group A) have not been considered so far. The great majority of these would of course show severe coronary artery disease, coronary occlusions, etc.; and, whatever proportion of such cases were added to set up a "model" of the total population, the totals of all 6 indicators, except (3), in the last panel would surely be raised. On the other hand, deaths from severe hypertension, as in Group B, are very likely over-represented. However that may be, it seems probable from what is known of the occurrence of clinical coronary heart disease in different occupations that the excess here reported of coronary occlusions among light occupations may be an underestimate. By the same token, there may well be some excess of severe coronary artery disease among light workers in the population as a whole.

* 0.02 > p > 0.01.

trend. But the picture is quite different in the smaller/multiple scars. Among the hypertensives the prevalence of this focal myocardial fibrosis was very high in light workers—22% of these patients aged 45–70 (21.5% and 21.6%) showed it. This rate is higher than that found in the active and heavy workers with hypertension, and much higher than in all with no record or evidence of hypertension (Others in Table). The effects are again clearer at 45 < 60 years; the light occupations showed these small scars almost three times more often at this age than the rest with hypertension, and six times more than the others without hypertension. At 60–70 years the figures are one and a half times, and three times, respectively. Indeed, this special excess of small, multiple scars in light workers with hypertension is largely responsible for the higher overall rate of such scars seen in hypertensives as a whole (Table III) when they are compared with the "others." (These "others" without record or evidence of hypertension, it is interesting, showed little variation of focal myocardial fibrosis with occupation among themselves, but what trend there was is also in the expected direction.) In brief, however,

The physical activity factor is clearly evident in the occurrence of smaller/multiple scars only in association with hypertension. At ages 45–70, light workers with hypertension showed these scars twice as often as active and heavy workers with hypertension, and five times more than all without record or evidence of hypertension. The excess in light occupations is, again, greater at 45 < 60 years than at 60–70.

Coronary Artery Disease

The next question, of course, is whether these various occupational differences in the prevalence of ischaemic heart disease are associated with corresponding differences in the prevalence of coronary artery disease and, in particular, of

Fig. 1.—Coronary artery disease, ischaemic heart disease, and physical activity of occupation. 1,800 non-coronary deaths. Males aged 45 < 60 years.

coronary narrowing. The pathogenesis of ischaemic myocardial fibrosis may be regarded for the present as coronary insufficiency, and the basic pathology is "atheroma" or "atherosclerosis" (the terms are interchangeable in Britain—and equally unsatisfactory) with focal coronary obstruction. Most ischaemic scars, it will be recalled, were associated with topical coronary narrowing, the large fibrous patches more commonly with complete or near-complete occlusions, the smaller/multiple scars with lesser degrees of coronary narrowing.

Statistical analysis of the condition of the coronary arteries in the 5,000 reports has only been started, and it will inevitably be on less sure ground than with myocardial fibrosis. Meanwhile, Table V presents some preliminary indices of macroscopic disease in the main arteries and large branches^{8 12 16 17 18 22 26 37 38 39 42 47 67} firstly for the basal group C and then for the high coronary artery disease group B, the main classification of the inquiry as a whole. These are the indices:*

(1) The presence of any reported coronary atheroma. Macroscopic intimal disease was reported in 85% of the cases in the light occupations of the basal group, 82% in the active occupations, etc.

(2) The proportion with severe coronary atherosclerosis, using mainly a simple quantitative five-point scale of "none," "little," "moderate," "much," "indefinite" disease. The minimum to qualify as "severe" was (a) "much" atheroma throughout the coronary arteries with large or confluent plaque formation—superficial flecking or streaking alone did not count—showing also (b) some focal obstruction.

(3) The presence of much mural disease without encroachment upon the lumen. Cases with arterial dilatation were also included here.

(4) The presence of calcification.

(5) The proportion with coronary obstruction—that is, lumen stenosis or narrowing of any degree; and including

(6) Complete occlusion or near-complete (e.g., "admitting fine probe only") of a main coronary artery (left, left anterior descending, circumflex, right). This alone was called "coronary occlusion."

Diffuse intimal fibrous thickening, by itself, was ignored.

There is much in Table V, but attention is here paid only to the frequency of coronary artery disease by occupation. Both in the basal group and in the cases of the high coronary artery disease group—Table V corresponds to Table I but is set out horizontally—gross coronary artery disease (1), (2), (3), and (4) is exceedingly common: however, there is no occupational trend of any interest. Index (5) again

reveals no material difference in the overall frequency of coronary obstruction among the occupation groups. In terms of one of the original hopes in the design of the inquiry the stability of these various indices of coronary artery disease is reassuring—if for other reasons disappointing! The first observation of note is in (6), the greater frequency of complete or near-complete occlusions in light occupations (5.8%) compared with heavy (3.2%). The rate of coronary occlusion, as defined, is about the same in light workers aged 45 < 60 as in heavy workers 10–15 years older (Table VI). Straightaway, however, it is obvious that the excess of occlusion in light workers is less than the excess of large healed infarcts already reported in Table II.

Comparison of the condition of the coronary arteries in cases with hypertension and in others showed much more atherosclerosis

*The Report of the World Health Organization's Study Group on the Classification of Atherosclerotic Lesions (*Wld Hlth Org. techn. Rep. Ser.*, 1958, 143) became available too late for use in this analysis.

TABLE VI.—Coronary Occlusion. 3,800 Non-coronary Deaths. Men

Ages	Occupation		
	Light	Active	Heavy
45-60	3.8%	2.8%	2.5%
60-70	7.6%	5.5%	3.9%

TABLE VII.—Severe Coronary Atherosclerosis. 3,800 Non-coronary Deaths. Males Aged 45-70

Cases	Occupation		
	Light	Active	Heavy
With hypertension	22%	19%	19%
No record or evidence of hypertension	12%	9%	12%

in the hypertensive throughout 45-70 years of age.^{26, 44} For example, the proportion with severe coronary atherosclerosis, as previously defined, was as shown in Table VII. The prevalence of coronary occlusions was higher in the hypertensive, and it was greatest again in the light occupations. There was no occupational trend, however, in the frequency of lesser degrees of coronary narrowing among the hypertensives; though, as stated above, these cases showed a strong light-heavy trend in the frequency of focal myocardial fibrosis, and the small/multiple scars are particularly associated with such lesser narrowing.

Fig. 1 illustrates these points in the most interesting cases, men under 60. If all such cases are taken together, there is no particular difference with occupation in the prevalence of severe coronary artery disease, or in the overall prevalence of coronary obstruction, but quite a clear trend in ischaemic scarring. There is a gradient with occupation in the frequency of complete or near-complete coronary occlusions—notice the change of scale—but a steeper one in the large healed infarcts. It is striking how, with similar occupational frequencies of coronary obstruction, the hypertensive cases (the most important cases in Group B have been used for this illustration—the deaths actually from hypertensive vascular disease, mostly cerebral) show a marked occupational difference in the frequency of focal myocardial fibrosis. On the other hand, in the cases without hypertension there are again similar prevalences of arterial obstruction in the occupation groups but, now, very little occupational trend in such scars. (The contrast with focal myocardial fibrosis is the same if the prevalence of lesser coronary narrowing alone is included.) It looks, then, as if much of the variation in ischaemic myocardial scarring with physical activity of work does not depend on occupational differences of, at any rate, gross coronary artery disease. Or, another way of looking at the data, there is no suggestion in the present material that habitual physical exertion materially affects coronary atheroma, but an indication that it is related to the frequency of coronary occlusion.*

*Hypertension. We have shown that focal myocardial fibrosis was commoner in hypertensive cases than in those without record or evidence of hypertension and that, among the hypertensives, light workers showed substantially more of these small scars than did the active and heavy workers. There is another point of interest. In this material, the proportion of cases with hypertension among heavy workers, throughout 45-70 years of age but more so in the younger men, is smaller than among light workers. In Group C, at 45-60, 3% of the men in heavy occupations showed it, compared with 8% in light; in Group B, 39% compared with 50%.⁴⁵ "Following through" this observation from the Group C through Group B into Group A, it may be seen in Table XII (next footnote) that the proportion with hypertension in these deaths from coronary heart disease, etc., was lower in heavy occupations than the others. Broadly speaking, in the material as a whole the frequency of hypertension in heavy workers aged 60-70 was the same as in light workers of 45-60 years of age.

Two special factors, then, may be operating in relation to hypertension: heavy workers possibly have less of it; and light workers with hypertension may be specially liable to cardiac damage. The suggestion that the combination of high blood pressure and light occupation may be particularly important, may provide a "way in" for the study of the complicated relations of hypertension with coronary heart disease.

Occupation and "Social Class"

The distribution, in Britain, of mortality from coronary heart disease by social class is well known. First established in 1930-2,⁴⁶ the most recent figures (Table VIII) relate to 1949-53.

TABLE VIII

Social Class	Scotland ⁴⁶ 58 Males, Aged 15 and Over		England and Wales ⁵³ 57 Males, Aged 20-64	
	I	II	III	IV
I	167	119	147	110
II	109	109	105	105
III	85	85	79	79
IV	79	79	89	89
All classes	100	100	100	100

The mortality in social class I (Osler's⁵² "better classes") when adjusted for age, as in the above, is much higher than in the rest and about twice that in classes IV and V.

"Social class" is intended to reflect "general standing within the community," social class I including the leading professions and business, class III the craftsmen and skilled workers, and class V the unskilled. Classes II and IV are intermediate. It seems clear that, for men in the age range dealt with, "class" also provides an economic grading.

The 3,800 non-coronary deaths of the present inquiry were analysed by social class⁵³: the present approach has the advantage that the "level" or "plane" of description and diagnosis is probably the same for all classes. The result in Table IX shows a steady fall in ischaemic myocardial fibrosis from 13.3% to 7.8%. This trend, however, disappears when the social classes are analysed in terms of the physical activity of the occupations in them. Table X(A), read downwards, shows that the frequency of the fibrosis in these light workers of similar ages is about the same in social classes I, II, III, and IV—that is, there is no

TABLE IX.—Proportions With Ischaemic Myocardial Fibrosis by Social Class. 3,800 Non-coronary Deaths. Males Aged 45-70

Social Class	No.	Proportion with Ischaemic Myocardial Fibrosis
I	98	13.3%
II	510	12.1%
III	1,847	10.5%
IV	605	9.2%
V	683	7.8%

The trend of the proportions with ischaemic myocardial fibrosis is statistically significant ($p < 0.01$). Occupations were allocated to social class in accordance with the General Register Office Classification of Occupations, 1950.⁵⁸ 102 cases could not be so allocated because of insufficient information.

TABLE X.—Proportions with Ischaemic Myocardial Fibrosis by Social Class and Physical Activity of Occupation. 3,800 Non-coronary Deaths. Males Aged 45-70.

Social Class	Light Occupations %	Active Occupations %	Heavy Occupations %	All %
I	13.7	(0)	—	13.3
II	13.4	9.2	(0)	12.1
III	13.8	8.0	8.2	10.5
IV	13.5	10.1	4.9	9.2
V	8.9	9.0	7.1	7.8
All	13.4	8.7	6.8	10.0

(A) Ischaemic Myocardial Fibrosis by Social Class and Physical Activity of Occupation:

I	13.7	(0)	—	13.3
II	13.4	9.2	(0)	12.1
III	13.8	8.0	8.2	10.5
IV	13.5	10.1	4.9	9.2
V	8.9	9.0	7.1	7.8

(B) Large Healed Infarcts by Social Class and Physical Activity of Occupation:

I and II	4.3	(2.1)	(0)	3.8
III	3.2	1.8	(1.2)	2.3
IV	(3.6)	2.1	(1.5)	2.3
V	(2.2)	(2.2)	(1.0)	1.5

(C) Focal Myocardial Fibrosis by Social Class and Physical Activity of Occupation:

I and II	9.1	6.9	(0)	8.6
III	10.6	6.2	6.9	8.2
IV	9.9	8.0	3.4	6.8
V	6.7	6.7	6.1	6.3

*No cases at all.

variation with social class and, incidentally, no indication of the particular excess seen in the national mortality data among social class I. There is again no class trend in the active occupations (middle column of Table X(A)) and less than none in the heavy. But reading Table X(A) across, the light-heavy trend previously reported is pretty clear within each social class, the light occupations showing more with scars than the active in class II, and the light in class III and class IV a higher prevalence than the active and heavy in these classes. That is to say, among men of comparable social-economic circumstances, those in light occupations showed a clear excess of ischaemic myocardial fibrosis.⁴³ As would be expected—Tables X(B) and (C)—the reduction in the frequency of fibrosis that occurs with physical activity of occupation within the social classes is more evident for the large healed infarcts; though the numbers in Table X(B) are impossibly small.

The irregularities in these tables are also interesting. Social class V stands out on its own, both in showing low rates among light workers and in showing little trend with occupation. It is just in these men that the classification of

occupations by "activity" is at its weakest. On the one hand, the light occupations—for example, lift attendant, night watchman—are reserved mostly for disabled persons; therefore the last and "light" job, more than in other classes, is apt to be an inaccurate indicator of the main or usual job during working life. On the other hand, all "general labourers" were perforce graded as "heavy" workers, though, as is well known, many an elderly "labourer," officially or unofficially disabled, does little more than odd jobs on a building site and the like, and may have been so occupied for years before his death. There is an irregularity in social class III because some very heavy workers—for example, stonemasons and boilermakers—have a high prevalence of scars, high for heavy workers; a hint here, perhaps, of the dangers of too much physical activity.⁴⁴ The rate for heavy occupations in class IV is particularly low because agricultural workers show little ischaemic fibrosis—little even for heavy workers. These special features of classes III and IV persist when the prevalence of scarring in these particular occupations is compared also with that of other heavy workers in the same

FIG. 2.—Frequency of ischaemic myocardial fibrosis, by physical activity of occupation. 3,800 non-coronary deaths. Males aged 45-70 years. In each block of three columns the first column is the rate among light occupations regarded as 100%. In the second column (active occupations) and the third column (heavy) the rates have been recalculated as proportions of the rate among light occupations. In each line the first block represents the large fibrous patches; the second block represents the smaller/multiple scars; and the third is the total of ischaemic myocardial fibrosis. n gives the numbers of cases in light, active, and heavy occupations in that order. The test of significance applies to the total of ischaemic myocardial fibrosis. In deaths from injuries active and heavy occupations have been amalgamated.

sets of necropsy reports, the kind of internal "control" that is so important in this type of study.⁴⁰

In brief, in this material there is no evidence of any important "class" factor. Most of the social class trend in ischaemic myocardial fibrosis seems to arise from the distribution of "light" and "heavy" workers among the classes (Table XI), though there is evidence also of other and it may be more specific occupational factors affecting the class rates. The association of ischaemic myocardial fibrosis with physical activity of work in these data seems to be independent of standards of living, including obviously in the present instance levels of education and skill and possibly also of responsibility.

TABLE XI.—Distribution of Occupations Within the Social Classes

Social Class	Percentage of			Total
	Light Occupations	Active Occupations	Heavy Occupations	
I	97	3	—	98
II	72	28	1	510
III	42	44	13	1,847
IV	18	47	34	605
V	13	26	60	683

Summing up the 3,800 Non-coronary Deaths

Fig. 2 sums up the main findings. In each block the rate of ischaemic myocardial fibrosis in the light occupations is regarded as 100%, and the rates in active and heavy occupations are calculated as proportions of this. In each line the first block illustrates the prevalence of the large fibrous patch, the middle block that of the smaller scars, and the third is the total of ischaemic myocardial fibrosis. (In the first two lines of the second column dealing with hypertensive disease the data have been amalgamated for 45-70 years of age in the large healed infarcts, but distinguished by the two age groups in focal myocardial fibrosis.) There is, of course, considerable overlapping in these various extracts from the data, and some of the numbers—the total is given in each line for light, active, and heavy in that order—are small. The tests of statistical significance apply to the total with scars in each line.

The consistency of the pattern is striking and makes it unlikely that the association of ischaemic myocardial fibrosis, and particularly the large healed infarcts, with physical activity of occupation is the product of some gross bias in this necropsy material. There is quite conceivably an association between ischaemic myocardial fibrosis and the chances of dying and/or undergoing necropsy. But it is less conceivable that such an association could be systematically greater in light occupations than heavy, so that with equal real prevalence of fibrosis among occupations the rate would appear higher in the light. And it is difficult to conceive how such a bias could be effective in the wide variety of disease (and other categories) illustrated in Fig. 2. But, of course, bias can be "built-in" in goodness knows how many ways, and no individual study can deal with all of even the recognized sources. Other studies will need to be done, and also on large numbers, to repeat these observations and to permit still further and quite different subdivisions of the data.

Evidence from 1,200 Deaths from Coronary Heart Disease

As stated before, about 1,200 of the 5,000 reports in the inquiry were on deaths in which coronary heart disease was the main cause—coronary heart disease by itself, or coronary heart disease with hypertension or with other pathology (for example, the post-operative cases)—together with a small number of less-defined though related

cardiac conditions. These 1,200 will be described elsewhere. Much less can be made of them because they raise acutely the intractable problem of selection of cases; problems that are of less moment, as just discussed, in conditions like ischaemic myocardial fibrosis which are not the main cause of death and are incidental and often chance findings at necropsy. Moreover, no base or denominator can be defined for the estimation of frequency rates of coronary heart disease—for example, by type of occupation. Less effort was therefore made to obtain a good national sample. Thus no request for co-operation was made to the coroners' pathologists in Greater London; though in the provinces many coroners' cases were included in the series of 25, and there were a fair number also, as a matter of fact, in the Metropolitan hospitals' series. However, the 1,200 deaths from coronary heart disease can be classified by occupation and ratios comparing the actual number of cases in each of the three occupation groups can be calculated. This was done.

There were 482 deaths from coronary heart disease and related conditions in light workers, 436 in active workers, and 230 in heavy workers, a ratio of 1.0:0.9:0.48; and there is little doubt, from previous inquiries by the unit,⁴¹ that if the London area had been fully represented the excess of light occupations among deaths from coronary heart disease would have been greater still. Meanwhile it may be noted that the trend with occupation in deaths from coronary heart disease is greater in the cases with hypertension than in the others.

Fig. 3 sets out the occupational ratios of the coronary heart disease and related deaths (Group A), and for completeness the ratios of the cases with ischaemic myocardial fibrosis in the high coronary artery disease group B, then of the cases with such fibrosis in the basal group C. Fig. d gives the ratio (using again the numbers in light, active, and heavy occupations) of all these cases with evidence of ischaemic heart disease in Groups A, B, and C added together—that is, in the whole series of 5,000. This is 1.0:0.84:0.43. Fig. 3e is for the rest of the 5,000 reports, those showing no evidence of ischaemic heart disease—1.0:1.05:0.64; and this ratio is plainly not of a kind with the previous ($p < 0.001$). For what such evidence is worth, then—and this is by no means the right way of asking this particular question—there is indication of higher mortality from clinical coronary heart disease among light workers.*

Discussion

An association has been demonstrated between physical activity/inactivity of work and one form of coronary heart disease, ischaemic myocardial fibrosis. Explanation of this may be attempted along several lines. First, that light occupation increases the incidence of ischaemic myocardial fibrosis, heavy jobs are protective. Second, that the association is effect rather than cause; on account of disability from myocardial ischaemia men give up heavy jobs for light ones and a higher prevalence of scarring is thereby created among light workers. Third, that the association is indirect:

*Other sums can be done with the data if required:

TABLE XII.—Number of Cases of Ischaemic Heart Disease in a National Sample of 5,000 Necropsies. Males Aged 45-70

Occupation	"Coronary" Deaths, Etc.		Non-Coronary Deaths, with Ischaemic Myocardial Fibrosis		Non-Coronary Deaths, with No Ischaemic Myocardial Fibrosis	Total

Total ..	323	825	89	287	3,355	4,879

160 cases were excluded for one reason or another, cf., Table I.

for example, susceptibility to coronary heart disease and individual choice of job may both be the product of host factors in constitution (and previous experience); or physical activity/inactivity may be reflections merely of the nervous strain of jobs, and it is this that really matters in coronary heart disease. All these processes, it could reasonably be proposed in the present state of knowledge, contribute to the community picture of coronary heart disease; but, of course, the first is the most interesting.

The present study sheds no light on personality factors, though we hope other inquiries in which we are engaged—on somatotype and occupation, for example—will do so.⁴² No attempt has yet been made to classify the 1,700 different job descriptions in terms, say, of responsibility, of nervous strain—and emotional support. This might be done; but it is an appalling prospect, and the similarity of the rate of fibrosis among the professional and business men of class I to that found in the semi-skilled light workers of class IV does not encourage us to try. The study of psychological stress in relation to coronary heart disease still lacks an appropriate method (we have long thought that a forward-looking study among doctors from their late thirties or early forties is the most hopeful). The possibility that the high prevalence of fibrosis in light jobs is the result of transfer by men into these because of coronary insufficiency has not

workers shows an excess. The heavy workers had less ischaemic fibrosis altogether, and relatively more of it took the form of smaller patches and small, often very small, scars. That is to say, in this material ischaemic myocardial fibrosis is not so severe in physically active and heavy workers. But the prevalence of these minor forms of myocardial fibrosis also was lower in active and heavy than in light occupations; which rather suggests that the excess of angina previously noted in physically active men (bus conductors and postmen) is more likely to be a matter of symptom formation, of the disease being elicited and made manifest in them by their physical effort, rather than of an absolute excess of any particular pathology in active workers.⁴³

Evidence can now be advanced relating physical activity of occupation to the incidence of coronary heart disease, to sudden death and other rapidly fatal cardiac infarction, to the prognosis in the survivors of the first clinical episode, to the prevalence of the disease, to total coronary mortality in middle-age, and to several forms of ischaemic myocardial fibrosis. The time seems to have come, in view of the convergence of such varied and independent evidence, for a restatement of the general hypothesis in causal terms: *Physical activity of work is a protection against coronary (ischaemic) heart disease. Men in physically active jobs*

have less coronary heart disease during middle-age, what disease they have is less severe, and they develop it later than men in physically inactive jobs.

It must be emphasized, however, that, overall, the evidence on this problem is quite conflicting.^{2 5 7 9 11 22 23 24 27 34 45 48 53 64 66 69}

In several studies coronary heart disease has been found to be associated with physical activity/inactivity of occupation in the expected way. In as many, no relationship was demonstrated, or an equivocal or opposite one; and why this is so is still quite unclear. Different methods are being

used by different investigators and different aspects of the disease are being studied. Moreover, the "epidemic constitution" may be different in the U.S.A. from the U.K.—the important causes may be present in different degrees and in different combinations.²²

Some speculations may be worth airing here. The diminishing physical activity of work during the present century may be one of the causes of the increasing incidence of coronary heart disease that seems to be occurring, and, if the increase is as modest as is now often suggested, a principal cause. This question might be studied through the historical experiences of "underdeveloped" populations becoming "westernized." If it is argued that constitution and mesomorphy is the crucial variable, unexpressed mesomorphy, the disuse of large-muscle masses, may be said to be one of the characteristic biological consequences of industrialization. Then, it may be asked whether regular physical activity outside work protects against coronary heart disease in middle-age. There is no information, meanwhile, on the relations, if any, between physical exertion in leisure, for example, and the incidence or prevalence of coronary heart disease; but plainly this is the main implication of observations such as the present for preventive medicine, and means of testing such a hypothesis must be found. Typical of to-day's problems in epidemiology, this will involve *ad hoc* studies of large numbers of individuals; and even preliminary indirect studies of coronary heart disease and leisure activities in ready-made social groups such as the social "classes" cannot be made.

A final speculation may be advanced that *habitual physical activity is a general factor of cardiovascular health in middle-aged men* since it may be related to blood lipid levels, to clotting and to fibrinolysis, to diabetes, to hypertension and its complications, to coronary occlusion, and to ischaemic heart disease.^{3 10 20 25 28 29 30 31 35 40 50 55 61} Regular physical exercise could be one of the "ways of life"

Fig. 3.—Ratios of the number of cases of ischaemic heart disease in the three occupational groups, the number in light occupations being regarded as 1.0. National sample of 5,000 necropsies. Males aged 45-70. Scotland, England and Wales, 1954-6. (a) Group A: Deaths from ischaemic heart disease, etc. (b) Ischaemic myocardial scars in cases of Group B. (c) Ischaemic myocardial scars in cases of Group C. (d) Showing a, b, and c added together. (e) All the cases without ischaemic heart disease.

been directly considered. It can only be said that the evidence available gives no hint that such transfer, which must surely be common, explains all or even much of the occupational distribution found. Thus the excess of scarring among light workers is no greater at 60-70 years of age than at 45-60, and, indeed, for the large patches it is more evident in the younger men. Moreover, it may again be pertinent that the rate among the light occupations of social classes I and II, drift into which from heavy jobs in unlikely, is just as high as that in class III, where such drift is more likely, and class IV, where it is very likely. In social class V itself there was little if any excess among the light occupations, which is as reassuring as it was unexpected: because, as already said, it is just these jobs—messenger, lift attendant, night watchman, and the like—that "disabled" manual workers so often select, and drift into, which for lesser impairment is also very likely. But this difficult and important problem needs to be tackled in other ways: an attempt is now being made in this unit, for example, to determine the prevalence of quite silent coronary heart disease by electrocardiographic study of workers with contrasting physical activity of jobs.

Restatement of Hypothesis

Another piece of evidence has thus been provided in this report that confirms the general hypothesis, and using on this occasion quite different material from before. In the present data as a whole, and in every sizable category of it, there was a lower prevalence of ischaemic myocardial fibrosis among men who had been in physically active and heavy jobs than among those in sedentary and light jobs. Study of the detailed morbid anatomy of this social difference supports the second part of the original hypothesis. It is particularly in the prevalence of the large, often and for obvious reasons solitary, patch of fibrosis, the probable result it may be said of major and acute infarction (and homologue of sudden death in the bus driver?) that light

that promote health in middle-age, and ischaemic heart disease may be in some degree a deprivation syndrome, a deficiency disease.

Mechanisms of the Occupational Difference

Nothing corresponding to the differences with physical activity which have been found in experimental atherogenesis^{11, 12} were observed in the present material. Clearly the main causes of coronary atherosclerosis in man have to be sought elsewhere—for example, in hypertension and, the principal field of interest at present, in diet and lipid metabolism. There is more coronary occlusion among the light occupations, which is particularly interesting because the factor of intracoronary thrombosis may be particularly associated with these complications of atheroma^{13, 14, 15, 16, 17, 18, 19, 20} and the present findings may be another indication of the relationship between physical activity and intravascular clotting.^{21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45, 46, 47, 48, 49, 50, 51, 52, 53, 54, 55, 56, 57, 58, 59, 60, 61, 62, 63, 64, 65, 66, 67, 68, 69, 70, 71, 72, 73, 74, 75, 76, 77, 78, 79, 80, 81, 82, 83, 84, 85, 86, 87, 88, 89, 90, 91, 92, 93, 94, 95, 96, 97, 98, 99, 100} If, as many would argue, the pathogenesis of all degrees of coronary obstruction is the same, then, it would appear, the capacity to cope and to resolve such obstructions must vary with occupation so that actual occlusion of large coronary vessels is less common in active and heavy workers than in sedentary and light workers. However that may be, the excess of coronary occlusion is inadequate to explain the excess of large healed infarcts in light occupations; and the other indicators of coronary artery disease so far studied do not help at all to account for the occupational distribution of the scarring. Mechanisms of the occupational differences in ischaemic myocardial fibrosis need therefore to be postulated that operate additionally to those of gross coronary artery disease,^{10, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45, 46, 47, 48, 49, 50, 51, 52, 53, 54, 55, 56, 57, 58, 59, 60, 61, 62, 63, 64, 65, 66, 67, 68, 69, 70, 71, 72, 73, 74, 75, 76, 77, 78, 79, 80, 81, 82, 83, 84, 85, 86, 87, 88, 89, 90, 91, 92, 93, 94, 95, 96, 97, 98, 99, 100} in general and local haemodynamics, it may be, in neuro-hormonal mechanisms, in special relationships with hypertension, in the physiological capacity of the main arteries and branches, in intercoronary collateral circulation.^{19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45, 46, 47, 48, 49, 50, 51, 52, 53, 54, 55, 56, 57, 58, 59, 60, 61, 62, 63, 64, 65, 66, 67, 68, 69, 70, 71, 72, 73, 74, 75, 76, 77, 78, 79, 80, 81, 82, 83, 84, 85, 86, 87, 88, 89, 90, 91, 92, 93, 94, 95, 96, 97, 98, 99, 100} Recently it has been observed that effective collateral vessels in dogs with coronary obstruction develop more profusely if the dogs are exercised; functional myocardial hypoxia might be the mechanism relating physical activity to collateral formation.^{19, 20}

Distinction of Ischaemic Heart Disease from Coronary Artery Disease

In the first report of the present series³⁹ it was suggested that the recent history of coronary thrombosis/myocardial infarction on the one hand, and that of coronary atheroma on the other, are different. The former, there is good reason to believe, have increased during this century; there is no evidence whatever in Britain that the latter has, and, indeed, coronary atheroma may have declined here during the past 40 years.^{40, 41} The historical material, that is to say, suggests that ischaemic heart disease is not a simple, proportional function of coronary atherosclerosis. The evidence now presented goes further in dissociating the heart disease from the arterial disease, because it suggests that even when the latter is analysed into obstructive and non-obstructive processes nothing like a 1:1 relationship emerges between myocardial damage and the obstructive arterial disease. Social grouping of the pathological data (by occupation) shows substantial differences in the frequency of myocardial fibrosis which correspond only moderately to the frequency of coronary occlusions and correspond not at all to the frequency of lesser narrowing of the coronary lumen. Such identification of syndromes from undifferentiated clinical material—in this instance of ischaemic heart disease from coronary artery disease—is one of the uses of epidemiology, and theoretically is of much interest.⁴²

A Word on the Method

Finally, it may be remarked that post-mortem reports are just about the most difficult medium for epidemiological analysis: many sources of bias in the material are known; as many, it must be assumed, are quite unknown. The use of necropsy data finds its main warrant in asking questions, such as the present report illustrates, that cannot be asked by any other method. But the limitations of any one set

of data, with its inevitably imperfect "population" samples and incomplete ascertainment of disease, make it very necessary that studies are repeated in quite different situations.

Summary and Conclusions

This report is one of a series on the epidemiology of coronary disease, and it continues the study of coronary (ischaemic) heart disease in relation to physical activity of work.

The hypothesis was previously stated that *men in physically active jobs have a lower incidence of coronary heart disease in middle-age than men in physically inactive jobs. More important, the disease is not so severe in physically active workers, tending to present in them in relatively benign forms.* The investigation now reported deals with the relations between physical activity of work and the frequency of ischaemic myocardial fibrosis in a sample of 3,800 middle-aged men dying from causes other than coronary heart disease.

All departments of morbid anatomy in the hospitals of the National Health Service of Scotland, England, and Wales were invited to take part in a national necropsy survey during 1954-6 by sending particulars in standard form of the naked-eye findings on the coronary arteries, the myocardium, and other specified items for a consecutive series of 25 males aged 45-70 years coming to necropsy. 206 departments co-operated, more than 85% of those eligible. About 5,000 reports were received, made up in round numbers thus: 1,200 deaths from coronary heart disease, etc. (Group A); 1,000 deaths from conditions with a specially high prevalence of coronary artery disease—for example, deaths caused by hypertension and its complications, deaths in diabetics, deaths from arterial disease in other sites (Group B); and, the remainder, 2,800 deaths from miscellaneous conditions, their main causes having no particular association with coronary artery disease—for example, injuries, infections, cancer (Group C). Groups B and C comprise 3,800 non-coronary deaths.

Two broad types of *ischaemic myocardial fibrosis* in the left ventricle and interventricular septum are described: (1) the large, discrete, often solitary patch which is probably the end-result of major and acute infarction and is associated particularly with complete or near-complete occlusion in a main coronary artery (90 cases among the 3,800 non-coronary deaths); and (2) smaller, commonly multiple scars, the result, it may be, of more chronic and less severe ischaemia, and occurring in hearts showing usually lesser focal narrowings of coronary arteries or branches (290 cases).

Cases were classified as "hypertensive" or "other" on the basis of the clinical and pathological information provided. About half the cases in Group B and 10% of those in Group C were thus regarded as hypertensive. The large healed infarcts—type 1 fibrosis above—were found equally in hypertensive and other cases; focal myocardial fibrosis of type 2 was commoner in hypertensive cases than in those without record or evidence of hypertension.

The last occupation of each man was graded on a three-point scale in terms of the physical activity the job typically involved as "light," "active," or "heavy."

Relation of Fibrosis to Occupation.—Ischaemic myocardial fibrosis in these 3,800 necropsies was commoner in the light occupations than in the active and heavy. Scarring among light workers aged 45-60 was as common as in heavy workers 10 to 15 years older.

The two main types of ischaemic fibrosis were differently related to physical activity of occupation:

The *large healed infarcts*, type 1 above, showed a strong gradient with occupation, being *three times* commoner in light workers than in heavy workers overall; *four to five times* commoner at 45-60 years of age, and *two to three times* commoner at 60-70 years. The excess of these severe ischaemic lesions in light workers was evident in Group B and in Group C, in hypertensive cases as in others, in every sizable medical and social category that was identified.

Focal myocardial fibrosis, type 2, was strongly associated with occupation only in hypertensive cases. Under 60 years of age, the light occupations among the hypertensives showed these small, multiple scars almost *three times* more often than active and heavy workers with hypertension, and about *six times* oftener than all without record or evidence of hypertension. The corresponding figures at 60-70 years of age were *one and a half* and *three times*.

In brief, ischaemic myocardial fibrosis was commoner in light occupations and it appeared earlier in them. It was also more severe among light workers, particularly at younger ages.

Coronary Artery Disease.—The pathological basis of ischaemic myocardial fibrosis is coronary "atheroma" or "atherosclerosis" with impairment of the coronary circulation. In the present data the overall prevalence of coronary atheroma was exceedingly high, and, little, moderate, or much, it did not vary with physical activity of occupation. Coronary narrowing was similarly common in all occupation groups. But actual occlusion of a main coronary artery, complete or near-complete, was commoner in sedentary and light workers than in the active and heavy. This excess of coronary occlusion was seen in the younger men and older, in hypertensive cases as in those without record or evidence of hypertension. In general, the frequency of coronary occlusion in light workers aged 45-60 was the same as that in heavy workers aged 60-70.

The main results of the inquiry may therefore be stated as follows: atheroma of coronary walls, no relationship with physical activity of occupation; occlusion of coronary lumen, some relationship; ischaemic myocardial fibrosis, much relationship.

Ischaemic Heart Disease and Coronary Artery Disease.—The excess of coronary occlusion among the light occupations was smaller than the excess of large healed infarcts found in them. Among hypertensive cases there was no trend with occupation in the frequency of lesser degrees of coronary narrowing, although, as stated, the frequency of focal myocardial fibrosis was greater in light workers with hypertension than in active and heavy workers with hypertension. That is to say, in the presence of coronary narrowing and occlusion light occupations showed more ischaemic lesions of the myocardium than did active and heavy workers. Analysis of this sample of pathological data by social (occupation) categories thus discloses only very limited correlation between the frequency of myocardial scarring and the condition of the coronary arteries. This is a further suggestion that ischaemic heart disease is not a simple function of coronary artery disease.

Hypertension was less common and occurred at later ages (10-15 years later) in the heavy occupations than in the rest; the excess of coronary occlusions in light workers was seen in hypertensive cases as in the others;

a specially high prevalence of small ischaemic myocardial scars in light workers with hypertension has been described. There are suggestions thus of multiple connexions between physical activity of occupation and the blood pressure which need to be followed up.

The expected trend of ischaemic myocardial fibrosis with *social class* was found, the rate falling from 13.3% in class I through 10.5% in class III to 7.8% in class V. This trend, however, disappeared when the social classes were broken down into categories of physical activity, and the occupations of which each class is composed were graded as "light," "active," or "heavy." Light workers in classes I, II, III, and IV all had similar prevalence of ischaemic scarring, and there was no class trend in the fibrosis among active workers or in heavy workers. On the other hand, the relationship of fibrosis to physical activity of occupation was independent of social-economic circumstances, being evident within single social classes: light occupations in class II showed more ischaemic fibrosis than the active in that class, light skilled workers a higher rate than the active and heavy occupations in class III, the light occupations of class IV more scarring than the active and heavy in that class. The overall trend with social class in this material is largely a function of the different proportions of light and heavy workers in the different classes.

Evidence has now been produced relating several aspects of clinical and subclinical coronary heart disease to physical activity of work. The general hypothesis may therefore be restated in causal terms that *physical activity of work is a protection against coronary (ischaemic) heart disease. Men in physically active jobs have less coronary heart disease during middle-age, what disease they have is less severe, and they develop it later than men in physically inactive jobs.* Since there are suggestions of other connexions between physical activity of work and cardiovascular disease of middle-age, and multiplying evidence from laboratory experiment of the beneficial effects of exercise on relevant cardiovascular physiology and pathology, the speculation may be advanced that habitual physical activity is a general factor of cardiovascular health in middle-age, and that coronary heart disease is in some respects a deprivation syndrome, a deficiency disease. In the present material the hearts of sedentary and light workers showed the pathology of the hearts of heavy workers 10-15 years older.

Perspective.—Coronary heart disease among heavy workers, though less common, less severe, and occurring later than among light workers, is nevertheless common enough to constitute a major health problem in them: absolutely; and in comparison with the greater freedom from the disease heavy workers, like the rest of the population, seem to have enjoyed earlier this century and in many countries apparently still enjoy.

We are greatly obliged to many for their participation and help in this inquiry: to the pathologists, and their medical and lay colleagues, of the hospitals listed in the Appendix, with associated hospitals, for a prodigious amount of painstaking work, carried out often, we know, in circumstances of considerable difficulty; to Dr. K. Ball, Professor T. Crawford, Dr. I. Doniach, Professor J. Duguid, Professor G. L. Montgomery, Dr. M. F. Oliver, Professor D. S. Russell, and Dr. C. S. Treip for advice on the design of the Report Form and/or pilot work; Dr. R. Murray, formerly H.M. Medical Inspector of Factories and now of the I.L.O., and Dr. D. Turner, of the Medical Research Council's Environmental Hygiene Research Unit, for the classification of occupations; the Factory Department of the Ministry of Labour and Dr. E. R. Bransby, of the Ministry of Health, for advice on this problem; Dr. Richard Doll and Professor A. Bradford Hill for access to

their original records; the General Register Office; the Medical Records Department of the London Hospital; Professor T. Crawford, Mr. J. A. Heady, and Professor D. S. Russell for reading the MSS.; Dr. R. A. Dale, who shared the task of classifying the pathology with us; Mr. J. A. Heady for statistical work; and our other colleagues in the Social Medicine Research Unit, in particular Mrs. D. Greystoke, clerk-computer, and Mrs. I. R. Murray and Miss E. B. R. Thomas, secretaries.

APPENDIX: PRINCIPAL PARTICIPATING HOSPITALS

SCOTLAND

NORTHERN REGION:
Royal Northern Infirmary, Inverness.
NORTH-EASTERN REGION:
Teaching Hospitals: Aberdeen Royal Infirmary; Woodend General Hospital, Aberdeen.
EASTERN REGION:
Teaching Hospitals: Dundee Royal Infirmary; Maryfield Hospital, Dundee; Perth Royal Infirmary.
SOUTH-EASTERN REGION:
Teaching Hospitals: Royal Infirmary, Edinburgh; Western, Northern, and Eastern General Hospitals; Leith Hospital.
Cameron Hospital, Windygates, Fife.
WESTERN REGION:
Teaching Hospitals: Western Infirmary, Glasgow; Royal Infirmary, Glasgow; Victoria Infirmary, Glasgow; Southern General Infirmary, Glasgow; Stobhill Hospital, Glasgow.
Kilmarnock Infirmary; Royal Infirmary, Dumfries; Stirling Royal Infirmary.

ENGLAND

Teaching Hospitals.—Manchester Royal Infirmary; Liverpool Royal Infirmary; Royal Victoria Infirmary, Newcastle upon Tyne; Queen Elizabeth Hospital, Birmingham; Accident Hospital, Birmingham; the General Hospital, Birmingham; Bristol Royal Infirmary; Addenbrooke's Hospital, Cambridge; Radcliffe Infirmary, Oxford.
Manchester Region.—Royal Lancaster Infirmary; Westmorland County Hospital, Kendal; Royal Infirmary, Blackburn; General Hospital, Burnley; Bolton Royal Infirmary; Hope Hospital, Salford; Salford Royal Hospital; Crumpsall Hospital, Manchester; Park Hospital, Davey Hulme; Withington Hospital, Manchester; Stockport Infirmary; Macclesfield Hospital.
Liverpool Region.—County Hospital, Whiston; Walton Hospital, Liverpool; Sefton General Hospital, Liverpool; General Hospital, Birkenhead; Chester Royal Infirmary.
Newcastle Region.—Newcastle General Hospital; General Hospital, South Shields; Preston Hospital; Hexham General Hospital; Royal Infirmary, Sunderland; Shotley Bridge General Hospital; Dryburn Hospital, Durham; Bishop Auckland General Hospital; Sedgfield General Hospital; Darlington Memorial Hospital; West Hartlepool General Hospital; Cumberland Infirmary, Carlisle.
Birmingham Region.—Selly Oak Hospital, Birmingham; Dudley Road Hospital, Birmingham; Staffordshire General Infirmary; City General Hospital, Stoke-on-Trent; North Staffordshire Royal Infirmary; Walsall General Hospital; West Bromwich and District General Hospital; the Royal Hospital, Wolverhampton; Royal Salop Infirmary, Shrewsbury; Warwick General Hospital; General Hospital, Burton-on-Trent; Worcester Royal Infirmary; County Hospital, Hereford.
Leeds Region.—Scarborough Hospital; County Hospital, York; Hull Royal Infirmary; Clayton Hospital, Wakefield; Huddersfield Royal Infirmary; Royal Halifax Infirmary; St. James Hospital, Leeds; Victoria Hospital, Keighley; Oley General Hospital; Harrogate General Hospital.
Bristol Region.—Southmead General Hospital, Bristol; Frenchay Hospital, Bristol; Cheltenham General Hospital; Manor Hospital, Bath; Musgrove Park Hospital, Taunton; Royal Devon and Exeter Hospital; North Devon Infirmary; Torbay Hospital, Torquay; Royal Cornwall Infirmary, Truro; St. Martin's, Bath; Redruth Miners' and General Hospital, Camborne; West Cornwall Hospital, Penzance.
Sheffield Region.—City General Hospital, Sheffield; St. Helen Hospital, Barnsley; Doncaster Royal Infirmary; Chesterfield Royal Hospital; Derbyshire Royal Infirmary; Nottingham General Hospital; Leicester Royal Infirmary; Lincoln County Hospital; Grimsby General Hospital; Leicester General Hospital; Victoria Hospital, Workson.
Oxford Region.—Royal Berkshire Hospital, Reading; Kettering General Hospital; Victoria Hospital, Swindon.
East Anglia Region.—Newmarket General Hospital; West Suffolk General Hospital; Ipswich and East Suffolk Hospital; Borough General Hospital, Ipswich; Norfolk and Norwich Hospital.
London Teaching Hospitals.—Charing Cross Hospital; Guy's Hospital; London Hospital; King's College Hospital; Royal Free Hospital; St. Bartholomew's Hospital; St. George's Hospital; St. Mary's Hospital, Paddington; St. Thomas's Hospital; University College Hospital; West London Hospital; Royal Marsden Hospital; Hammersmith Hospital.
North-west Metropolitan Region.—Bedford General Hospital; Luton and Dunstable Hospital, Luton; Lister Hospital, Hitchin; Canadian Red Cross Memorial Hospital, Taplow, Bucks; King Edward VII Hospital, Windsor; Barnes General Hospital; St. Albans City Hospital; Peace Memorial Hospital, Watford; Hillingdon Hospital, Uxbridge; West Middlesex Hospital, Isleworth; King Edward Memorial Hospital, Ealing; Central Middlesex Hospital, Willesden General Hospital; Royal Northern Hospital; the Royal London Homoeopathic Hospital; Whittington Hospital.
North-east Metropolitan Region.—Chase Farm Hospital; Prince of Wales Hospital; Bethnal Green Hospital; Hackney Hospital; Mile End Hospital; St. Andrew's Hospital, Bow; Queen Mary's Hospital, Stratford; Whipps Cross Hospital; Oldchurch Hospital; Southend General Hospital; Rochford General Hospital; St. Margaret's Hospital, Epping; St. John's Hospital, Essex; Essex County Hospital, Colchester; Black Notley Hospital, Braintree.
South-east Metropolitan Region.—St. Olave's Hospital; Miller General Hospital; St. Alfege's Hospital, Greenwich; Lewisham Hospital; Brook General Hospital; Dreadnought Seamen's Hospital; Queen Mary's Hospital, Sidcup; West Hill Hospital, Dartford; St. Bartholomew's Hospital, Rochester; Kent and Canterbury Hospital; Ramsgate and Margate General Hospital; Buckland Hospital, Dover; Pembury Hospital, Kent; Queen Victoria Hospital, East Grinstead; Orpington Hospital; Farnborough Hospital; Bromley Hospital; Princess Alice Memorial Hospital, Eastbourne; St. Mary's Hospital, Eastbourne; Cuckfield Hospital, Haywards Heath.
South-west Metropolitan Region.—Lambeth Hospital; St. Mary Abbot's Hospital; Kingston Hospital; St. Helier Hospital, Carshalton; St. Peter's Hospital, Chertsey; St. Thomas's Hospital, Godalming; Royal West Sussex Hospital; Worthing Hospital; Portsmouth and Isle of Wight Area Patho-

logical Service, Central Laboratory, Portsmouth; Royal South Hants Hospital, Southampton; Poole General Hospital; Royal Hants County Hospital; Salisbury General Infirmary; County Laboratory, Dorchester; Royal Portsmouth Hospital; Royal Isle of Wight County Hospital; Southampton General Hospital.

WALES

Teaching Hospital.—Royal Infirmary, Cardiff.
Welsh Region.—Royal Gwent Hospital, Newport, Mon.; St. Woolos Hospital, Newport, Mon.; St. James Hospital, Tredegar; Caerphilly District Miners' Hospital; St. David's Hospital, Cardiff; St. Tydfil's Hospital, Merthyr Tydfil; East Glamorgan Hospital; Neath General Hospital; Morriston Hospital, Swansea; General Hospital, Swansea; West Wales General Hospital, Carmarthen; Pembroke County War Memorial Hospital, Haverfordwest; the Llandudno General Hospital; Royal Alexandra Hospital, Rhyl; Denbigh Infirmary; War Memorial Hospital, Wrexham; North Wales Mental Hospital, Denbigh.

PREMATURITY AND "CEREBRAL PALSY"

BY

PAUL E. POLANI, M.D., M.R.C.P., D.C.H.

Medical Research Unit, National Spastics Society,
Department of Child Health, Guy's Hospital, London

That there is an association between prematurity and "cerebral palsy" impressed the earliest students of this neurological condition (Little, 1862; Freud, 1897). Its nature has puzzled many; for some, like Brissaud (1894), the effect of prematurity is to cause a developmental anomaly of the pyramidal tracts; for others, like Collier (1924), the two conditions are parallel manifestations of an intrauterine abnormality causing both prematurity and primary antenatal degeneration of cerebral neurones.

Although data on prematurity are available in the collection of cases published by Little, it is largely in recent times that the association between prematurity and cerebral palsy has been put on a quantitative basis. Evans (1948), in 76 cases, and Asher and Schonell (1950), in 400 cases, found an incidence of prematurity of 39%, about eight times that in the normal population, while Lilienfeld and Parkhurst (1951), for 505 cases, give a figure of 22.2% with an incidence of prematurity in their control population (115,281) of 4.8%. It is to be noted that the controls used by Lilienfeld and Parkhurst were survivors at the end of the first month of life, those of Asher and Schonell were survivors at the end of the first year, and those of Evans were matched for age with his cerebral palsy cases. So that in these studies an attempt was made to overcome the error that would result from using figures referring to incidence of prematurity at birth due to the high mortality of premature infants (mainly in the neonatal period), particularly those of lower birth weight (Alm, 1953; Dunham, 1955).

A further idea of the importance of prematurity in cerebral palsy can be obtained from Evans's (1948) data, by considering the proportion of premature infants weighing 4½ lb. (2,040 g.) or less at birth. The relevant figures are: 21 such premature infants among 76 cerebral palsy cases and 1 among 50 controls (28% and 2% respectively). The figures given by Knobloch *et al.* (1956) further support this point. They found an incidence of "overt neurological defect" at 40 weeks of gestation of 57 premature babies weighing 1,500 g. or less, 12.3% in 443 larger prematures, and of 0.6% in 492 full-term controls matched for race, season of birth, parity, hospital of birth, and socio-economic status.

Cerebral palsy is an aggregate of clinical syndromes with various origins, and so is prematurity. The causes of prematurity act on the foetus with varied intensity and at different developmental stages. Furthermore, the foetus prematurely delivered is exposed to extra risks during labour, and the premature newborn baby also faces numerous hazards.

Incidence of Prematurity in Cerebral Palsy

One might expect some types of cerebral palsy to be more strongly associated with prematurity than others. Freud (1897) and Brissaud (1894) correlated prematurity particularly with diplegia. The combined figures of Evans (1948)

*This term is used here to mean a persisting qualitative motor disorder due to non-progressive damage of the encephalon occurring before the growth of the central nervous system is complete.

and Asher and Schonell (1950) show a significant difference in the incidence of prematurity between "non-rhesus athetoids" (29% of 74 cases) and "paraplegias and tetraplegias" (44% of 223 patients). The proportion of prematures among 104 cases of congenital hemiplegia was reported by Asher and Schonell as 30% and by Perlstein and Hood (1953) in their 222 cases as 12%.

A series of 93 cases of dystonic and choreo-athetoid cerebral palsy† was analysed (Polani, 1957, unpublished data). Of 28 cases with severe neonatal jaundice due to blood-group iso-immunization three were premature (11%); of 20 patients with a history of severe neonatal jaundice not associated with blood-group incompatibility 14 were premature (70%); and of 45 patients who did not have severe neonatal jaundice 16 were premature (35.5%). By contrast, in a group of 42 patients with cerebral spastic paraplegia/diplegia, 59.9% were premature (Polani, 1957, unpublished data). Thus the association with prematurity seems high in cerebral palsy due to non-rhesus jaundice and in cerebral spastic paraplegia/diplegia.

The figures given by Ingram and Kerr (1954) confirm the striking association between cerebral spastic paraplegia/diplegia and prematurity (see Table). These figures suggest

Survivors, by Birth Weight, Edinburgh, 1948-52 (Ingram and Kerr, 1954)

Birth Weights	No. of Survivors	Diplegics/Paraplegics Total No.	Incidence per 1,000
All weights	36,400	36*	1
Over 5½ lb. (2,500 g.)	35,143	23*	0.65
4-5½ lb. (1,800-2,500 g.)	1,017	2	1.96
Under 4 lb. (1,800 g.)	240	11	45.83

* Estimated on the basis of the period 1943-7 (33 cases in 35,866 children).

that, compared with full-term children, premature babies of high birth weight show a threefold increase in the incidence of cerebral spastic paraplegia/diplegia and those of lower birthweights a seventyfold increase. Thus among premature infants weighing under 4 lb. (1,800 g.) at birth the chance of cerebral spastic paraplegia or diplegia is apparently about 1 in 20.

If we accept Lilienfeld and Parkhurst's (1951) idea of a "continuum of reproductive wastage," with cerebral palsy as one link in a chain of unfavourable reactions, other elements of which are mental defect (Pasamanick and Lilienfeld, 1955b; Lilienfeld and Pasamanick, 1956), epilepsy (Lilienfeld and Pasamanick, 1954; Pasamanick and Lilienfeld, 1955a), behaviour disorder (Pasamanick, 1954; Rogers *et al.*, 1955, Pasamanick *et al.*, 1956), and foetal and neonatal death, we may observe even more subtle cerebral effects associated with prematurity. For example, the lowered intelligence quotient found by Douglas (1956) in his group of premature children, and confirmed by Dann *et al.* (1956), may represent more limited (or different) results of a harmful association between prematurity and brain function.

Causal Connexion

What could be the causal connexion in the association between prematurity and cerebral palsy? As stated, this association may manifest itself in different effects, depending on the different causes of prematurity, the different times in foetal development when they act, their different intensities, and the various stresses to which prematurity itself subjects

†In dystonic cerebral palsy abnormalities of muscle tone predominate, and the hypertonus, when present, is plastic in character (Denny-Brown, 1946). In choreo-athetoid cerebral palsy the outstanding motor abnormality is the presence of unwanted movements—dyskinesia of Perlstein (1952) and Balf and Ingram (1955).

‡Cerebral spastic paraplegia denotes a condition of lower-limb paralysis of cerebral origin, without notable functional involvement of the upper limbs. Patients with spastic diplegia have predominantly lower-limb and trunk involvement, and also upper-limb involvement, which, however, is less marked than that of the lower limbs. The difference between the two conditions may be essentially one of degree.

the developing organism. To deal with one example, prematurity may cause cerebral palsy (generally dystonic or choreo-athetoid cerebral palsy) through the mechanism of neonatal jaundice. Premature babies have a greater tendency to a rise in the serum-bilirubin level, presumably because of an inability of their livers to conjugate the liposoluble bilirubin (indirect-reacting bilirubin) with glucuronic acid and transform it into the water-soluble pigments I and II (direct bilirubin, bilirubin mono- and diglucuronide) (see Cole and Lathe, 1953; Billing *et al.*, 1957; Gray, 1957). For this reason, in a proportion of premature infants, even in the absence of increased haemolysis due to blood-group iso-immunization, the serum bilirubin will rise to dangerous levels and the liposoluble pigment cross the blood-brain barrier and produce kernicterus*.

If the breakdown of red cells is increased, as, for instance, when certain vitamin-K analogues are given in excess (Laurance, 1955; Crosse *et al.*, 1955; Allison, 1955), the extra production of bilirubin will increase the proportion of premature babies who get kernicteric damage. It has furthermore been shown by Diamond (1956) that the administration of sulphafurazole ("gantrisin") to premature babies may favour kernicteric damage without an excessive rise in serum bilirubin; Lathe (1957) has suggested that this is due to a lowering of the threshold of the blood-brain barrier. Kernicterus in a rabbit has been produced by this mechanism (Ernst *et al.*, 1957).

Anoxic and Mechanical Trauma

But prematurity may be responsible for cerebral palsy through other mechanisms. The premature baby is generally frail and his respiratory efficiency is often less than that of the full-term infant, with consequent possibilities of "anoxia." Furthermore, the lower the birthweight of premature infants (Calkins, 1955) the higher the incidence of breech delivery, which exposes the foetus and the newborn to added risks from mechanical or asphyxial injury, with consequent possibility of brain damage and so of cerebral palsy. Such mechanical or "anoxic" trauma would explain reasonably well some forms of cerebral palsy, such as double hemiplegia and "post-anoxic" choreo-athetoid and dystonic forms of the disorder.

Although, admittedly, anoxia can be selective in its action, the frequency of the association between cerebral spastic paraplegia and prematurity is more difficult to explain adequately on the grounds of a relatively indiscriminate and diffuse cerebral damage. The post-prematurity spastic paraplegia type of cerebral palsy is a striking clinical entity, striking for the symmetry of the neurological signs, for their distribution, for the relatively good intelligence of the patients, and for their comparative freedom from seizures; and all these features tend to militate against the idea of brain injury being responsible.

Possibility of a Development Mechanism

A developmental origin (Brissaud, 1894) seems a more logical explanation for the syndrome, and it might be reasonable to accept Collier's (1924) idea that the same factors which are responsible for the disturbed mother/foetus relationship, and so for prematurity, are also responsible for the disorder of brain development and so for cerebral spastic paraplegia. If this were so, the incidence of cerebral spastic paraplegia (and diplegia) might be expected to vary in groups of premature infants when the prematurity is due to different causes. If the disordered development were related to the cause of prematurity it would follow that the cerebral abnormality would be of prenatal origin. Prevention would be possible only if the causative factors were avoidable.

It should be made clear that when cerebral palsy cases are compared with a control population to assess the impor-

*The present evidence is in favour of the cerebral damage being due to a direct action (Claireaux *et al.*, 1953; Ernst *et al.*, 1957).

tance of obstetric factors in the aetiology of cerebral palsy (toxaemia of pregnancy, ante-partum haemorrhage, breech delivery, forceps delivery, breathing "difficulty," etc.) the control population generally contains a much lower proportion of premature children, so that what such comparisons reveal in the cerebral palsy population is the excess of obstetrical factors responsible for the prematurity though not necessarily for the cerebral palsy. Such comparisons would be more valid if the control population were matched for incidence of prematurity.

Few studies have separated prematurity into aetiological groups and correlated them with the frequency of cerebral palsy, thus trying to link causes of prematurity and cerebral palsy. Douglas's (1956) findings are worth noting in this context, though they do not refer to cerebral palsy but to mental ability of premature children. He examined a prospectively studied national sample of premature children aged 8 years and found a small group of them who made "outstandingly poor scores in all tests—namely, those whose prematurity is unexplained either by obstetric abnormality" or by their genetic background. Lilienfeld and Parkhurst (1951) found a higher incidence of prematurity among those cases of cerebral palsy where complications of pregnancy and labour had not been present than among those where they had. They tried to explain this finding by suggesting a higher mortality rate among cerebral palsy premature infants with complications of pregnancy. Eastman and DeLeon (1955) have shown that in only one-third of their cerebral palsy cases associated with prematurity was there a complication of pregnancy that could have been responsible for the cerebral palsy through the mechanism of foetal anoxia. In two-thirds they concluded that the origin of cerebral palsy was in some way attributable to the prematurity itself.

It is possible to suggest mechanisms by which prematurity, by itself, is at times the operative factor in determining the paraplegia/diplegia type of cerebral palsy. The condition might be of post-natal origin, from failure of final structural and functional maturation of the brain, and it would then be the degree of prematurity rather than its cause that would be linked with the frequency of the condition. The figures of Ingram and Kerr (1954), given in the Table, stress the association between a greater degree of prematurity and a greater frequency of cerebral spastic paraplegia/diplegia.

A Matter for Conjecture

How this particular type of cerebral palsy could be produced by prematurity itself is a matter for conjecture. A possible explanation would be one that took into consideration the relatively anaerobic metabolism of the foetal nervous system, and its maturation, centre by centre, to the adult aerobic metabolism, apparently essential for the quick release of high energy presumably required for brain function. This has been demonstrated in the experimental animal by Himwich (1951) and his collaborators, and has been suggested in the human by the work of Racker (1942). It is a plausible conjecture that, possibly through interference with enzymic maturation or adaptation, premature birth deprives those parts of the nervous system which are at a crucial stage of anatomical development or functional maturation of the environment favourable to this development or maturation. The damaging factor may well not be anoxic, but rather hyperoxic, though even a hyperoxic insult may ultimately result in anoxic damage through interference with oxidative enzymes (Himwich, 1953; Dickens, 1946a, 1946b). Alternatively, brain structure and function may be damaged by a prolonged condition of absolute or relative hyperoxia, through alteration of the blood vessels of the differentiating cortex, much as can happen in the eyes of premature babies, with consequent retrolental fibroplasia.

It is perhaps relevant in this connexion to mention the work of Ashton *et al.* (1957), who poisoned the eyes of kittens with fluoride and iodoacetate and observed changes

similar to those resulting from exposure to high oxygen concentrations. They tentatively suggested that the mechanism at work was one of inhibition of glycolysis resulting in swelling of retinal tissue and subsequent vascular compression and obliteration (see also Graymore, 1958). By this technique they were able to produce a biochemical lesion owing to a particular vulnerability linked to a definite stage of functional development and maturation, and it is worth noting that similar changes could not be produced by them in the eyes of more adult cats. If the incidence of cerebral palsy (particularly cerebral spastic paraplegia/diplegia) were greater in babies stressed by high oxygen concentrations, the hyperoxic hypothesis would perhaps be more acceptable. Fuldner (1955) found an association between cerebral spastic paraplegia and retrolental fibroplasia. That the incidence of cerebral spastic paraplegia/diplegia in babies with retrolental fibroplasia is greater than would be expected has been shown by Ingram and Kerr (1954). However, they suggested that the cause of cerebral damage in their patients was abnormality of pregnancy and of labour, leading to post-natal asphyxia which necessitated oxygen therapy and in turn caused retrolental fibroplasia.

The above suggestion that premature birth may at times cause post-natal interference in development and maturation of critically maturing neurones is entirely hypothetical. It can be put to the test by experiments with high oxygen pressures in immature animals. The understanding of the delicate metabolic mechanisms involved can be furthered by detailed studies of the vascular, enzymic, histological, and functional maturation of the human brain, in continuation of the work done by Racker (1942) and Vilce (1953). The main use of such a hypothesis is that it directs attention to possibilities of prevention.

Summary

The incidence of prematurity in various clinical types of cerebral palsy is reviewed. A particularly strong association is found with two neurological syndromes: dystonic/choreo-athetoid cerebral palsy following severe neonatal jaundice not due to blood-group incompatibility, and cerebral spastic paraplegia/diplegia. The possible mechanisms of this latter relationship are considered and a selective developmental origin for the neurological troubles is favoured tentatively. Because of the association between retrolental fibroplasia and cerebral spastic paraplegia/diplegia, and because of the clinical features of the cerebral spastic paraplegia syndrome without history of perinatal or postnatal troubles, a postnatal interference with development is the mechanism postulated for this clinical type of cerebral palsy.

The terminology on cerebral palsy used in this paper is based on the discussions of a group of workers interested in the subject at meetings of the Little Club. The help of those concerned is gratefully acknowledged.

CORTICOTROPHIN AND STEROIDS IN THE DIAGNOSIS AND MANAGEMENT OF "OBSTRUCTIVE" JAUNDICE

BY

W. H. J. SUMMERSKILL, D.M., M.R.C.P.

Senior Registrar

AND

F. AVERY JONES, M.D., F.R.C.P.

Physician

(From the Department of Gastro-enterology,
Central Middlesex Hospital, London)

Jaundice due to hepatitis with prolonged bile retention (Eppinger, 1937; Watson and Hofbauer, 1946) or occurring as a complication of therapy with chlorpromazine and other drugs (Hanger and Gutman, 1940; Hollister, 1957) may have clinical and biochemical features indistinguishable from that associated with extrahepatic biliary obstruction. Solem and Olsen (1953), aware that jaundice in patients with hepatitis often clears rapidly with steroid therapy (Ducci and Motlis, 1951), reported that the effect of a four to seven-day trial of corticotrophin (A.C.T.H.) therapy on the icteric index permitted a clear-cut distinction between extrahepatic obstructive jaundice, which was not significantly influenced, and hepatitis. However, later observations showed that the effect of corticotrophin or steroids in hepatitis was very variable (Sborov *et al.*, 1954) and that considerable reduction in serum bilirubin concentrations could follow use of the drugs in extrahepatic biliary obstruction, thus invalidating their application as a diagnostic test (Chalmers *et al.*, 1956; Katz *et al.*, 1957).

The subject has received only passing mention in this country (Shaldon and Sherlock, 1957; Summerskill, 1958), although the laparotomy indicated in extrahepatic obstruction may be unnecessary and hazardous in hepatitis. We therefore report the effect of corticotrophin and steroid drugs on serum bilirubin and alkaline

† Presumed to have hepatitis on the basis of a negative laparotomy and surgical cholangiography. However, nine months later, jaundice and itching continued and the possibility of a bile-duct carcinoma becomes increasingly likely.

bilirubin excretion. The decreases in serum bilirubin concentrations during treatment in Case 9 cannot be attributed to this, and delay in red cell or haemoglobin breakdown due to steroids (Katz *et al.*, 1957) seems unlikely to explain such great reductions. Alternatively, deviation of haemoglobin metabolism to compounds which do not react with the diazo reagent, or increased storage of bilirubin in the reticulo-endothelial system and other tissues, might be responsible, but the coincident decreases in this study in serum levels of alkaline phosphatase, which is thought to be eliminated mainly in the bile, are more compatible with increased excretory activity.

The usefulness of corticotrophin and steroids in distinguishing between intrahepatic and extrahepatic jaundice has encouraged us to incorporate the test in the routine investigation of obstructive jaundice of uncertain cause. After two weeks, in which time standard investigations (stool occult blood, haematology, barium meal, liver-function tests) have been done, a five-day trial of corticotrophin or steroids on the serum bilirubin level is performed if the diagnosis remains in doubt. Oral prednisone (20 mg. t.d.s.) may be the drug of choice. It reaches the liver direct in portal blood, and corticotrophin has the disadvantage of variable potency due to batch differences. An apparent response to this measure is followed by continued treatment. In patients who fail to respond and in whom there is no haematological contraindication, liver biopsy can be performed with less hazard than laparotomy in the jaundiced patient, and its interpretation in obstructive jaundice was well reviewed by Johnson and Doenges (1956).

Unfortunately, cases which are equivocal from clinical and biochemical standpoints often have non-specific histological findings. However, dilatation of large intrahepatic bile ducts and bile extravasation suggest extrahepatic obstruction, while, as in Case 2, evidence of liver-cell damage and cellular infiltration indicates hepatitis. In addition, cirrhosis or another unsuspected lesion may be demonstrated, as in Case 12. If the diagnosis is still in doubt, laparotomy with arrangements for cholangiography must be considered to resolve the doubts of both doctor and patient. Obstructive jaundice is not harmful (Atkinson *et al.*, 1956), and it is reasonable to wait eight weeks for possible improvement, as operation is poorly tolerated by patients with hepatitis (Sherlock *et al.*, 1954). Sometimes, as in Case 1 (who was jaundiced for nine months), laparotomy appears inevitable in a patient subsequently shown to have hepatitis, but the relative absence of liver-cell damage on clinical, biochemical, and histological investigation probably allows these patients to withstand operation better than others with hepatitis.

Summary

In 12 patients with obstructive jaundice of uncertain cause, the effect of a five-day trial of steroid or corticotrophin therapy was of great value in reducing serum bilirubin levels and in differentiating between intrahepatic obstruction due to hepatitis and extrahepatic obstruction. Serum alkaline phosphatase concentrations also fell during treatment, although to a less extent, thus suggesting that the reduction of jaundice caused by corticotrophin or steroid drugs was due to increased bile excretion. The drugs acted immediately and no difference was apparent between corticotrophin and steroids.

The place of these drugs and other measures in the diagnosis and management of obstructive jaundice is discussed.

We are grateful to the consultant staff of the Central Middlesex Hospital for permission to study these patients and to Dr. G. Discombe and Miss Mavis Smith for the biochemical results.

THROMBOCYTOPENIC PURPURA DUE TO QUINIDINE

BY

R. J. SCHEN, M.B., B.S.

Department of Internal Medicine "C"

AND

M. RABINOVITZ, B.A.

Bacteriological and Haematological Laboratory
Hadassah Municipal Hospital, Tel-Aviv, Israel

The fundamental observations on drug-induced thrombocytopenia were made by Ackroyd (1949a, 1949b, 1951, 1954) in his classical work on "sedormid" purpura. He showed that the drug caused agglutination and lysis of the patient's platelets *in vitro*, and that the addition of the drug to the patient's blood *in vitro* inhibited clot retraction.

We describe below a simple method for showing platelet agglutination. This method enables the investigator to obtain suspensions of platelets which have no tendency to spontaneous clumping. Stress is laid on the clinical features of quinidine purpura and the practical conclusions to be drawn from them.

Case Report

On December 31, 1957, a man aged 50 was admitted to Hadassah Hospital because of haematuria and purpura. He looked seriously ill. There were widespread petechiae, and blood-filled blisters were seen in the mouth and on the tongue. The urine had the appearance of blood. The blood pressure was 170/100. The blood count showed haemoglobin, 69%; erythrocytes, 3,500,000; leucocytes, 10,000 (neutrophils 59%, eosinophils 2%, monocytes 2%, lymphocytes, 37%). No platelets were seen; bleeding-time was 2 minutes; coagulation time 2 minutes, and prothrombin 58%. The urine showed many red cells. The tourniquet test was strongly positive. Prednisone, 60 mg. a day, was given. By his fourth day in hospital the urine was clear, the platelet count had risen to 25,000, and he was feeling much better. By the seventh day the platelets had risen to 100,000; two days later they numbered 240,000.

A detailed history revealed that the patient had had a myocardial infarction two years previously. In July, 1957, he was given quinidine because of palpitations; he took four 0.2 g. tablets. A month later he took another tablet. Two days before admission he felt palpitations and took two tablets, one at midday and one in the evening (0.4 g.). That night he had a severe rigor and his temperature rose to 39° C. (102.2° F.). Next day he felt weak and noticed a rash on his hands. On the following day blood appeared in his urine and he was sent to hospital. He had taken 1.4 g. of quinidine at intervals, over a period of six months.

In the third hospital week—that is, when the patient's blood picture had become entirely normal and the prednisone treatment had been stopped—the following tests were carried out:

Clot Retraction Test, Qualitative Method

This test was done in the ward as follows: solutions (in normal saline) of quinidine sulphate 1:2,000 and quinine hydrochloride 1:2,000 were procured. Three standard laboratory test-tubes were taken; to the first was added 0.2 ml. of the quinine solution, to the second 0.2 ml.

FIG. 1.—The clot-retraction test (qualitative method) as performed in the ward. The two outside tubes (quinine and saline) show negative results; the centre tube (quinidine) shows a positive result. In this photograph the test was done with Linzenmeier blood sedimentation tubes.

FIG. 2.—The thrombocyte-rich plasma of the patient after incubation with quinidine solution at 37° C. for one hour, showing agglutination of platelets (+++).

FIG. 3.—The thrombocyte-rich plasma of the patient with saline (control), showing complete absence of agglutination. Photographs of Figs. 2 and 3 were taken with the phase contrast microscope. (x400.)

of the quinidine solution, and to the third 0.2 ml. of normal saline. Blood was taken from the patient by venepuncture, using a ward syringe. To each tube was added 2 ml. of blood. The tubes were inverted four times. They were kept at room temperature and examined after 4 and 24 hours. If free serum was seen the test was taken as negative; if no free serum could be seen it was regarded as positive. In this way quinidine repeatedly gave positive reactions, while quinine and saline always gave negative reactions (Fig. 1). Quinidine gave negative results when tested similarly with the blood of 10 other patients.

The reliability of this simple procedure is stressed, since it enables the clinician to make the diagnosis in the ward. This test, as performed above, was still positive 10 weeks after the patient's admission; a further test four weeks later was negative. These results were confirmed in the laboratory, using the quantitative method.

Patch Test.—This was carried out according to the method of Freedman, Brody, and Barr (1956). The results were negative.

Thrombocyte Agglutination Test

The anticoagulant was Na₂ "sequestrene" 5% at pH 7.2 (corrected with NaOH). Glassware was siliconized with "siliclad." Drug solutions were made up as follows in normal saline: quinidine sulphate, 2 and 20 mg., quinine hydrochloride 2 and 20 mg., phenobarbitone 2 and 20 mg. per 100 ml. A siliconized bacteriological test-tube (5 cm. long with outside diameter 9 mm.) was marked with wax pencil at the 1-ml. level; 0.1 ml. of anticoagulant was added. After warming the hand a deep finger puncture was made. When the blood was flowing freely it was collected straight into the tube up to the mark and well mixed with the anticoagulant; 1 ml. of blood was usually enough. The tube was then centrifuged at room temperature at 800–1,000 r.p.m. for three to five minutes. The upper layer of thrombocyte-rich plasma was removed with a siliconized pipette and transferred to a small siliconized test-tube, which was tapped gently to secure even spread of the platelets. This thrombocyte-rich plasma was distributed into small siliconized test-tubes, two drops in each tube. To each tube was added one drop (of the same size) of one of the drug solutions under test. The mixtures were incubated for one hour in a water-bath at 37° C. The tubes were removed and, using a siliconized pipette, a small drop was placed on a siliconized slide, covered with a siliconized coverglass, and examined microscopically. Incubation for a further hour caused the agglutination to be even more marked; platelet flocculation could then be seen with the naked eye.

Results.—This test, and the clot-retraction test, were performed on the patient's blood in the third hospital week, and repeated once a week for eight weeks. Tests with the controls were done twice. The results were graded as follows:

- +++ Complete agglutination into large clumps with no free platelets (as in Fig. 2).
- ++ Agglutination into smaller groups with free platelets to be seen.
- +, Agglutination into very small groups; from 2 to 3 agglutinates visible in every field.
- , No tendency to agglutinate whatsoever. (As in Fig. 3.)

	Quinidine		Quinine		Phenobarb.		Saline
	2 Mg./100 ml.	20 Mg./100 ml.	2 Mg./100 ml.	20 Mg./100 ml.	2 Mg./100 ml.	20 Mg./100 ml.	
Patient	+++	+++	—	—	—	—	—
20 controls .. .	—	—	—	—	—	—	—
6 patients on quinidine ..	—	—	—	—	—	—	—
Patient's daughter ..	—	—	—	—	—	—	—

Follow-up: fourteen weeks after admission the patient's platelet-rich plasma was examined again with quinidine; result was ++. At examination seven months after admission the result was +.

Clot Retraction Test, Quantitative Method

In this test the drugs and glassware were as above. 0.1 ml. of the drug solution was mixed with 0.9 ml. of the patient's blood, taken as above. The test-tubes were incubated for three hours at 37° C. Readings were made according to the formula:

$$\frac{\text{serum expressed, in ml.}}{\text{whole blood in ml.}} \times 100$$

Results are shown in the following Table.

	Quinidine 20 Mg./ 100 ml.	Quinine 20 Mg./ 100 ml.	Phenobarb. 20 Mg./ 100 ml.	Saline
Patient	0	52–56	52–56	52–56
20 controls .. .	48–60	48–60	48–60	48–60
6 patients on quinidine ..	52–58	52–58	52–58	52–58
Patient's daughter ..	51	53	53	51

Follow-up: The test was repeated on the patient's blood 14 weeks and seven months after admission; clot retraction

in the presence of quinidine showed no difference from the saline control on both occasions.

Controls.—The controls for both tests were 20 patients and medical personnel of both sexes and various age groups who had never received quinidine. We also tested six patients who had regularly been receiving quinidine for periods varying from a month to a year. The blood of the patient's daughter was also examined.

Other Laboratory Procedures

In order to eliminate the possibility of idiopathic thrombocytopenic purpura due to a platelet panagglutinin in the patient's serum, the following procedure was carried out.

Samples of platelet-rich plasma from two normal persons, of the same blood group as the patient, were prepared as above. Two drops of the patient's serum (after inactivation for 30 minutes at 56° C.) were added to one drop of normal platelet-rich plasma, mixed and incubated for one hour, one sample at 4° C. and another at 37° C. Controls were: physiological saline and serum from two blood-compatible normal persons in place of the patient's serum. Thus, samples of platelet-rich plasma from two normal persons were tested with the patient's serum, the serum of two normal persons, and with saline. No agglutination was observed.

In order to find evidence of a factor in the patient's serum capable of agglutinating normal platelets in the presence of quinidine, the above procedure was repeated with the addition of one drop of quinidine solution (2 mg. per 100 ml.) to each mixture. Control tests were done simultaneously without quinidine. No agglutination was observed. This finding is commented upon below.

(These procedures were carried out in the third and fourth weeks following admission.)

Discussion

Dose of Quinidine

Purpura may appear at any time in any patient taking quinidine. Thus a patient may take quinidine for years, either continuously or intermittently, when suddenly purpura appears (Freedman *et al.*, 1956; Bigelow and Desforges, 1952). Sensitization may develop during a patient's first course of quinidine; in such cases there is a "lag" period before the onset of purpura; this period may be as short as five days (Collins, 1950). Some of the reported cases resemble our case, in which there is a definite history of a sensitizing dose, followed after an interval by the precipitating dose.

Patients suffering from quinidine purpura vary considerably in their sensitivity to the drug. This is readily seen in the summary compiled by Bolton and Dameshek (1956), in which are tabulated the results of the test doses given in the reported cases. Thus as little as 15 mg. caused the platelet count to drop to 5,000 with bleeding in one case, whilst in another case 0.2 g. caused the platelets to fall to 90,000, no bleeding taking place. The sensitivity of the individual patient also does not remain constant. This is exemplified in the case of Moodie (1950): here a test dose of 0.2 g. a day led to purpura after four days, but later on purpura appeared after a total of only 64 mg. had been administered during four days.

Since the sensitivity varies from patient to patient, and since the sensitivity varies in the same patient from time to time, it is impossible to fix an "optimal" test dose in any given case; by "optimal" is meant a dose which causes a drop in the platelet count large enough to be convincing but which does not cause bleeding. We believe that it is ethically wrong to give a test dose, because its outcome can never be predicted.

Although there is no definite correlation between the amount of quinidine ingested and the extent of the bleeding which it provokes, we stress that in the fatal case reported by Bourne and O'Sullivan (1957) the patient went on taking 0.96 g. of quinidine daily for four days after the onset

of purpura. Death was due to cerebral haemorrhage. It follows that a patient should stop taking the drug at the very first signs of thrombocytopenia; it is of practical importance to know what these signs are.

Prodromal Symptoms

In our case there appeared to be a definite prodromal stage; after having taken two tablets of quinidine, the patient had a severe rigor during the night and his temperature rose to 39° C. Several authors describe similar features. Siegal and Horn (1950) reported fever after a test dose. Hirsch and Dameshek (1950) described a case in which gum bleeding and purpura were preceded by a chill and a feverish sensation. In Case 2 of Bolton and Dameshek (1956) the bleeding episode was preceded by a period of a week marked by chills, fever, and fatigue followed by nausea, abdominal pain, and diarrhoea.

Other symptoms are described. Nussbaum and Shulman (1952) described lethargy and somnolence. In the case of Collins (1950) lethargy followed a test dose. In Case 4 of Bolton and Dameshek (1956) weakness, nausea, and tiredness are mentioned. In the case of Norcross (1950) the illness began with coma and convulsions. Larson (1953) mentioned headache after a test dose. In the case of Breu and Zollner (1940), which terminated fatally, the illness started with anaphylactic shock and urticaria. Other symptoms mentioned in the case reports are itching, feeling uncomfortable, and pains in the limbs.

It is impossible to assess in what proportion of cases the purpura is preceded by prodromal symptoms, since some authors omit to state how the patient felt before the bleeding started. Barkham and Tocantins (1954) described a case without such symptoms.

It may be concluded that in an appreciable proportion of cases the bleeding episode is preceded by various symptoms, the main ones being fever, chills, weakness, lethargy, nausea, and headache. It may be noted that the prodromal symptoms of quinidine purpura share certain features with "cinchonism" (as described by Goodman and Gilman (1955)), such as nausea, headache, and fever.

The Haemorrhagic Episode

The bleeding may start in an atypical fashion. Our patient noticed black spots on his tongue, but their importance was understood only next day. In the case of Nussbaum and Shulman (1952) there occurred gum bleeding, which at the time was attributed to local causes. Local causes could easily be blamed for epistaxis or for uterine bleeding. Bleeding of all kinds and in all grades of severity have been described, including melaena, cerebral haemorrhage, haemoptysis, and haematuria. In the great majority of cases a purpuric skin rash is present.

It is worth noting that the best-known complication of quinidine treatment—embolism after reversion from atrial fibrillation to sinus rhythm—might be confused with the results of haemorrhage due to thrombocytopenia. For example, either of these complications might be the cause of haemoptysis during quinidine treatment. Should haematuria or hemiplegia appear the same differential diagnosis must be considered.

Duration of the Haemorrhagic Episode

Our patient was seriously ill on admission. His condition rapidly improved: seven days after his taking the quinidine the haematuria had ceased and the purpura was beginning to fade; return of the platelet count to normal levels took another four days. All the case reports of quinidine purpura show the same picture—that is, a haemorrhagic state which lasts from one to seven days after stopping the drug, full haematological remission usually coming some days later. Likewise, this same pattern is reported to be usually seen in cases of sedormid purpura. This "seven-day pattern" of thrombocytopenic purpura, characterized by cessation of bleeding within a week of stopping the drug, seems to be the typical result of the action of a rapidly eliminated factor whose primary effect is the destruction of

thrombocytes in the peripheral blood. Many reports of drug purpura in the literature conform to this "seven-day pattern." As examples may be cited the following cases: butobarbitone (Young, 1957), quinine (Steinkamp *et al.*, 1955), digitoxin (Berger, 1952), "mapharsen" ("mapharside," oxophenarsine hydrochloride) (Schwartz and VonderHeide, 1945). However, the clinical pattern cannot be taken as the only criterion in classifying the drug purpuras; it is merely suggestive. It may be postulated that the purpuras due to quinidine, quinine, and sedormid form a clinico-pathological entity.

To this group may be added other drugs if they conform to the following criteria: (a) The clinical picture should be typical, with cessation of bleeding within a week of stopping the drug, full haematological remission coming some days afterwards. (b) The primary action of the drug is platelet destruction in the peripheral blood. This may be assumed when thrombocytopenia follows within a few hours of giving the drug; absence of megakaryocyte aplasia in the bone marrow tends to confirm this. (c) Thrombocyte agglutination should be demonstrable in the presence of the drug *in vitro*. This should be confirmed by the inhibition of clot retraction in the presence of the drug.

Practical Considerations

The physician using quinidine will wish to know how common quinidine purpura is, and what should be done about it. In 1941 Broch described the first undoubted case: by 1956 Bolton and Dameshek were able to list 28 cases. If we add our case, the fatal case of Bourne and O'Sullivan (1957), and the four cases of Freedman *et al.* (1956), at least 34 cases are on record. The last-mentioned authors comment on the fact that they diagnosed their four cases during a period of seven months at one hospital. The condition is not common, but it is not merely of academic interest.

It is pointless to do daily platelet counts during the administration of quinidine, since the drop can occur suddenly at any time. It is the usual practice to give a test dose of one tablet before starting a course of quinidine; two to three hours later the treatment is begun if there are no untoward effects. We make the suggestion that if any suspicious symptoms arise a tourniquet test should be performed and, if possible, a platelet count done before proceeding. The physician prescribing quinidine should be alert for the prodromal symptoms of thrombocytopenia, described previously; the similarity of these symptoms to those of cinchonism must not be ignored. The appearance of constitutional symptoms calls for the immediate cessation of the drug, which must not be resumed until a platelet count is done. As many of the recorded cases of quinidine purpura were in patients who had been taking the drug at home with little or no supervision, it is important to impress on domiciliary patients to stop the drug and seek medical advice on the appearance of constitutional symptoms, a rash, or bleeding.

Serological Findings

The addition of quinidine to the patient's platelet-rich plasma caused the platelets to clump into large discrete masses. No lysis of platelets occurred; this agrees with Ackroyd's (1951) observation that lysis appears only in the presence of complement. We used sequestrene as anticoagulant, making use of its anticomplementary effect (Bolton, 1956), so as to prevent platelet lysis and thus simplifying the reading of the results.

In his studies on sedormid purpura, Ackroyd (1949a, 1949b) showed that there is a factor in the serum of sensitized patients, which, when added to the platelets of normal persons, causes agglutination in the presence of the drug. He concluded (Ackroyd, 1954) that sedormid unites with platelets to form an antigen which reacts with the factor in the serum. A similar factor in the serum of patients with quinidine purpura has been demonstrated by Bolton and Young (1953), Weisfuse, Spear and Sass (1954), and Bolton and Dameshek (1956); they were able to obtain

agglutination of normal platelets on the addition of the patient's serum and quinidine. Bigelow and Desforges (1952) had inconsistent results, as they found the factor in plasma but not in serum. However, Barkham and Tocantins (1954) were unable to find such a factor in the serum of their patient. We, too, were not successful in demonstrating the presence of a serum factor. Apparently these inconsistencies are due to variations in technique, such as the choice of anticoagulant and the period and temperature of incubation.

However, we wish to put forward for consideration the following theoretical possibility: that the serological process is a direct antigen-antibody reaction between quinidine and sensitized platelets. It might then be postulated that changes in the platelets *in vitro* due to blood coagulation or to centrifugation could detach the factor from the platelets, and this could account for its presence in the serum. The extraordinary rapidity of action of quinidine in cases of sensitivity seems to support the idea of a direct reaction.

Summary

A case of quinidine purpura is described. It is shown that the diagnosis can be made in the ward by a simplified version of the clot-retraction test.

A simplified method for demonstrating platelet agglutination is described.

The prodromal symptoms of quinidine purpura are described and their importance is stressed.

It is shown that many of the drug-induced thrombocytopenias conform to a definite clinical pattern, and certain criteria are proposed for classification.

We are grateful to Dr. W. N. Wolff and Professor F. Rappaport for their help and encouragement. Our thanks are due to the patient for his willing co-operation.

A memorandum on the care of epileptics has been prepared for the Central Health Services Council by the Standing Medical Advisory Committee and is to be sent to all general practitioners in the National Health Service. Concentrating on the medical and social aspects of epilepsy, the memorandum offers advice on the "management" of epileptics, and on their training and employment. There are paragraphs about the welfare services available to them, about epileptic colonies, and about the problems of marriage and having children. The memorandum states that there are about 180,000 epileptics in England and Wales: probably about 70% of cases occur before the age of 20 and 85% before the age of 25.

PLACE OF ROUTINE EXAMINATIONS IN PROMOTION OF HEALTH AMONG INDUSTRIAL EXECUTIVES*

BY

OTIS B. SCHREUDER, M.D.

Medical Director, Atlantic Division, Pan American
World Airways, Inc., New York

Although occupational medicine has been well recognized and well implemented in industry in the United States for a number of years, it is only during the past eight to ten years that the executive health phase of this programme has been stressed to any great extent. That industrial medicine has progressed rather rapidly during the past several years in the United States is shown by its recognition as a specialty under the American Board of Preventive Medicine, other subspecialties under this board being public health and aviation medicine.

Industrial Medical Programme

Management has recognized the value of a medical programme in industry, including an executive health programme. Ruffin (1957) has stated that "the health, wellbeing and morale of the men and women are among the most precious assets that we have in industry," and, in general, industry has accepted its measure of responsibility for the health and safety of its employees. Health maintenance programmes are of primary benefit to the employee, but they play their full share in keeping down the competitive costs, reducing operating expenses, and increasing efficiency. According to Proudfoot (1957), the accumulated experience of companies that have fostered modern industrial medical programmes has made it plain that an investment in health is good business and that any manager who is required to operate without needed medical service or with expensive unsolved health problems in his employees knows it is bad business not to have available good medical counsel and service. He refers to a report furnished by the American Management Association in which it is concluded that, from data furnished by a number of industries with medical departments, there is a consistent profit of \$3.50 to \$5 for each dollar spent in the medical department.

Irvin (1952), as the result of comments obtained from a questionnaire submitted to executives who had undergone a periodic health check, concluded that health maintenance of key personnel was a sound financial investment and that the executive was very appreciative of the annual check-up on his physical status. Trickett (1952), in a survey of industry having executive health programmes in the San Francisco area, found that as a rule such a programme was of value. However, his study revealed that health problems of management employees were often overlooked, which seemed amazing, since direct or indirect financial loss can result from inadequate performance and also since executives are often careless of their own health.

There is considerable variance of opinions on whether or not the death rate among executives is greater than in similar age groups of individuals not occupying executive positions. However, we do know that disease incidence and trends have changed remarkably in the past several decades. There is less tuberculosis, and cases of communicable disease and pneumonia are fewer. The infant mortality is less and longevity is greatly extended. With increasing age there is less resistance to disease and consequently an increase in the number of degenerative diseases, with heart disease and malignancies being responsible for a large percentage of deaths in the older age groups. Since the executive is usually in the older age group he is more prone to

acquire one of the degenerative diseases and therefore should be included in the health maintenance programme. Executive ability represents great worth to any industry, the potential value of the executive being variously estimated to be between \$50,000 and \$250,000, depending on how far down or up he is categorized on the management scale. The sudden death of or a serious disabling disease in a top executive has in some cases proved to be almost disastrous because of lack of continuity of management.

Objectives of a Health Programme

The objectives of an executive health programme are to provide health maintenance for the purpose of improving health, increasing efficiency, and prolonging life, protecting the company's investment, and ensuring continuity of management.

There are several guiding principles that are generally accepted. First, the programme must have the whole-hearted support of management, since without such support it will fail. Second, it must be decided which groups are to be examined; in other words, will only the top executive groups be included in the programme or will it extend to the lower management groups down to and including the foremen? Third, how often will the periodic examination be given? This depends upon the number of personnel and equipment available and the economic cost. An annual examination is desirable if it can be accomplished within the provisions stated. An annual periodic examination after the age of 40 or 45, with a biennial examination up to that age, might be advisable. Fourth, should the examination be done by the company medical department or should the executive be referred to an outside hospital or clinic? There are arguments on both sides. It is generally believed that an examination by the company medical department is the better of the two plans, since it is more convenient, the medical director of the company is more familiar with the working conditions, follow-up medical procedures are easier to implement, and it is usually more economical. Fifth, the findings should be treated as confidential between the examinee and the examining physician. Sixth, those cases requiring definite medical care should be referred to outside physicians.

Before discussing the routine examination, it is felt that a few words would be appropriate on the preplacement examination. In airline operation the preplacement examination for the pilot is very thorough, very exacting, and very selective. The examination is conducted not only on the basis of the applicant's present condition but also on the pilot's potential physical and mental condition twenty to thirty years in the future. On this basis a fair percentage of pilots are disqualified physically because of one or several minor defects which may in the future prove to be detrimental to his health. The disqualification rate of pilot applicants varies between 10 and 15%. On the other hand, the examination of the ground employee, including the potential executive, is not as exacting, since the condition of many of these individuals is acceptable for ground duty but not for pilot duty.

After the initial examination for employment, subsequent routine or periodic examinations are for the purpose of conserving or maintaining health. The main intent of this examination is to disclose disease processes in their incipency so that corrective action can be taken. The principles of preventive medicine are first involved in the preplacement examination and continued during the periodic and special examinations.

Periodic Physical Examination

What should the routine physical examination include? Once again the extent of the examination depends upon the time available, the number of personnel, and the amount of available equipment in the medical department. However, a good periodic examination should include the following: a good history, thorough physical examination, including

some procedures which often are overlooked, such as an ocular tension determination, an examination of the fundi, palpation of the peripheral blood vessels, rectal examination, and a detailed vision examination; laboratory studies, including urinalysis, haemoglobin estimation, sedimentation rate, blood sugar if over 40 years of age; x-ray picture of the lungs; and an electrocardiographic tracing if over 40 years of age. Other laboratory procedures, such as serum cholesterol and non-protein nitrogen estimations and a glucose-tolerance test, should be requested if and when deemed necessary. Unless definitely indicated it is not believed that routine diagnostic x-ray procedures such as gastro-intestinal series, barium enemas, or cholecystography should be done. Likewise, routine serological tests have now been discarded by many.

It is generally conceded that the routine periodic examination is of very definite value. Roberts (1958), in a review of the literature, found that 37.1% of 16,715 individuals examined had significant disease. He also reported that in a tabulation of the results of "routine" laboratory examinations 2.5% of 425,005 cases were abnormal for sugar, 3.2% of 45,961 cases were abnormal for albumin, and 11.91% of 15,619 subjects examined electrocardiographically had abnormal tracings. Franco (1950) found that 149 of 307 executives examined had major medical defects. Cardiovascular conditions accounted for 36% of the defects, and obesity was diagnosed in 25%. Thompson and Staack (1956) found that, in a study of 600 executives, diseases of the arteries and heart made up the largest percentage of newly discovered diseases. These consisted mainly of hypertension and arteriosclerotic heart disease, which occurred in approximately 25% of the cases examined. Hartman (1952), in the proctoscopic examination of executives over 45 years of age at the Mayo Clinic, found that 13% had rectal polyps without symptoms, some of which had undergone adenocarcinomatous changes. In a series of 2,000 cases regardless of age or symptoms he reported that the incidence of rectal polyps was 8%.

During the three and a half months from January 1 to April 15, 1958, a statistical analysis was conducted of 120 periodic examinations in the management group in our company. These cases were taken consecutively. Of the 120 examination, 60 were in the top pilot group aged 35 or older, and 60 were in the management group aged 35 or older. The average age of the pilot group was 40.3 years and of the management group 41.4 years. In the pilot group 38 physical defects were found, eight of which were considered of sufficient significance to warrant follow-up corrective action. In 28 of the 60 pilots examined no abnormalities were found. In the management group there were 78 physical defects, 33 of which were classified as significant, no abnormalities having been found in seven cases. In other words, significant defects were found in approximately 50% of the management group as compared with approximately 13% in the pilot group. There are several reasons for the difference in findings in the two groups—namely, those in the pilot group are specially selected from a physical and health standpoint, a health maintenance programme for this group has existed for many years, and, lastly, as a group they are a great deal more "health conscious" than those not engaged in pilot activities.

Examination Findings

Year in and year out the significant conditions most often disclosed, about which we can take positive and definitive measures, are certain metabolic diseases, including obesity, cardiovascular conditions, and gastro-intestinal conditions including peptic ulcers and parasitic infestations.

Obesity is a common finding, and at times it is difficult to convince the individual that weight reduction is indicated. This is particularly true if no other abnormal findings are disclosed. To reduce, the executive must be properly motivated, be convinced of the potential ill effects of overweight and have the will-power to remain on a low-calorie diet.

In those cases where obesity is associated with diabetes or beginning hypertension little or no difficulty is encountered.

Other diseases that have been disclosed are thyroid conditions which are very obvious, and the employees in whom such a condition has been found have been very grateful for the information after corrective action has been taken. Diabetes mellitus is also a relatively common finding. In the original examination of the pilot and executive groups a postprandial urinalysis and blood sugar test is made. It is believed that this procedure is superior to the fasting urinalysis and blood sugar test in recognizing the early or latent diabetic. Applicants are not accepted as pilots if they have diabetes or if they show diabetic tendencies. Postprandial blood sugar tests are made on the pilot group after the age of 35 and on the management group after the age of 40. Prevention of diabetes in the older age group is closely related to the prevention of obesity, control of overweight being particularly important if there is a familial history of diabetes. The close observation of the occasional individual who has a slight glycosuria is also important, since it is believed that transient or alimentary glycosuria is often the precursor of diabetes. It is also a well-recognized fact that the well-controlled diabetic is less apt to develop the early degenerative changes that occur in the uncontrolled diabetic.

In cardiovascular diseases the potential hypertensive individual is seen fairly often, usually associated with obesity. Occasional cases of angina are also disclosed. Electrocardiograms are taken of the pilot and executive applicants so as to have a baseline electrocardiogram for future reference. In the routine physical examination, electrocardiograms are taken annually in the pilot group at 35 years of age and in the executive group at 40. Very infrequently cases of recent coronary thrombosis have been disclosed by the use of the electrocardiogram. Other abnormalities have been found, such as bundle-branch blocks, A-V blocks, etc. Although serious coronary disease may exist with a normal electrocardiogram, depression of RST and T waves in leads I and II and the chest leads may be suggestive of this condition.

In the routine periodic examination it is very rare that hidden asymptomatic malignancy is disclosed. However, those cases in which malignant or pre-cancerous growths can be seen may be picked up and corrective action taken. These include those with lesions involving the skin, nasopharynx, and oral cavity. Although sigmoidoscopy after the age of 45 would be desirable, because of certain limitations we have not been able to include this in our routine examinations.

Certain gastro-intestinal diseases, such as peptic ulcer, have been suspected in a number of cases from the history, and referral has led to corrective action with relief of symptoms. Closely associated with this is the occasional case of cholecystitis and cholelithiasis. Parasitic disease has been a relatively frequent finding consequent upon operation in the tropics.

Mental Stress and Strain

No paper on executive health is complete without some mention of the mental stress and strain which the average executive undergoes in carrying on his duties. In this connection there is an excellent pamphlet by C. G. Roberts (1951) which states: "The ever-increasing intricacy of industrial techniques accompanied by an equally rapid advance in the complexity of social, governmental, commercial and industrial organizations seems now to be taxing the highest levels of man's mental ability to the full." He writes in considerable detail about the nature of mental skill and the responsibility as related to the executive, the cause of stress with its resultant breakdown in some executives, and the solution.

An important phase of the periodic examination is the conference or discussion with the examinee with a view to obtaining any history of previous or intercurrent diseases and informing him of any defects found during the examination. Of particular importance is a discussion relative to

*Read in the Section of Occupational Health at the Annual Meeting of the British Medical Association, Birmingham, 1958.

any stress or strain which he is undergoing, informing him of the importance of the annual vacation, of leaving his work and worries in the office, of hobbies and outside interests, and, finally, of relaxation.

Conclusion

The employee is one of the most valuable assets in any company, and of the employees the management group or executives are particularly valuable because of their training, motivation, and high degree of technical and administrative skill. A health maintenance scheme for the executive is an essential part of any industrial medical programme. Its main object is the detection of disease in its incipency in order that corrective action may be taken so as to maintain him in good health and increase his longevity and efficiency.

EFFECT OF PREDNISOLONE ON ANAEMIA ASSOCIATED WITH MACROGLOBULINAEMIA

BY

W. R. PITNEY, M.D., M.R.A.C.P.

Department of Haematology, Royal Perth Hospital

W. J. O'SULLIVAN, B.Sc.

Department of Biochemistry, Royal Perth Hospital

AND

J. A. OWEN, Ph.D., M.B., B.Sc.

Department of Biochemistry, University of Melbourne

In spite of numerous case reports, the pathogenesis of macroglobulinaemia remains obscure. The diversity of clinical features in patients with this abnormality (Waldenström, 1952; Wilde and Hitzelberger, 1954; Long *et al.*, 1955; Ferriman and Anderson, 1956; Mackay *et al.*, 1956, 1957; Jim and Steinkamp, 1956; Martin and Close, 1957; Wanner and Siebenmann, 1957; Kappeler *et al.*, 1957) suggests that it does not itself constitute a disease entity, though it appears in many cases to be associated with neoplastic disease of reticulo-endothelial tissue. In most cases therapeutic measures have not affected the macroglobulinaemia and have failed to shed light on the nature of the anomaly. In view of this, we record the findings in an elderly woman with unexplained anaemia and macroglobulinaemia who has shown marked improvement, in respect both of her anaemia and of her macroglobulinaemia, while being treated with prednisolone.

Case Report

The patient, now aged 73, has attended the Royal Perth Hospital periodically for the past 15 years. Hospital records show that in 1943 and again in 1945 the haemoglobin value

of her blood varied between 8 and 9 g./100 ml. No further haematological investigations had been undertaken at those times.

In 1955 she was investigated for anaemia. The clinical history was not informative. She did not suffer from a bleeding tendency. Apart from pallor, clinical examination revealed no abnormality. The liver and spleen were not palpable and the lymph nodes were not enlarged. Anaemia

was of normochromic normocytic type with a haemoglobin value varying between 7.1 and 8.6 g./100 ml. The erythrocyte sedimentation rate was elevated, lying in the range 74 to 155 mm. fall in one hour (Westergren). The total serum proteins as determined by the alkaline biuret reagent of Weichselbaum (1946) were 9.2 g./100 ml. Salt fractionation with 26.9% sodium sulphate solution gave values of 2 g./100 ml. for albumin and 7.2 g./100 ml. for globulin. Paper electrophoresis of serum (Flynn and de Mayo, 1951), using azocarmine B as a protein stain, showed a discrete band of abnormal protein in the γ -globulin region similar to that shown at A in Fig. 1. Bence Jones proteinuria was not present. Examination of sternal marrow and radiological examination of the skeleton failed to reveal any further abnormality, so that a provisional diagnosis of myelomatosis was not sustained. After unsuccessful therapy with a variety of haematinics the patient was treated with blood transfusions.

In 1956 an enlarged lymph node was noted in the left axilla. Further investigations showed that the abnormal serum protein was macroglobulin. It did not migrate from the point of insertion when electrophoresis was carried out in starch gel (Silberman, 1957). On examination in the ultracentrifuge* the serum was found to contain an abnormal component constituting 23% of the total protein (total protein 7.3 g./100 ml.) with a sedimentation constant of 15.3 S. There was also a small amount of a faster sedimenting protein (Fig. 2, A). In addition the serum gave a positive result with the Sia test, although this is not exclusive to macroglobulinaemia.

At this time the haemoglobin value of the blood was 9.1 g./100 ml. and the haematocrit 29%. The reticulocyte

*Spinco model-E ultracentrifuge; rotor An-A; centrifugal force, number $\times$ gravity = 182,000; serum dilution of 1+4 in 0.2 M NaCl solution; pH=7.0; temperature of rotor, 20° C.

FIG. 2.—Ultracentrifuge pattern of serum. A, Before prednisolone therapy (October, 1956). B, On cessation of prednisolone (June, 1957). Arrows indicate the major macroglobulin component.

count was 2.4% and the Coombs reaction on the patient's red cells negative. Survival of the patient's ^{51}Cr -labelled red cells in her own circulation was normal. The total leucocyte count was 6,600/c.mm., with 53% polymorphs, 37% lymphocytes, 8% monocytes, and 2% eosinophils. The sternal bone marrow was of normal cellularity and showed a moderate increase in lymphocytes, which numbered 29% of all nucleated cells present. There were 2% plasma cells and 16% normoblasts. Further skeletal x-ray films showed no abnormality.

Progress is illustrated in Fig. 3. The patient was transfused in October and December, 1956. Prednisolone therapy was then begun at an initial dosage of 40 mg. a day, which was soon reduced to 20 mg. After an initial fall in the haemoglobin value there was a steady improvement, first noticed one month after starting prednisolone. By April, 1957, the haemoglobin value was 14.2 g./100 ml. and the haematocrit 43%. The patient was in good health except for recurrent furunculosis.

In June she developed an acute sinusitis, which progressed to an orbital cellulitis requiring surgical drainage. During her stay in hospital prednisolone therapy was discontinued. The haemoglobin value of the blood fell to 10 g./100 ml. over a period of a week. With the control of infection it

FIG. 3.—Effect of therapy on blood haemoglobin value and concentration of protein migrating electrophoretically as γ globulin. The figures 3 and 4 refer to pints of blood transfused. Concentrations of dye eluted from the γ -globulin region are expressed as a percentage of the concentration found in October, 1956.

FIG. 4.—Reticulocyte percentages (lower curve) and haemoglobin values (upper curve) during the second course of prednisolone therapy (January, 1958).

spontaneously rose to 12 g./100 ml. and maintained itself at about this level for six months without further therapy.

In December she suffered from influenza. When she was seen one month later, her haemoglobin value was 8.6 g./100 ml. and therapy with prednisolone was recommenced. Subsequent haematological findings are shown in Fig. 4. After 23 days the reticulocytes rose to 8.3%. The haemoglobin value improved shortly after this, and has been maintained since between 12 and 13 g./100 ml. At the time of writing the patient was being treated with a maintenance dose of 10 mg. of prednisolone daily.

Since the beginning of treatment in December, 1956, total serum proteins have been estimated and serum paper electrophoresis performed at frequent intervals. By May, 1957, the dense band of abnormal protein in the γ -globulin position on the electrophoretic strip was distinctly less, and by June, 1957—that is, six months after beginning prednisolone therapy—it had disappeared (Fig. 1, B). Paper electrophoresis at this time showed a slight increase in the α_1 - and α_2 -globulins. Macroglobulins could still be detected on ultracentrifuge analysis, however, but in less amount than previously (12% of total protein; total protein, 6.4 g./100 ml.) (Fig. 2, B). The Sia test was still positive.

Fluctuations in the amounts of serum protein migrating as γ -globulin were followed by eluting the dye from the relevant area of the electrophoretic strips with 2.5 M sodium hydroxide and measuring the amount of dye photometrically. The results, expressed as a percentage of the initial value, are shown in Fig. 3. Between October, 1956, and June, 1957, there was a steady decrease in protein concentration in the γ -globulin position to 21% of the initial value.

On cessation of prednisolone therapy, concurrent with the onset of orbital cellulitis, the γ -globulin fraction rose sharply, then fell again and has since maintained a fairly steady value. The abnormal band reappeared in the γ -globulin position on the electrophoretic strip one month after prednisolone therapy was stopped and has persisted since then. The second course of treatment had produced no obvious change in the electrophoretic pattern at the time of writing.

Discussion

The mechanism of the anaemia is obscure and its duration uncertain. In the absence of other demonstrable causes of anaemia, it seems reasonable to suggest that the low haemoglobin values recorded in 1943 had the same aetiology as the present anaemia. Although the bone marrow contained an excess of lymphocytes, it is unlikely that the anaemia was due to marrow infiltration, as erythropoiesis appeared adequate. The anaemia was not haemolytic in nature. The degree of marrow erythropoiesis was normal, reticulocyte counts have not been increased apart from therapy, and the patient's red cells gave a negative Coombs reaction. Furthermore, the patient's red cells survived normally in her own circulation. On the other hand, an autoimmune mechanism is suggested by the response to prednisolone therapy. The delayed reticulocyte response noted during the second course of prednisolone therapy suggests that the drug corrected the anaemia through some intermediary mechanism, as specific haemopoietic factors usually show demonstrable effects in a shorter time than this.

A patient of Wilde and Hitzelberger (1954) suffered from autoimmune haemolytic anaemia associated with macroglobulinaemia. As might be expected, this responded to cortisone therapy. Other reports in the literature of cortisone therapy in patients with macroglobulinaemia refer to cases in which the clinical findings resembled lymphosarcoma (Di Guglielmo and Antoninix, 1955; Mackay, 1956; Jim and Steinkamp, 1956). In these patients the therapy had little effect.

The duration of macroglobulinaemia in our patients is uncertain. Almost certainly macroglobulins were responsible for the abnormal serum protein results first noted in 1955.

No cause for macroglobulinaemia has been demonstrated. Although the patient has a marrow lymphocytosis and one enlarged axillary lymph node, the liver and spleen are not enlarged, and the findings differ from many of the cases of macroglobulinaemia so far described—for example, Mackay *et al.* (1956), who suffered from a disease resembling lymphosarcoma. However, it is possible that she may eventually develop this syndrome. It is purely speculative to suggest that lymphocytes might be the source of the abnormal protein.

The alteration in the serum electrophoretic pattern after prolonged prednisolone therapy is of great interest. It should be stressed that the values for γ -globulin shown in Fig. 3 represent both "normal" γ -globulin and macroglobulin. Therefore there are difficulties in interpreting fluctuations in their values, as a diminution in either would result in a decrease of total γ -globulin. However, the decrease in values between October, 1956, and June, 1957, was so marked that it is reasonable to conclude that it represents diminution in macroglobulin concentration. This is also confirmed by ultracentrifuge data, which estimated the macroglobulin to have diminished during this time. Furthermore, the discrete component on the paper electrophoretic strip which was presumably due to macroglobulin (Fig. 1, A) could not be seen on the later strip (Fig. 1, B).

The patient probably shows an increased susceptibility to infection, having suffered from recurrent furunculosis, orbital cellulitis, and a respiratory infection over a period of 18 months. It is possible that she suffers from hypogammaglobulinaemia, demonstration of which would be made difficult by the appearance of macroglobulin in the γ -globulin region on serum paper electrophoresis. Evidence to suggest hypogammaglobulinaemia is furnished by the electrophoretic strip performed in June, 1957 (Fig. 1, B). This shows an intensity of staining in the γ -globulin region within normal limits. As the serum still contained a considerable amount of macroglobulin demonstrable by ultracentrifuge analysis, the normal γ -globulin component was probably reduced.

Summary

The clinical findings are described in the case of an elderly woman who suffered from an unusual form of anaemia and macroglobulinaemia for at least three years. Treatment with prednisolone corrected the anaemia, and this was associated with a diminution in the amount of abnormal protein in the blood.

Dr. John O'Dea, Commonwealth Serum Laboratories, Victoria, carried out the ultracentrifuge analyses. One of us (J. A. O.) has received a grant from the National Health and Medical Research Council.

DEATH CERTIFICATION OF CHILDREN

BY

JOHN L. EMERY, M.D., D.C.H.

AND

K. A. IRVINE, M.B., B.Ch., D.C.H.

Department of Pathology, the Children's Hospital, Sheffield

The certification of the cause of death is, to the lay person and the administrator, a simple statement of fact. To the pathologist, on the other hand, the "cause of death" is the summation of a number of factors each of which in isolation may be of little importance. At best one knows in part what a person dies with, but not necessarily what he dies from.

The practice of clinical medicine necessitates a concentration on the treatable aspects of disease and a simplification of pathology requisite for a practical approach to the patient. The present form of death certification is designed by necessity for use by clinicians. It has a twofold approach: first, steps in the progress of a major disease, and, secondly, associated disease. Its form is probably as good as can be devised.

The present small survey of 150 deaths was made to assess the efficiency of death certification as carried out in a children's teaching hospital. The resulting figures are statistically significant and show a degree of inaccuracy not generally appreciated.

Material and Method of Survey

Permission is requested to carry out a post-mortem examination on every child dying in the Sheffield Children's Hospital and is granted in over 90% of cases. At the same time the house officers are asked to indicate on the death certificate that additional information may be available later as a result of the necropsy. The cause of death is revised by the pathologist when the final necropsy diagnosis is made.

Other than this being a consecutive series, no particular selection of the 150 cases was made. The children's ages at death varied from several hours to 12½ years: 78 (52%) died at or before 3 months; 12 (8%) between 4 and 6 months; 24 (16%) between 7 months and 1 year; 23 (16%) between 2 and 3 years; and 13 (8%) between 4 and 12½ years. Thus 137 (92%) of the deaths occurred at or before 3 years of age. The cause of death entered on the death certificate was compared with the final pathological diagnosis made after consideration of the clinical findings, naked-eye pathology, and histology of the case. A record was also made of the duration the child had been in hospital, or, in cases where there had been more than one admission for the same condition, the duration under medical supervision was estimated. Each case was then placed in one of five groups, according to the following criteria.

Group 1.—Cause of death recorded on the death certificate accurate and complete as compared with the pathological findings.

Group 2.—Cause of death accurate in major respects but incomplete in minor points, which did not alter the final diagnosis.

Group 3.—Cause of death inaccurate as compared with the major pathological findings, but minor points accurate.

Group 4.—Pathological findings necessitated a complete revision of the cause of death.

Group 5.—Cause of death as recorded not substantiated by post-mortem examination and no adequate pathological cause of death found.

The following are examples of cases placed in the above groups.

<i>Certified Cause of Death</i>	<i>Pathological Findings</i>
Group 1: Girl aged 10 months	
(a) Acute adrenal insufficiency.	Congestion of the adrenal glands and histochemically greatly reduced lipid content. Meningococcal meningitis and septicaemia.
(b) Meningococcal meningitis.	
(c) Meningococcal septicaemia.	
Group 2: Boy aged 4 months	
Tuberculous meningitis.	Tuberculous meningitis. Miliary tuberculosis involving lungs, spleen, liver, kidneys, and meninges. Primary tuberculous complex in right lower lobe of lung and caseating hilar glands.
Group 3: Girl aged 11 days	
(a) Bronchopneumonia.	Purulent meningitis associated with hydrocephalus due to congenital obstruction between lateral and third ventricles and lumbar meningomyelocele. Oedema of lung (no pneumonia).
(b) Congenital meningomyelocele.	
Group 4: Girl aged 1 day	
(a) Asphyxia neonatorum.	Cerebral haemorrhage due to tears in the falx cerebri and tentorium. Bilateral atelectasis and left-sided pneumothorax. Bilateral adrenal infarction and renal vein thrombosis. Breech delivery.
(b) Breech delivery.	
Group 5: Boy aged 3 weeks	
(a) Gastro-enteritis.	Post-mortem findings showed wasted mature child, but no adequate cause of death.
(b) Prematurity.	

Group 1 comprises 23 (15%) cases; group 2, 59 (40%); group 3, 33 (22%); group 4, 28 (18%); and group 5, 7 (5%). If one omits group 5 and combines groups 1 and 2, as those cases where there was no significant change in the certification, and combines groups 3 and 4, where the pathological findings differed considerably from the clinical assessment, the distribution becomes: groups 1 and 2, 82 (55%); groups 3 and 4, 61 (40%). These figures may be regarded as having a statistical trustworthiness—that is, as indications of a firm underlying rate—of about ± 15 ($\pm 10\%$) in both cases.

In seven of the 150 cases no pathological diagnosis was eventually made. These deaths all occurred at or before 3 months and represented almost 10% of deaths occurring under 3 months or 5% of all deaths.

Effect of Age.—The ratio of groups 1 and 2 to groups 3 and 4 at different ages is shown in the Table. The figures

Group:	1	2	3	4	5	Total
No. in group	23 (15%)	59 (40%)	33 (22%)	28 (18%)	7 (5%)	150
	82 (55%)		61 (40%)			
Age at death:						
0-3 days	7		13		3	23
4 days-3 months	32		19		4	55
4 months-1 year	22		14		—	36
1 year-3 years	12		11		—	23
4-10 years	9		4		—	13
Duration under medical care:						
24 hours or less	26		17		4	47
2-5 days	9		18		1	28
6 days-6 months	36		21		2	59
7 months+	11		5		—	16

give no statistically significant—that is, by tests using the 5% level of significance—or even strongly suggestive evidence that the age of death played any part in determining the accuracy of the cause of death given.

Duration under Medical Supervision.—In assessing the consistency of diagnosis related to the duration of the children's medical care, of 47 children who died after medical care for 24 hours or less, 26 (55%) had an accurate diagnosis. Among the 28 dying after medical care of two to five days' duration, 9 (32%) diagnoses were accurate. Of 59 under care for six days to six months, 36 (61%) diagnoses appeared accurate, and among the 16 cases with medical care of over six months, 11 (69%) were apparently accurate. These figures show no significant difference, and suggest that the duration under treatment is not a major factor in the accuracy of diagnosis.

Discussion

In this series of 150 certifications the correct cause of death, as assessed by the pathologist, was not given in more than 55% of the cases. The accuracy or inaccuracy of the primary entry was influenced very little by the age of the child at the time of death or by the length of time the child was under medical care.

The cause of death entered on the certificate is not necessarily the complete clinical diagnosis made in hospital. That 40% of the total number of cases fell into group 2 (accurate but incomplete) and 40% into groups 3 and 4 suggests that the information submitted on the death certificate was not adequate.

It would seem possible that doctors may have been to some extent influenced by the knowledge that they were initialling the reverse side of the death certificate, but this would affect only the accuracy of certifications as between our groups 1 and 2, but not between groups 2 and 3. The same applies to the use of different terms to describe similar conditions.

The accuracy of the cause of death statistics according to death certification appears to have been of more concern to American workers than to workers in this country (Lane and Holla, 1954; West, 1955), and varying degrees of accuracy of certification have been given as a result of several surveys. We have been unable to find any published figures of this kind for this country.

The Registrar-General is well aware of the problems of accuracy of death certification, and has discussed these in his reports for 1940 and 1950, stressing improvement in certification which follows necropsy.

The extent of the problem is shown in his report for the year 1953 (Registrar General, 1956), where he analyses the certification of causes of 114,642 deaths for the June quarter of 1953, grouping the certifications according to whether the certificate was filled in by the coroner or by the general practitioner, and whether death occurred inside or outside hospital. Great variation in the causes of death in these different groups was found, ranging from 1% disagreement for senility to 70% for pneumonia in the newborn and 75% for meningococcal infections. These certifications obviously involve different groups of cases, and the Registrar-General, by the very nature of the information available to him, is able to compare only the causes of death certified by different groups of people on different cases, but he is not directly able to compare the differing diagnoses in the same cases, the essential for a fair comparison.

Swartout and Webster (1940) report an accuracy of 79% in a study of 8,000 deaths in Los Angeles. They compared the necropsy diagnosis with what they considered would have been the clinical diagnosis, but without reference to the original death certificates. Evans (1949) found an accuracy of only 43% in a study of 3,900 death certificates, basing the findings on his own judgment and without the aid of necropsy findings. Korns and Lintz (1949) found disagreement between the clinical cause of death statement

and pathological findings in 11–20% of 500 hospital cases; and James, Patton, and Heslin (1955) found 71% of original certificates agreeing with necropsy reports in a survey of 1,889 necropsies, but with wide variation within the groups of different diseases, ranging from 21% agreement in the group of arteriosclerotic heart disease to 93% agreement in the group covering tuberculosis. Pohlen and Emerson (1942, 1943) found consistency in diagnosis in 96% of tumours of the heart, compared with 26% in liver tumours, 99% in measles, and 52% in heart disease.

In the above articles, all of which come from public health departments, there is a tendency to state that errors in registration occur between the few larger groups of causes of death, and that the errors in one direction tend to cancel the others out, making the overall statistics relatively accurate. This seems to be an unfortunate argument, as it would appear to give the published figures false accuracy—the type of accuracy obtained by drawing random diagnoses out of a hat—and minimize the danger of arguing from any of the registrar's statistics.

In assessing the accuracy of certification, any comparison made must be between the cause of death as originally certified and the cause of death after survey of all information obtained by clinical and necropsy examination. Inaccuracies in certification arise in two ways: first, a failure to record accurately the knowledge available at the time of death—that is, negligent certification; and, secondly, the inadequacy of the knowledge available at the time of certification.

In a teaching hospital, where every child, particularly an ill child, is under constant discussion, it is unlikely that faulty certification is due to the absence of available knowledge of diseases; on the other hand, certificates are often filled in by junior housemen who have not acquired the art of avoiding terminology that may lead to inquiries by the coroner. The tendency in both of these instances would be towards a more accurate registration if not conventional. We would thus expect the registration in the present survey to be at least as accurate as is likely to occur in the general field of child deaths.

Summary

A survey of the accuracy of the causes of death given to the registrar at a children's hospital showed that almost one-half of the certifications were not correct as judged by the final pathological diagnosis.

We are grateful to Dr. G. H. Jowett, head of the Department of Statistics of the University of Sheffield, for his advice and comments, and to our clinical colleagues for permitting these diagnostic ablations.

In an address on "The Art and Science of Research," before a sectional meeting of the Manchester Medical Society last month, Dr. J. H. SCOTT, lecturer in anatomy at Queen's University, Belfast, defined research as the intellectual fashion of our time. He compared "useless" and "useful" research as illustrated by the discovery of Nasmith's membrane in 1839 and of penicillin in 1929, and the part played by chance in certain cases. Discussing Humphry's work on jaw growth in pigs, he pointed out how the results of research were not always applied successfully to the solution of the problems they were supposed to solve. Research, he said, did not primarily depend on money, or on complicated apparatus, but on a peculiar attitude of mind in which curiosity, persistence, and clarity were essential features.

INFLUENCE OF MATERNAL MALARIA ON NEWBORN INFANTS

BY

H. M. ARCHIBALD, M.B.E., M.B., Ch.B., D.P.H.
Specialist (Malaria) and Northern Region, Nigeria

It is well known that schizonts of *Plasmodium falciparum* tend to concentrate in the maternal tissue of placenta in the latter half of pregnancy in women infected with that parasite (Blacklock and Gordon, 1925; Garnham, 1938; Bruce-Chwatt, 1952). There has, however, been considerable controversy about what effect this concentration has on the infant born of such placenta to women who are natives of territories where malaria is so prevalent that adult immunity to it is substantial. On the one hand is the Sierra Leone series of Blacklock and Gordon containing "proof of a very complete association between maternal infection of the placenta and death of the child in utero or within a seven-day observation period after birth." On the other hand is Garnham's (1949) diametrically opposite assertion from observations in Kenya that "malarial infection in the mother seldom resulted in stillbirths or in death of the infant in the first week," and that "Luo children are unlikely to suffer ill effects from infection in the mother."

Observations in Lagos (Bruce-Chwatt, 1952) have shown that, although there is no apparent correlation there between neonatal mortality and malarial infection of the placenta, yet there are grounds for believing that such infection is a cause of prematurity and, more generally, of the birth of underweight babies. A further report from Southern Nigeria (Archibald, 1956) confirmed these ill effects.

The present paper presents evidence from Northern Nigeria that this infection commonly prevents African infants born there to malarious mothers from reaching their proper weight at birth.

Present Investigation

The evidence was collected from a number of centres in Northern Nigeria where the birth weight of infants was noted, a number of particulars were obtained from the mother, and blood smears were collected from the maternal surface of the placenta and from the mother's finger at the delivery. The blood smears were examined by the regional malaria unit. The group investigated was mainly drawn from deliveries which took place in medical institutions, and was obviously a selected sample of the population. This was underlined by the finding of malaria parasites in only 15% of the smears examined, a rate much lower than the adult parasite rate generally found in the Northern Region of Nigeria.

The present series consisted of 484 women, 73 of whom were infected at delivery with *P. falciparum* (a few were also infected with *P. malariae*). In most of the mothers, parasites could be detected in the smear both from the finger and from the placenta, but in eight cases they were found only in the placenta and in seven only in the finger. Of the 484 pregnancies, 18 were multiple, two of triplets; and of the 504 infants born, 30 (5.9%) were stillborn, 4 (0.8%) were born alive before term, and 470 born alive after pregnancies which had gone to full term. Of these full-term babies, 440 were single deliveries, and it is with these that the further analysis deals.

Table I shows the distribution of birth weights of these babies. Of the 62 infants born from malarious placenta, 13 (20.6%) were premature—that is, weighing 5½ lb. (2.495 g.) or under (W.H.O., 1950)—as contrasted with 31 (8.2%)

of 378 infants born from uninfected placenta. This contrast is significant ($\chi^2=9.7$; $P<0.01$). The mean weight of the 62 infants born from malarious placenta was 10½ oz. (298 g.) less than that of the 378 infants born from uninfected placenta.

The distribution of the 440 single full-term deliveries according to the race to which the mother belonged is shown in Table II. The mean weight of infants born from malarious placenta is consistently lower than that of infants born from uninfected placenta, irrespective of the mother's race. It is of interest to note that the mean birth weight of the infants born from uninfected placenta is very much the same for all racial groups represented in this series, whereas the Hausa infants born of infected placenta were on the average of lower weight at birth than either the Yoruba or Ibo babies. This is consistent with the hypothesis that the immunity developed by the indigenous people of Northern Nigeria, where there is a strictly circumscribed wet season and an explosive seasonal intensification of malaria transmission, is less well established than is that developed by Southern Nigerians who have been bred in conditions where malaria is stable.

An attempt was made to classify the families into which those 440 infants were born in accordance with the standard classes used by the Registrar-General of the U.K. (class I, professional; class III, skilled workers; class V,

TABLE III.—Record of Birth Weights of 440 Infants Born Alive in Deliveries After Full-term Pregnancies Recorded by Social Grouping

Social Group	Delivered from Malarious Placentae			Delivered from Non-malarious Placentae		
	No. in Group	Average Weight at Birth		No. in Group	Average Weight at Birth	
I	2	5 10	2,550	1	5 12	2,610
II	1	6 7½	2,935	24	6 12	3,060
III	30	6 1	2,750	206	6 12½	3,075

unskilled). This was not very successful because of the large number of families claiming to be "traders," a group which might embrace the merchant prince or the match-box seller. In fact, the average weight of infants at birth was surprisingly similar for all social classes, although for each class the babies born from malarious placenta were under weight as compared with those born from uninfected placenta. The finding that the birth weight did not improve with social class is not in accord with experience in developed countries, but the explanation may be that in the conservative polygamous society of Northern Nigeria a wife may not enjoy her husband's social advantages. Table III shows the social classification of the 440 infants. The small numbers in this series from social classes I and II indicate that advantage of Western obstetric facilities is not taken by the conservative orthodox leaders of Northern Nigerian society.

The influence of maternal parity on the weight of an infant at birth is well known. In the present small series it was found that, in each class, the infants from malarious placenta were less heavy than the others, but the overriding importance of parity was shown by the poor weights of babies born to primiparae.

Discussion

The present series of cases differs from those previously published from Southern Nigeria (Bruce-Chwatt, 1952; Archibald, 1956) in that the effect of malaria on birth weight is more pronounced in this northern than in previous southern groups. This is shown in Table IV.

The proportion of mothers in the series who at the same time showed infection in both blood and placenta was also much higher than has usually been found. In these women in Northern Nigeria, 79% of infections were manifest in both blood and placental smears. Schwetz and Peel (1934) reported a similar coincidence (74%) from the Congo, but in Blacklock and Gordon's (1925) Freetown series only 20% of infections were found in blood and placenta at the same time; in Garnham's (1938) Kenya series it was 59%, and in Bruce-Chwatt's (1952) Lagos group 43%. It is probable that these differences can be explained as being due to

TABLE IV.—Influence of Malarial Infection of Placenta on Birth Weight of Nigerian Babies

Series	Premature		Average Weight	
	In Malarious	In Non-malarious	In Malarious	In Non-malarious
Northern Nigeria	13/62 (20.6%)	31/378 (8.2%)	6 lb. 2 oz. ± 14.4 oz. (2,778 ± 408 g.)	6 lb. 12½ oz. ± 16.4 oz. (3,076 ± 465 g.)
Southern Nigeria	20/68 (29.4%)	65/395 (16.5%)	6 lb. ± 10 oz. (2,722 ± 283 g.)	6 lb. 6 oz. ± 14.6 oz. (2,892 ± 414 g.)
Lagos	15/73 (20.5%)	26/237 (11.0%)	5 lb. 13½ oz. ± 17.4 oz. (2,651 ± 493 g.)	6 lb. 2 oz. ± 15.1 oz. (2,778 ± 428 g.)

variations in the immunity of the mothers. Probably coincident infection of blood and placenta indicates that the woman has not succeeded in mastering the infection. On that postulate, the high coincidence of infection of both blood and placenta in the present series would signify that these women did not have a strong immunity. This is consistent with earlier impressions that immunity to malaria in Northern Nigeria is not firmly established.

Summary

A series of 440 full-term deliveries of single infants is analysed to elicit the effect produced by *P. falciparum* infection of the placenta on the weight at birth of African babies.

The series is analysed by race, social class, and maternal parity, and in each group the effect of malaria infection has been that infants born from infected placenta have a mean weight at birth below that of those born from uninfected placenta.

The effect of *P. falciparum* infection is more pronounced in the present series than in previous groups collected in Southern Nigeria.

The series showed an unusually high proportion of mothers with both blood and placental infections detectable at the same time.

It is postulated from the last two observations that the mothers in the present series were not succeeding in mastering their parasitaemia, and this is thought to strengthen earlier impressions that malarial immunity is not firmly established in the population of Northern Nigeria.

I am indebted to those members of the Medical Department of the Northern Region who assisted in the investigation, and to Dr. R. A. B. Dikko, Acting Principal Medical Officer of the Endemic Diseases Division of the Ministry of Health of the Region, for permission to publish this paper.

ISOLATION OF E.C.H.O. VIRUS TYPE 9 DURING AN OUTBREAK OF MENINGO-ENCEPHALITIS

BY

P. B. STONES, M.B., B.S.

Formerly National Fund for Poliomyelitis Research Fellow,
Department of Bacteriology, University of Manchester

During July, 1956, an epidemic of lymphocytic meningo-encephalitis with marked myalgia occurred in Newton-le-Willows, Lancashire (Lyle, 1956). At the same time type I poliomyelitis was occurring in Manchester and Cocksackie B meningitis in Stockport. Neither the epidemiology nor the symptomatology of the Newton-le-Willows outbreak suggested non-paralytic poliomyelitis or the clinically indistinguishable Cocksackie meningitis, but attempts were made in tissue cultures to isolate an agent from the faeces of seven patients.

Virus Studies

Faecal suspensions were prepared in saline and purified by high-speed centrifugation to remove contaminating bacteria. The resulting supernates were inoculated into stationary monolayer tube cultures of monkey-kidney cells prepared by a modification of Youngner's (1954) method.

Two specimens were tested shortly after receipt and both were found to be highly toxic to the culture cells, non-specific degeneration occurring within 24 hours of inoculation.

The residue of these, together with five other prepared specimens, were stored in a low-temperature refrigerator (-25°C), as prolonged storage has been found to diminish the toxicity of faecal extracts.

At the end of four months all the specimens were tested in monkey-kidney cultures as before, and also in stationary HeLa-cell cultures. Negative results were obtained in both types of culture with specimens from two adults and one child taken on the third, seventh, and sixteenth days of illness respectively. Of the other four specimens from children, two showed slight degenerative change in kidney cells with no effect in the HeLa strain, while the other two showed no change in either type of culture. In all four cases sub-inoculation of culture fluid was made to fresh kidney- and

HeLa-cell cultures. It was not until the fourth blind passage that definite cytopathogenic degeneration was noted in HeLa cells, although it was evident in all the monkey-kidney cultures at the second passage. A further series of blind passages in tissue culture was made with the three negative specimens previously referred to, without results at the fifth passage, when the material was abandoned. Lesions were not produced in 1-day-old mice either by original faecal suspensions or by tissue-culture fluids from cultures showing cytopathogenic effect inoculated by the intracerebral or subcutaneous routes.

Neutralization tests on tissue-culture fluids were carried out with antisera against poliovirus types 1, 2, and 3, and Cocksackie virus types B1-B5, with negative results. Tests with E.C.H.O. virus type 9 antiserum gave positive results identifying the agent.

Significant rises in neutralizing antibody in E.C.H.O. 9 virus were demonstrated by Dr. D. A. J. Tyrrell, of the Virus Research Laboratory, Sheffield, and by Dr. A. D. Macrae, of the Virus Reference Laboratory, Colindale, in 8 out of 10 cases from which paired sera were available, including one with negative faeces, and three of the four cases from which isolations were achieved. The fourth case had a high neutralizing antibody titre in the first serum specimen, and this was unchanged 15 days later.

Clinical Notes.—The ages of the children from whom isolations of virus were made were 5, 6, 7, and 12 years. All had fever, headache, and enlargement of posterior cervical lymph nodes. In three of the cases axillary glands were also involved, and two of these had inguinal gland enlargement as well. Central nervous symptoms were not prominent, but one child had a positive Kernig sign with slight neck rigidity, one had a transient loss of knee-jerks, and a third had some neck stiffness.

Discussion

The association of E.C.H.O. virus type 9 with cases of aseptic meningitis has been reported from West Virginia (Committee on E.C.H.O. viruses, 1955), and Belgium (Nihoul *et al.*, 1957). In the United Kingdom, Tyrrell and Snell (1956) and Tyrrell (1957, personal communication) recovered this agent from cases similar to Lyle's occurring in the Sheffield area in September, 1956, and a closely related agent with the additional property of pathogenicity for suckling mice has been isolated during outbreaks in East Suffolk (Boissard *et al.*, 1957), Leicester (Rotem, 1957), and Sweden (Wesslén *et al.*, 1958).

The initial negative findings in HeLa-cell cultures suggest that these are less sensitive than monkey-kidney cells for the primary isolation of this virus, and this is confirmed by the findings of Jamieson *et al.* (1958), who isolated five strains in monkey-kidney cells, but could not detect any virus using HeLa-cell cultures.

Although repeated passage in HeLa cells may lead to adaptation to this cell strain (Archetti *et al.*, 1957), this is not normally a practicable diagnostic procedure.

Summary

An agent serologically identical with E.C.H.O. virus type 9 has been isolated from four cases of lymphocytic meningo-encephalitis with myalgia and a rash occurring in an epidemic outbreak.

The expenses of this work were defrayed by a grant from the National Fund for Poliomyelitis Research. Clinical details of cases were made available by Dr. W. H. Lyle, to whom I express my thanks.

Medical Memoranda

Pituitary Deformity from Carotid Compression— a Potential Hazard in Pituitary Ablation

One of the ways in which certain hormone-dependent tumours are treated is by ablation of the pituitary body. Among the methods used is one involving the injection of a radioactive substance into the gland. This is performed by needle puncture of the floor of the sella turcica via the nasal route. The procedure is done under some form of x-ray control, but is nevertheless one that requires great skill if numerous important anatomical relations of the pituitary are to escape injury. The object of this paper is to draw attention to a change in the carotid arteries which makes them more vulnerable and puncture or irradiation of them an added hazard of this form of treatment.

The normal relations of the carotid arteries to the pituitary are such that they do not impinge on the lateral extremities of the organ.

I have frequently observed, *post mortem*, that atheromatous internal carotid arteries may be varicose to a greater or less degree. Where the carotid dilatation is slight one sees small oval depressions on the sides of the pituitary.

Upper aspect of dumb-bell type of pituitary deformity. Posterior lobe is below.

With further ectasia of the vessels the pituitary becomes hollowed inferolaterally, and in extreme varicosity the pituitary is bilaterally compressed about its middle and acquires a dumb-bell shape. The accompanying photograph shows the appearance in such an advanced case and also, what is often seen, that the carotids are unequally

affected, so that the dumb-bell is asymmetrical. It measures 4.5 mm. across its waist instead of the normal 12 to 13 mm. The youngest subject in whom I have seen the most severe degree of the deformity was a man of 57. Clearly the encroachment towards the midline of the carotid arteries is a potential hazard in closed operations in the fossa. The condition is mentioned by Henke and Lubarsch (1926), and a photograph in their handbook shows the appearance of the sella turcica in such a case. It was not noted by Beattie and Heasman (1958) in a recent study of 82 pituitaries from elderly mental patients with and without hypertension. (Sheehan and Summers (1949) do not mention it under "Extrasellar tumours—miscellaneous," but remark about this group in general: "In many cases there is an astonishing lack of symptoms despite quite gross compression of the pituitary.") In the cases I have seen there were no post-mortem findings or clinical data to suggest that hypopituitarism existed, nor would it be expected with such a volume of surviving glandular tissue.

I thank Dr. N. F. C. Gowing and Mr. W. P. Greening for their advice and help.

ARNOLD LEVENE, F.R.C.S.,
Royal Marsden Hospital, London.

Tuberculous Meningitis as a Cause of Mental Deficiency

Some 17 years ago I saw a series of cases of tuberculous meningitis admitted to a psychiatric observation ward on account of acute psychotic features (Kirman, 1943). At that time there was no effective treatment for the disease, and residual effects were not a problem. Tuberculous meningitis was always looked upon as a fatal disease until the introduction of streptomycin. It was not, therefore, a cause of mental deficiency.

A SERIES OF CASES

The first case admitted to the Fountain Hospital was in 1951, since when a total of 13 cases have been admitted (Table I). The condition is best described as meningo-encephalitis, and unless response to treatment is prompt permanent damage to mental capacity is inevitable. Our hospital accommodates 600 children with mental deficiency, and the admission rate is approximately 80 a year, being the majority of mentally defective children admitted from the counties of London and Surrey. The cases admitted represent the intermediate group between those who die and those whose illness results in lesser degrees of brain damage expressed as educational retardation or behaviour disturbance. It is difficult to draw conclusions from small numbers, but our experience does suggest that there has been an improvement in the situation since 1949–50 and that this disease should very seldom in the future be a cause of mental defect.

Social factors are very important in our group of cases. In part this is the result of tuberculosis in the family (Table II), which may reduce the income or the ability to provide a home, but low incomes and inadequate housing appear often to have anteceded the infection.

The mental grade in these cases was: idiot in 7, imbecile in 4, and educationally subnormal in 2. After much patient effort it was possible to return to the educational system the two children who proved to be above imbecile level. The main handicap in these two cases was restlessness, and they later became stabilized.

Physical disabilities found were: blindness in 6, strabismus in 5, hemiplegia in 3, spastic diplegia in 2, hydrocephalus in 2, deafness in 2, and epilepsy in 2.

In our experience tuberculous meningitis has about the same importance at the present time as kernicterus as a cause of mental defect. It is about six times as important as cretinism or congenital syphilis, and accounts for about one-third of the number of cases produced by phenylketonuria.

REFERENCE

- Kirman, B. H. (1943). *Brit. J. Tuberc.*, 27, 63.

The Ministry of Agriculture, Fisheries, and Food has reminded farmers of the very serious danger to anyone entering a grain bin or silo when the grain is being run out of the bottom of the bin. A vortex is created and anyone on the grain is liable to be drawn down and suffocated. Two fatal accidents have recently occurred in this way.

Reviews

HORMONE PRODUCTION IN ENDOCRINE TUMOURS

Ciba Foundation Colloquia on Endocrinology. Volume 12. Hormone Production in Endocrine Tumours. Edited by G. E. W. Wolstenholme, O.B.E., M.A., M.B., B.Ch., and Maeve O'Connor, B.A. (Pp. 351+xii; illustrated. 48s.) London: J. and A. Churchill, Ltd. 1958.

Laboratory studies of the endocrinological background of human breast cancer need the support of the experimental approach if we are materially to increase our understanding of the general biological significance of hormone dependence or, and to a far greater extent, of the state of independence which is so often its tragic sequel. This report of a Ciba Colloquium reveals the encouraging possibility that the study of hormone dependence in naturally occurring or experimentally produced animal tumours may lead us farther towards the solution of this urgent problem. It records twelve major contributions and eight short papers given by workers from Denmark, Sweden, the Netherlands, the United States of America, and Great Britain. Half the papers dealt with hormone-dependent animal tumours, the majority being hormone-induced. These included pituitary tumours in mice (Furth) and in hamsters (Hornig), in the thyroid (Leatham), the ovary (Mühlbock and also Gardner), the adrenal cortex (Woolley), and the testis (Huseby). In most of these papers accounts of the author's own work were prefaced by short, valuable general surveys of each problem. The other papers reported intensive investigations into tumours of the human endocrine organs and included reports on the iodinated compounds in the serum in thyroid cancer (Tata), and the study of body fluids in patients having functioning tumours of the gonads and adrenal cortex. In this paper given by Ralph Dorfman, the chairman of the symposium, the results, obtained by all the refinements of modern techniques, were correlated with biosynthetic studies of the tumour itself in a successful attempt to clarify the biosynthesis of the steroid hormones. Other papers dealt with the histology, enzymology, and hormone production in tumours of the human adrenal cortex (Symington and Currie), the estimation of urinary steroids in the differential diagnosis of hyperplasia and neoplasia of the adrenal cortex (Robinson), the bioassay of urinary gonadotrophins in hydatidiform mole and uterine chorion epithelioma, and of gonadotrophins, androgens, and oestrogens in malignant testicular tumours (Hamburger).

As in all Ciba Colloquia, the discussions reached a high critical standard by the inclusion of workers of long experience in their own subject. The omission of these discussions would certainly rob these Colloquia of what is probably their most valuable feature. For the more general reader, two commendably clear accounts of hormone dependence in animal tumours by W. U. Gardner, of the Yale University School of Medicine, are outstanding. This is the twelfth of the "Colloquia on Endocrinology" and includes a carefully compiled cumulative index of Volumes 1 to 12.

GEOFFREY HADFIELD.

TRENDS IN ANAESTHESIA

Modern Trends in Anaesthesia. Edited by Frankis T. Evans, M.B., B.S., F.F.A.R.C.S., D.A., and T. Cecil Gray, M.D., F.F.A.R.C.S. (Pp. 318+ix+13; illustrated. 67s. 6d.) London: Butterworth and Co. (Publishers), Ltd. 1958.

In any branch of medicine in which rapid development is going on there is a real need for a bridge between the textbook, which rarely includes matters at the spearhead and in which the fundamentals may be out of date by the time the book appears, and the specialist journals, which may be nearly impossible for one individual to cover adequately. The "Trends" series bridges this gap admirably. This newest number on anaesthesia lives up to the reputation of the others. In the space of only 300 pages most of the

important aspects, both theoretical and practical, of anaesthesia are dealt with by well-chosen experts who do their job well. For example, W. D. M. Paton discusses very competently the nature of the mechanisms involved in neuromuscular transmission and block. Current work on the behaviour of the motor endplate to relaxants, and on the role played by the small myelinated gamma motor fibres in reflex action, is particularly clearly summarized. C. Gray gives a picture of the present status of hypothermia that could not be bettered for brevity and completeness. Both the methods of cooling patients and the physiological effects that follow are described in the light of modern work. While the indications are clearly expounded, the risks and limitations of the methods are no less so.

Other equally outstanding contributions come from A. B. Dobkin on pulmonary ventilation and control during anaesthesia, J. J. Bonica on the place of regional anaesthesia, and I. C. Geddes on local analgesics. There are 17 other chapters, however, all full of interest and well documented with references. The authors have been gathered widely. Besides Britain, the United States (J. J. Bonica, E. M. Papper), Canada (A. B. Dobkin), and Sweden (E. Nilsson) are represented. Illustrations, mostly graphs, are comparatively few (30) and far between. There is little hesitation in describing this book as an important and valuable contribution to anaesthetic literature. At its present standard a life of many editions is assured.

W. W. MUSHIN.

GENERAL SURGICAL OPERATIONS

Orr's Operations of General Surgery. By George A. Higgins, M.D., F.A.C.S., and Thomas G. Orr, Jr., M.D., F.A.C.S. Third edition. (Pp. 1,016+vi; illustrated. £7.) Philadelphia and London: W. B. Saunders Company. 1958.

This well-produced and lavishly illustrated volume of over 1,000 pages is intended for general surgeons. This raises the question, What (or who) is a general surgeon? By looking through this book one may find some limitations which the authors would impose. We find, for example, that partial gastrectomy is well described but total gastrectomy is omitted; that there is a description of partial pancreatectomy but removal of the whole pancreas is not included. The only operations on the skull which are described are for fracture, extradural and intradural bleeding, and, curiously enough, arterial encephalography. All operations on the brain are excluded, and there appears to be no mention of operations on the mastoid process in the book. But there is still a wide range left. There are detailed descriptions of removal of a lung or larynx, excision of coarctation of the aorta or an abdominal aneurysm, and all types of amputation (including the hind-quarter); even vaginal hysterectomy and vesico-vaginal fistula are included. It is, of course, impossible to set a limit for any particular general surgeon. Experience, opportunity, personal skill and inclination, all have a part in determining which operations a surgeon will be prepared to perform. It would be a retrograde step to make too hard-and-fast limitations. Certainly most general surgeons will find this book useful.

ZACHARY COPE.

CHILDHOOD ASTHMA IN KANSAS

The Management of Childhood Asthma. By Frederic Speer, M.D. (Pp. 116+xii; illustrated. 36s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1958.

This small volume is essentially concerned with the management of extrinsic allergic factors in asthmatic children as they are found in Kansas in the United States. It is emphasized that foods and inhalants are the basic causes of asthma in children, and only by careful investigation and treatment on these lines can success be obtained. Foods are considered the "leading" allergens, milk, chocolate-cola, egg, and "legumes" accounting for just over 80% of food allergens. The limitations of skin testing for foods are discussed, and the emphasis is on detection of food allergens by thorough trial dieting. In the chapter on the

management of problem cases the author writes: "The problem of intractable asthma which is at once the most important and difficult is that of hidden or latent food allergies. It is a difficult problem because hidden food allergens may become manifest only when the child is under stress"—a viewpoint which has little support in Great Britain.

The investigation and treatment of inhalant allergens follows conventional lines, but it is surprising to us in Britain to find that *Alternaria* mould spores are considered of outstanding importance, occurring in 67% of all inhalant allergens, ragweed-pollen sensitivity occurring in 43%, house dust in 38%, *Helminthosporium* in 23%, and grass pollen in 18%. The mould-spore and pollen counts found in Kansas are set out. These findings, both botanical and clinical, emphasize the considerable differences which exist between Kansas and Great Britain. In the latter country there is no ragweed, *Helminthosporium* is rarely caught on our slides and culture plates, and *Alternaria* occurs only in relatively small numbers. "Psychic stress" is a recognized contributory factor in certain cases, and infection is considered as a common and treacherous problem in asthmatic attacks, especially in infants; but comparatively little space is given to these aspects of asthma. The treatment of the asthmatic is well set out and includes advice on cortisone and corticotrophin dosage. It is an easily read and well-produced book.

D. A. WILLIAMS.

ENCHONDRAL DYSOSTOSES

Wesen und Bedeutung der Enchondralen Dysostosen. By Hans Mau. (Pp. 219+xii; illustrated. DM.27.) Stuttgart: Georg Thieme Verlag. 1958.

In this book on the "Nature and Significance of Enchondral Dysostoses" Dr. Hans Mau has with great application collected and correlated a large number of skeletal abnormalities whose origins lie in the maldevelopment of the epiphysis or the metaphysis. He has reconsidered the aetiology, pathology, and clinical, biological, and radiological aspects of the congenital disturbances of ossification called chondrodystrophy or multiple dyschondroplasia, and with this he has also studied gargoylism and chondrodystrophia calcificans. The object of the work is to relate various deformities one to another under the term "enchondral dysostoses." By this is meant a hereditary metaphysal or epiphysal ossification—collectively uncomplicated and without resemblance to tumour formation and varying in severity. To this group also belong asymmetrical forms and some cystic forms, even if these are not hereditary.

A very wide range of bony abnormalities is included in this definition; to quote a few: cleido-cranial dysostosis, osteogenesis imperfecta, Ollier's disease, osteochondritis vertebralis, dyschondroplasia, varieties of coxa vara, and osteochondritis dissecans. It is not Dr. Mau's fault that many of these syndromes, recognized entities and single cases, have in many instances several names of a complicated nature, in English and in other languages. Some of these names appear even more terrifying and incomprehensible in German. This makes hard reading. Dr. Mau, however, makes his main points, and deserves great credit for drawing attention to the essential similarity of many skeletal abnormalities and their hereditary basis, and for emphasizing the need to examine the whole skeleton if the general manifestations which frequently accompany a particular deformity are not to be overlooked—for example, dwarfism and skeletal disproportion or coxa vara. Of the propriety of casting his net so widely only time will tell. In discussing osteochondritis dissecans the massive, often bilateral, form with a hereditary basis is not clearly distinguished from the minute, more common, post-traumatic form, but so many conditions are included that the discussion of each one must inevitably be short.

The book will stimulate those who read it to take a deeper interest in hereditary and epiphysal defects, and to examine their cases more carefully both clinically and radiologically to exclude defects elsewhere. Of the primary

cause of these defects the author can say nothing new. A rationalized approach such as he gives should lead to wider observation and the collection of associated defects which may eventually assist in solving the mystery of their formation.

J. G. BONNIN.

INTERNATIONAL CARDIOLOGY

L'Année Cardologique Internationale: Tome VI. By Camille Lian. (Pp. 360; illustrated. 2,000 fr.) Paris: Expansion Scientifique Française. 1957.

The "International Cardiological Year" is edited, as before, by Dr. Camille Lian. There are 26 contributors, all working on the Continent of Europe. The first paper, dealing with obliterative arterial disease, recommends "raubasine" (rauwolfia) and the subcutaneous injection of radioactive waters. A discussion of the regimens for treating heart failure warns against too rigid restrictions, which may be worse than the malady. There is an interesting discussion of the effects of mitral disease on the lungs, and of the relief by valvotomy. The treatment of acute pulmonary oedema is helped by anti-foam preparation, such as silicones if an irritating substance has been inhaled; otherwise aerosol in alcohol is recommended. The clinical picture of the premonitory period of myocardial infarction is discussed. Transient subendocardial or subpericardial lesions are shown in the electrocardiogram. Anticoagulants and vasodilators may prevent actual infarction. In the prevention of myocardial infarction by anticoagulants it is suggested that this be used only in grave cases; the difficulties of proper control and really efficacious treatment are emphasized. For Stokes-Adams attacks isopropylnoradrenaline is favoured. In the diagnosis of myocardial infarction a rise of transaminase in the serum is found in all cases in the first three days; it does not occur in pulmonary infarction. Hydatid cysts of the heart are the subject of a paper. There is an interesting article on the familial incidence of derangements in the metabolism of cholesterol. Ammi visnaga (khellin) is thought to be of some use in effort angina.

This is a useful collection of papers from various countries showing the trends of thought and interest on various important topics that stand out at the present time. Many papers have references; in some it is a pity that only names are given, but no references at all.

TERENCE EAST.

The Dr. Albert Wander Memorial Lectures have been delivered in Berne biennially since 1952. The first three lectures have recently been published in one volume (*Dr. Albert Wander Gedenkvorlesung, Heft 1*; 89 pp., illustrated; Hans Huber, Berne and Stuttgart, 12.40 Swiss francs) and comprise "Das Höhenklima und sein Einfluss auf den Menschen," by Alexander von Muralt, "The Conquest of Bacterial Disease," by Sir Howard Florey, and "Sulfamides et Biologie," by Jacques Tréfouël.

In 1947 the Universities Federation for Animal Welfare produced the first edition of its *Handbook on the Care and Management of Laboratory Animals*. The considerable advances in knowledge of the subject since that time have now been incorporated in a second edition, obtainable from the Federation, 7a, Lamb's Conduit Passage, London, W.C.1 (pp. 951, illustrated: 70s.). Joint editors of the new edition are Mr. A. N. Worden and Dr. W. Lane-Petter, and Sir Harold Himsforth has contributed a foreword. The first 16 chapters deal generally with housing, breeding, and other considerations common to laboratory animals, while the remainder of the book discusses some 50 individual species or groups of species. Relevant references are appended to each chapter and there is a full index.

In *New and Non-Official Drugs 1958* the Council on Drugs of the American Medical Association describes drugs that have been newly introduced. Short monographs give chemical and biological details, notes on therapeutic administration and dosage, and contraindications. The drugs are "evaluated on the basis of available scientific data and reports and investigations." Published by J. B. Lippincott and Co., the book is marketed in Great Britain by the Pitman Medical Publishing Co. Ltd. for 30s.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY DECEMBER 20 1958

PHYSICAL ACTIVITY AND CORONARY
DISEASE

In Britain coronary thrombosis, angina, and arteriosclerotic myocardial degeneration are now registered as the cause of about one-quarter of all male deaths over the age of 40. Even though the rising incidence of ischaemic heart disease may not be so dramatic as is sometimes stated, it is one of the principal sources of ill-health and premature death in middle age.

Investigations into the causes of coronary heart disease in Britain have been principally directed towards an assessment of the significance of intravascular thrombosis,¹ defects in blood coagulation,^{2,3} hormonal factors,⁴ and physical activity.⁵ J. N. Morris and his colleagues⁶ have reported that rapidly fatal ischaemic heart disease is more common in the sedentary drivers of London's double-decker buses than in the more physically active conductors, and more common in the sedentary postal and telephone clerks than in physically active postmen. Moreover, the bus conductors and postmen, when they did suffer from coronary disease, had it less severely than drivers and clerks. On the basis of these observations Morris advanced the hypothesis that men in physically active jobs have a lower incidence of ischaemic heart disease than men in sedentary jobs, and that the disease is not so severe in physically active workers, in whom it tends to present first as angina pectoris. Subsequently, a study of the sizes of the uniforms worn by bus drivers and conductors indicated that the drivers were larger and presumably

fatter than the more active conductors when they entered the transport service⁷; thus factors other than physical activity, such as selection of occupation, appear to be operating.

Nevertheless, Dr. J. N. Morris and Dr. Margaret Crawford in a remarkably interesting study printed in the opening pages of this issue have gone far towards confirming their hypothesis. Throughout Britain they have had the co-operation of many pathologists, who each completed a standard form of inquiry for 25 unselected consecutive necropsies on men between the ages of 45 and 70 years. From an analysis of the reports of 5,000 necropsies the incidence of large discrete areas of myocardial fibrosis (greater than 1.5 cm. in any one dimension), multiple small myocardial scars, and coronary atheroma was related to occupational activity during life. There were 1,700 different descriptions of occupations, and these were classified into light, active, and heavy jobs according to the physical activity demanded. In 3,800 necropsies on patients dying from some cause other than coronary disease twice as much ischaemic myocardial fibrosis was found in light workers (13.4%) as in heavy workers (6.8%). This was more obvious in cases with large fibrous myocardial infarcts than in those with smaller multiple scars, and an excess of large fibrous infarcts was particularly evident in the younger age groups. In contrast to this striking correlation between ischaemic myocardial fibrosis and physical inactivity, there was only slightly more coronary occlusion in light workers and no significant difference in the prevalence of severe coronary atheroma between the three groups of occupational activity. The necropsies performed on patients whose deaths were due to clinical coronary heart disease numbered 1,200, and heavy workers were the least common among these.

Morris and Crawford include in this article a study of physical activity in relation to the incidence of ischaemic heart disease by social class. In 1910 Osler⁸ commented on the "remarkable fact with which we are all familiar—that angina pectoris is an affection of the better classes, and not often seen except in private practice." After the 1931 census the Registrar-General⁹ published the standardized mortality ratio for various diseases according to occupation. Physicians and surgeons headed the list of deaths from coronary disease. The proprietors of wholesale businesses, the legal profession, and the Church followed close behind. In contrast, chemical workers, agricultural workers, stone quarriers, and certain grades of miners had an unusually low death rate from coronary disease. The pattern is much the

same to-day. J. A. Ryle and W. T. Russell¹⁰ interpreted these findings as a reflection of the exacting character of sustained mental effort required in intellectual and responsible occupations.

J. N. Morris, J. A. Heady, and R. G. Barley¹¹ showed that the incidence of first attacks of angina and myocardial infarction is twice as high in general practitioners as in consultants and specialists, whose rates of morbidity and mortality are similar to those of members of other professions than medicine. They wisely refrained from offering any explanation of these findings, but these various social differences in the incidence of coronary disease are often attributed to the different emotional tensions and environmental stress of contrasting occupations. It is very difficult to judge what is stressful to any particular individual, and W. M. Arnott¹² has emphasized that excessive psychological stress has never been shown to be more harmful in the professional and intellectual classes than in the less privileged classes. Indeed, it might be argued that the stress factor could be expected to operate more in communities where poverty, insecurity, and starvation are rife. P. Stocks¹³ examined the mortality from coronary disease in the various social classes, relating it to the physical demands of occupation, and suggested that the differences could be as well explained by physical activity as by the mental stress of the occupation. Morris and Crawford have confirmed this suggestion by reporting that the incidence of ischaemic myocardial fibrosis shows a steady fall from the professional and executive classes (13.3%) through the skilled technician groups to the unskilled labourers (7.8%). While supporting the popular belief that ischaemic heart disease is commoner in the better-off sections of the community, they found that this trend disappeared when the social classes were analysed in terms of the physical activity of the occupations in them. Thus the frequent occurrence of ischaemic heart disease in the professional and executive classes seems to be more dependent on physical inactivity than on high standards of living, education, skill, and responsibility.

As the authors are undoubtedly aware, their study is open to several criticisms. The nature of only the last occupation has been recorded, and thus no allowance has been made for any alteration in physical activity consequent upon a change of occupation. It is a common aspiration of manual workers to progress towards executive and more sedentary jobs, particularly if they have an ambitious and conscientious personality. It is also possible that the development of ischaemic myocardial fibrosis could so reduce the exertional capacity of active and

heavy workers as to induce them to seek lighter jobs and yet be insufficient, once they had changed their work, to lead to symptoms. Details about earlier employment might therefore have been informative. Again, no account of leisure activity has been given; this is often erratic and hard to assess, but some apparently sedentary workers are probably more active than they seem from analysis of their physical activity at work alone. Much depends on the accuracy of the description of occupation, which is so often casually recorded in case histories. An omission which many will regret is a record of the weight or obesity of the patients in this series. Without further knowledge, therefore, many will not be able to accept unconditionally Morris and Crawford's hypothesis that work entailing physical activity is a protection against ischaemic heart disease.

Although greater physical activity may possibly reduce intravascular clotting, probably its more important effect is to increase the coronary collateral circulation. Physical exertion increases the cardiac output and the coronary blood flow, but not necessarily in parallel. Most adults have some degree of coronary atherosclerosis and rigidity of the coronary arteries; it might be expected, therefore, that coronary flow will not always keep pace with the increase in cardiac output. Minimal myocardial anoxia could develop, and this has been shown to act as a stimulus to the formation of collateral coronary anastomoses.¹⁴ Indeed, effective collateral vessels develop more profusely in dogs with coronary obstruction if the dogs are exercised.¹⁵

Further studies are required, but if they support the proposition that habitual physical activity might reduce the incidence of ischaemic heart disease, then there are certain practical implications to be considered. Artificial restrictions should not be placed on the physical activity of patients who already have symptoms of coronary disease, and, within reason, the patient should be allowed to decide his own level of exercise tolerance. In this way a better coronary collateral circulation might be encouraged, and, in theory at least, the extent of a further myocardial infarct might be limited. The rest of us in sedentary occupations should endeavour to take more exercise regularly, although sudden and violent exertion is probably undesirable, particularly in middle age. Studies of the protective action of leisure activities are now indicated. Meanwhile some good might be done by walking part or all of the way to work and by being less dependent on cars, buses, and lifts. The active in mind should make time to remain active in body.

LUMBAR PUNCTURE

Examination of samples of cerebrospinal fluid obtained by lumbar puncture is one of the most important and valuable diagnostic measures utilized in the investigation of neurological cases. Consequently it is tempting to carry it out as a routine in all varieties of neurological disease. This is a temptation worth resisting firmly, because lumbar puncture may in certain cases carry serious dangers to life, while at the least it may occasionally prove to be a painful procedure, no matter how skilful the operation; severe and incapacitating headache follows in some cases. Thus the decision to carry it out needs careful consideration of each individual case, with an attempt to weigh the risks against the possible information it may yield.

Of all the contraindications to lumbar puncture, raised intracranial pressure due to a focal intracranial lesion is perhaps the most complete. In such a case removal of spinal fluid from the lumbar theca may result in sudden death from compression of the brain stem due either to herniation of the cerebellar tonsils into the foramen magnum, or of the medial part of one or both temporal lobes through the tentorial hiatus. Hence papilloedema, or clinical suspicion of a cerebral tumour, particularly in the posterior fossa, is usually a contraindication, though it is generally safe to carry out the procedure with caution in patients who are believed to have an infiltrating neoplasm in one or other cerebral hemisphere but who show no clinical evidence of increased intracranial pressure. No hard-and-fast rules are applicable to every case, since in tuberculous meningitis, for instance, there may be papilloedema, but lumbar puncture is nevertheless essential for diagnosis. This fact only serves to underline the necessity for regarding this investigation as a matter for individual decision, based on clinical appraisal and experience. Local cutaneous and spinal abnormalities such as skin sepsis and ankylosing spondylitis are among other possible contraindications. The belief once widely held that lumbar puncture may promote relapse in disseminated sclerosis no longer appears to be valid, and in certain patients presumed to be suffering from this disease the investigation is essential in order to exclude surgically remediable compression of the spinal cord.

Once the decision to carry out a lumbar puncture is made, all possible steps should be taken to make the procedure as tolerable as possible for the patient. Prior sedation may occasionally be necessary, with paraldehyde for noisy or restless patients, or with sodium amytal or methylpentynol for the

apprehensive. This is not the place to describe many details of technique, except to suggest that the old-fashioned wide-bore needle with a built-in two-way tap should no longer be used, since much finer needles of the Harris type are more satisfactory. There is general agreement that infiltration of the skin and interspinous ligaments with local analgesic should be carried out, but deep infiltration is unnecessary. With these precautions, and with the patient relaxed on his left side with the back arched and the knees drawn up to the chin, the insertion of the needle should be virtually painless. Care is taken not to insert the needle too far, as it may then enter vertebral veins, causing bloody contamination of the fluid, or alternatively it may enter the annulus fibrosus of an intervertebral disk and possibly be responsible for subsequent disk prolapse.

The avoidance of the unpleasant headache which so often follows the examination, even in normal people, is a matter of some difficulty. The headache is believed to be due to continual seepage of cerebrospinal fluid into the extradural space through the hole in the dura left by the exploring needle. It is certainly true that, the smaller the needle which is used, the less frequent are these headaches. It might be expected that in patients whose cerebrospinal fluid pressure is lower than the average these headaches would tend to be more frequent, but no such correlation has been detected. Some recent observations of R. J. Brocker¹ are of interest. He points out that if the patient lies supine after a lumbar puncture the spine is flexed, a negative pressure is created in the extradural space, and cerebrospinal fluid is drawn out through the hole in the dura. He suggests that, in order to separate rather than cut the dural fibres with the point of the needle, it should be inserted with the bevel vertical instead of horizontal; then, immediately the needle has been withdrawn, the patient should be turned into the prone position and should remain there for three hours. Brocker suggests that maintenance of this position, which causes some degree of spinal hyperextension, increases the pressure in the extradural space and prevents leakage of cerebrospinal fluid. His own observations certainly seem to support these views, for, in 894 patients who remained prone for three hours following lumbar puncture, headache occurred in only 4 (0.5%), while the incidence of headaches in 200 patients who were kept supine was 36.5%. Some confirmation of these observations from other workers would be welcome, but it seems that assumption of the prone position immediately after lumbar puncture may be an effective means of reducing the incidence and severity of headache.

ADMINISTRATION OF OXYGEN TO INFANTS

Oxygen has for long been an accepted part of the treatment of so many disorders and a life-saving remedy in emergencies that it is sometimes overlooked that there may be certain hazards associated with its administration. Unfortunately these hazards are most often encountered just when the need for oxygen is greatest—namely, in premature infants immediately after birth. At this time it is certainly a potentially iatrogenic agent; the two diseases for which it has been held responsible, at least in part, are retrolental fibroplasia and hyaline membrane disease.

Retrolental fibroplasia first attracted attention after the report by T. L. Terry¹ in the U.S.A. in 1942. Within a short time it became clear that cases of the disease were widespread in many different countries and the incidence of blindness in babies rose alarmingly. It was not until 1953 that oxygen was finally incriminated² and, with the recognition of the fact that high concentrations must be avoided, the incidence of retrolental fibroplasia fell as precipitously as it had arisen. Nevertheless in the comparatively few years of its existence it brought blindness to many hundreds of infants. It is now general practice in all maternity units and in children's hospitals admitting premature infants for the concentration of oxygen to be carefully controlled and not allowed to exceed 40%.

The recognition of hyaline membrane disease is also of recent origin. It is almost entirely confined to premature infants, is particularly common after caesarean birth, and is usually fatal. The exact cause is not known, but experimental work suggests that oxygen may play an important part. The latest report, from Sweden, by R. Berfenstam and colleagues,³ suggests that excessive oxygen may act by diminishing the ciliary activity in the bronchial tree and thereby favour the retention of the material forming the hyaline membrane. In rabbits exposed to oxygen in 70–80% concentration for 48 hours the ciliary action was both quantitatively and qualitatively reduced. Berfenstam and colleagues suggest that premature infants, adapted to low oxygen tension *in utero*, may show evidence of oxygen toxicity at relatively low concentrations in extrauterine life, and they stress the necessity for determining what level of oxygen concentration is safe for such infants in their earliest days after birth. They also found experimentally that excessive oxygen caused vascular damage with increased capillary permeability, and the resulting exudate probably furnished the main part of the hyaline membrane.

In view of these toxic properties of oxygen the methods of administering it to premature infants require careful supervision. Whereas in later infancy the problem may be how to keep the concentration sufficiently high in such emergencies as laryngotracheobronchitis, bronchopneumonia, and cardiac failure, the problem in the emergencies associated with the establishment and

maintenance of adequate respiration in premature infants is how to do this with an oxygen concentration not exceeding 40%. There are many ways of enriching the infant's atmosphere with oxygen, some simple, some complex; they include administration through a rubber or plastic face mask periodically; by nasal catheter or by a catheter passed into the stomach; and by oxygen tents and complicated incubators incorporating constant humidity and temperature control, carbon-dioxide absorption, and atomized mists to accompany the oxygen. Whenever a closed method is used, repeated estimations of the oxygen concentration are desirable. Simple "perspex" bell covers are notoriously deceptive in the rate at which the oxygen tension rises, even with a flow of only 1 litre per minute, and not all flowmeters are sufficiently accurate for the physician to assume that if the flow remains below a certain rate the oxygen tension will not rise above a certain level. Dry oxygen is more irritating to the lungs than when it is adequately moistened, but bubbling it through a Woulfe's bottle does not produce sufficient moisture unless there are means for maintaining the humidity of the infant's surroundings at or above 65%.

A simple device for administering oxygen to infants and young children has recently been described by R. Batson and W. C. Young.⁴ It consists of a transparent plastic open-top box. Its advantages are that, as oxygen is heavier than air, its maximal concentration is near the bottom of the box, where the infant lies; adequate therapeutic levels can be obtained in 10 minutes; the nursing care of the child is easy and does not interfere with the maintenance of the oxygen supply; there is less likelihood of claustrophobia; and carbon dioxide is adequately disposed of without the necessity for soda-lime. In an emergency they improvised an efficient makeshift with a transparent plastic laundry bag suspended from the cot sides; the infant was placed in the bag and oxygen supplied through a nebulizer with the outflow tube directed into the lower level of the bag. In the treatment of acute bronchopneumonia and similar emergencies in infancy such a simple, cheap, and easily constructed home-made apparatus must have great value. Certainly the open-top box method offers many advantages in the nursing of sick children who require oxygen therapy.

STERIODS IN IDIOPATHIC STEATORRHOEA

In 1951 T. P. Almy¹ described a patient with refractory idiopathic steatorrhea who responded well to treatment with A.C.T.H. There was a striking increase of weight, cessation of diarrhoea, return of normal appetite, and disappearance of abdominal distension. At about the same time A. B. Taylor and his colleagues² reported favourable results from the use of cortisone in six patients, the improvement being accompanied by increased absorption of fat and diminished faecal loss of nitrogen. D. Adlersberg and his colleagues³ used oral hydrocortisone with beneficial results. They found that the free alcohol of hydrocortisone was superior to hydrocortisone acetate. It also appeared to have some advantages over A.C.T.H. and cortisone in that it was

effective in small doses without side-effects. "No adverse effects, no habit formation, and no resistance to this mode of therapy have been noted."

While these observations were being made in America, European workers were more occupied with the Dutch discovery^{5,6} that a gluten-free diet would render children with coeliac disease symptom-free and permit normal growth and development. These original observations were rapidly confirmed^{7,8} and it has since been found that a considerable proportion of adult patients with idiopathic steatorrhoea respond well to a gluten-free diet.^{9,10} Indeed, the consensus of opinion is that idiopathic steatorrhoea in the adult is the same disease as coeliac disease in children, though tropical sprue appears to be a different illness.

J. M. Finlay and K. J. R. Wightman¹¹ compared the effects of cortisone and a gluten-free diet in adult cases of idiopathic steatorrhoea and found that cortisone rapidly relieved the diarrhoea and improved the absorption of fat. On the other hand, the response to a gluten-free diet, though more slow, was more complete. In terms of practical medicine, the corticosteroids have generally appeared to have only a small part to play in the treatment of idiopathic steatorrhoea, although useful in initiating a remission especially when given in combination with a gluten-free diet. However, M. J. Lepore¹² has now described six patients whom he has maintained in good health on long-term treatment with corticosteroids in quite small doses, such as 40 mg. or less of hydrocortisone a day, for periods of up to seven years. When corticoids have been stopped, these patients have relapsed, sometimes in two or three weeks and sometimes after a longer period. Lepore remarks that in his experience the best responses to a gluten-free diet have been seen in patients with a definite history of coeliac disease in childhood; none of these six patients treated with adrenal steroids had such a history.

The mode of action of adrenal steroids in idiopathic steatorrhoea remains problematical. However, J. W. Paulley's¹³ original observation that the mucosa of the small intestine is histologically abnormal in idiopathic steatorrhoea has been abundantly confirmed by recent studies.¹⁴⁻¹⁷ It is possible that the adrenal steroids act directly on this abnormal mucosa and block whatever

mechanism is responsible for defective absorption in this disease. Even though we do not understand the mode of action, Lepore's work suggests that maintenance treatment with small doses of corticosteroids is worthy of trial in patients who fail to respond well to a gluten-free diet. It is probably wise to continue with the gluten-free diet in addition.

DOES B.H.C. DAMAGE THE BONE MARROW?

When a new chemical is introduced into general use under a variety of conditions, a heavy responsibility rests on those called upon to give an opinion on its safety for such uses. At an early stage reliance must be placed on the reaction of experimental animals and that of the people who may handle the compound during its manufacture and early development. By these standards B.H.C. (benzene hexachloride, "gammexane") seemed at least as safe as D.D.T., on whose heels it followed closely. It seemed to be safe for use as an insecticide under a wide variety of conditions, and has been widely used in public health work and agriculture. There is no evidence that it will produce poisoning except (rarely) under conditions of gross carelessness or misuse.¹⁻³ Enormous quantities have been sprayed in malaria control, and often the wettable powders are dispensed by hand and the suspension stirred by hand. When the same methods were used to handle dieldrin, poisoning soon became evident.⁴

Now, however, a few scattered reports are appearing implying that exposure to B.H.C. can cause agranulocytosis or leukaemia. When such cases are discussed together, as in a recent study of leukaemia in cousins,⁵ the record against B.H.C. at first sight appears rather black. Nevertheless caution is advisable before jumping to conclusions. No cases have been reported among the most heavily exposed people. Have they been missed? This is possible. Among 79 people with illness following the misuse of B.H.C.² there is no report of agranulocytosis, though these people were anaemic—they were also undernourished. It is worth considering the exposure of the victims of these blood disorders: two cousins unloaded bags of B.H.C. for a month about eight months before their illness⁵; one man sprayed crops for two days just before his illness⁶; another disinfested clothes and other articles at irregular intervals in full protective clothing⁷; another worked in a shop in which a vaporizer had been installed a few months earlier.⁸ Both cases of agranulocytosis had a preceding infection. One had received 2.5 g. chloramphenicol; the other had had 6 g. sulphonamide, 0.5 g. chloramphenicol, 200 mg. phenylbutazone, and a suppository containing amidopyrine. It may thus be unreasonable to blame the vaporizer for the

illness. If agranulocytosis were caused by B.H.C., surely it would be much more common among people who handle large quantities of the drug with no particular precautions. At any rate it is among such people that any attempt to substantiate that suspicion should be made.

An unfortunate gap in the technique of experimental toxicology is the lack of any method for reproducing in animals those conditions such as agranulocytosis seen with such regularity after certain drugs are widely introduced into medicine. Indeed, little or nothing is understood about the mechanism of the reaction except that it is believed to be a form of hypersensitivity and therefore presumably has some immunological basis. Meanwhile if anyone is tempted to sum the individual reports referred to here and make out a case against B.H.C., it is also worth bearing in mind the caution expressed by each author about his own case. Such qualifications in the appraisal of individual cases tend to get lost when generalizations are made.

THE EPIDERMIS IN ECZEMA

In patients whose inborn pattern of reaction to stress is dermatological and eczematous, the catarrhal reaction which emanates from the papillary capillaries is thought to result from the action of metabolites derived from epidermal cells. J. H. Allison and F. R. Bettley,¹ by some neatly executed experiments, show that the epidermis of the normal skin in such eczematous patients is "fragile" in the sense of being abnormally sensitive to injury. Cantharidin has a toxic effect on epidermis, causing acantholysis, and can be used to produce a blister on the skin. Allison and Bettley show that the acantholytic effect of cantharidin is more marked in the eczematous than in the non-eczematous subject and is not influenced by the oral administration of prednisone. There is also a significantly greater exudation of fluid and it contains a higher proportion of protein in the atopic subject than in the normal or in those suffering from urticaria or from so-called seborrhoeic, hypostatic, or nummular eczema. The urticarial subjects were chosen as controls because they were presumed to have an abnormality of vascular response leading to increased capillary permeability.

These results suggest that over and above any effect, direct or indirect, of cantharidin on capillary walls, in the atopic subject the vulnerable and damaged epidermal cells contribute something which affects the permeability of the vessel walls, influencing the quantity and character of the plasma exudate. The authors do not give clinical details, but it is presumed that under the not very satisfactory term atopic they imply a state of chronic eczema starting at infancy and associated with hay-fever or asthma and often with urticaria. This syndrome, also known as the asthma-eczema-prurigo syndrome or Besnier's prurigo, may be associated with

xeroderma and sometimes with a special type of juvenile cataract. It is commonly familial. It would have been interesting to know the results of similar investigation with cantharidin in patients with simple xeroderma, but so far as it goes it does perhaps support the suggestion previously put forward that Besnier's prurigo is in part dependent upon an ectodermal defect.²

The investigation is important in suggesting some difference in mechanism between eczema of the inherited or atopic variety and other forms of acquired eczema. The significantly altered reaction in the patients with atopic disease, pointing to a peculiar epidermal component in the reaction, may explain in part the difficulties encountered in treating them and should direct attention to measures which act more directly upon the epidermis.

LEUCINE AMINOPEPTIDASE

Enzyme tests are being increasingly used in diagnosis. One of the latest enzymes to be studied is leucine aminopeptidase, a proteolytic enzyme which hydrolyses leucine-containing peptides. It is present in many tissues but is particularly abundant in duodenal juice and in the kidney and liver. It can be estimated by a colorimetric method based on the formation of an azo dye.¹ Normal values for serum average 142 units for men and 130 for women, while urinary activity is about 82 units in men and 43 units in women. A. M. Rutenburg and his colleagues² have recently analysed the results from determinations of leucine aminopeptidase in over 300 patients with a variety of clinical conditions. Exceptionally high levels in serum and urine—three or four times normal—were found in patients with carcinoma of the pancreas, whether jaundiced or not. The serum activity was significantly higher than that encountered in cases of gallstone in the common duct, in which the level of aminopeptidase was moderately raised. Acute pancreatitis also results in a moderate, though transient, rise in contrast to acute cholecystitis, in which enzyme activity is normal. Serum aminopeptidase is also increased in patients with parenchymatous liver disease, but again to a less extent than in carcinoma of the pancreas. A striking finding was the increased urinary levels in patients with malignant lymphomata, in spite of normal or only slightly raised activity in the serum. Cancer at sites other than the pancreas did not affect aminopeptidase except when liver metastases were present.

It is difficult at this stage to predict the diagnostic value of this particular enzyme. Normal values rule out carcinoma of the pancreas, and its estimation may be of use both in this disease and in the malignant lymphomata. Further work may possibly show that it is a means of differentiating not only extra-hepatic from parenchymatous jaundice, but also jaundice due to stone from that caused by a carcinoma of the head of the pancreas.

Drug Treatment of Disease**THE CONTROL OF THE SALE OF POISONS AND DANGEROUS DRUGS**

BY

JOHN GLAISTER, M.D., D.Sc., F.R.S.Ed.*Regius Professor of Forensic Medicine, the University of Glasgow*

AND

EDGAR RENTOUL, M.B.E., M.A., M.B., Ch.B., LL.B.*Lecturer in Forensic Medicine, the University of Glasgow*

"It is more than likely that the annual global injury and number of deaths due to poisoning (excluding alcohol, hashish, opium, and other addictions) exceeds by far the destruction which would be caused by an annual atomic bomb explosion in a heavily built-up area."

Parliament in Great Britain has recognized the risk to the community from poisoning—homicidal, suicidal, and accidental—and for many years has been concerned with legislative measures to lessen the risk. This has been accomplished by restricting the availability of toxic substances to the public. The legislature has distinguished between substances which are toxic and substances which are not only toxic but also lead to addiction. Substances in the first category are described as poisons and those in the second as dangerous drugs.

The current law dealing with these matters is contained in the Pharmacy and Poisons Acts and the Dangerous Drugs Act, 1951, together with their relevant regulations and orders. Owing to the rapid development of the drug industry and the large number of toxic substances being brought into medical use, frequent alterations in the poisons regulations have been necessary. This has made them rather complicated. The following is an attempt to produce a short and simplified account of the present position.

The principal Act is the Pharmacy and Poisons Act, 1933. Section 17 of this Act instructed the Secretary of State to cause the Poisons Board to prepare and submit to him a list of the substances to be treated as poisons and also to divide the list of poisons into two parts—Part I to contain all the poisons in medical, scientific, dental, and veterinary use, and Part II to contain substances in common use.

Substances in Part I of the Poisons List can be sold only by authorized sellers of poisons—namely, registered pharmacists. Substances in Part II of the Poisons List can, however, be sold by authorized sellers of poisons and by listed sellers of poisons—namely, persons whose names are on the local authority's list. Examples of these are iron-mongers and seedsmen who have made successful application to the local authority for inclusion on the list.

Section 23 of the 1933 Act gave the Secretary of State power to make rules for the sale or supply of the listed poisons. This is the authority for the various rules and orders which at present control the manufacture, supply, and sale of poisons.

The most important rules and orders made in accordance with this section are those of 1935. These rules listed poisons to which detailed regulations for supply, purchase, and storage apply. The list appeared in the First Schedule to the regulations, and this is the origin of the term "First Schedule poison." The rules also listed a number of poisons which were to be obtained only on a medical prescription, and these were contained in the Fourth Schedule of the Rules; this is the origin of the term "Fourth Schedule poison." The other schedules to the Act detail further

restrictions, exemptions, and regulations which are chiefly of interest to sellers of poisons.

When new substances are made available and recognized as poisons they are added to the Poisons List, and if they are to be subject to special restrictions they are added also to the First Schedule. If it is considered that they should be available only on a medical prescription, then, in addition to being added to the Poisons List and the First Schedule, they are also added to the Fourth Schedule.

Restrictions on Poisons in First Schedule

These restrictions are concerned mainly with the labelling of the poisons, the recognition of the purchaser as a suitable person to obtain the poison, and the recording of the details of the transaction. A knowledge of them is of importance chiefly to those doctors who dispense their own medicines. Doctors who require First Schedule poisons can obtain them from authorized sellers of poisons either by attending at the premises and signing the poisons register recording the sale or by providing a written order.

Doctors cannot supply poisons except as medicines for their patients. The medicine must be labelled with the name and address of the practitioner. If it is a liquid for external application, the container must bear the words "For external use only" and the name of the article—for example, "The Liniment." The container must be impervious to the poison and must be distinguishable by touch. If the poison is supplied in any way, apart from personal administration, a record must be made in a book showing the date of supply, the ingredients of the medicine, the amount of the poison, and the name of the patient. These records must be made on the same day as the medicine is supplied or, if this is not practicable, on the following day.

All the potent medicinal poisons are included in the First Schedule—for example, arsenical poisons, barbiturates, ergot, hydrocyanic acid.

Restrictions on Poisons in Fourth Schedule

The Fourth Schedule contains a list of substances which can be sold by retail only on a prescription given by a registered medical practitioner, registered dentist, or registered veterinary surgeon. In cases of emergency, when the doctor is unable to give the prescription immediately, the authorized seller may provide the poison in accordance with the doctor's instructions, provided the doctor undertakes to forward the appropriate prescription within 24 hours. The prescription for a Fourth Schedule poison must be in writing, must be signed and dated by the person giving it, and, if it is not a National Health Service prescription, must specify his address. The prescription must also specify the name and address of the person for whose treatment it is given, and must also show the total amount of the substance to be supplied with the dose to be taken.

Restrictions are also imposed upon the dispenser of Fourth Schedule poisons. He cannot dispense these poisons more than once unless the prescriber has stated that they may be dispensed a stated number of times or at stated

intervals. A prescription containing a direction that it may be dispensed a stated number of times, but omitting direction as to the intervals at which it may be dispensed, cannot be dispensed more often than once in three days. A prescription which contains a direction that it is to be dispensed at stated intervals, but without direction as to the number of times, cannot be dispensed more than three times.

In the Rules of 1935, the Fourth Schedule occupied seven lines; the current list of Schedule Four poisons contains thirty-seven lines. This illustrates a tendency which is likely to continue and explains some of the practitioner's difficulties. In this long list, probably the seven most frequently used drugs are: the barbiturates; the sulphonamides; amphetamines and its associated compounds; the antihistamines; chlorpromazine; phenylbutazone; troxidone.

The Dangerous Drugs

These are poisons which also produce some degree of addiction. In addition therefore to being dealt with by the Dangerous Drugs Acts, they are contained also in Part I of the Poisons List and in the First Schedule to the Poisons Rules.

The purpose of the Dangerous Drugs Acts is to regulate the import, export, manufacture, sale, and use of drugs of addiction. The addiction-producing drugs are also an international problem, and developments in their use are kept under constant review by the World Health Organization.

The current Act is the Dangerous Drugs Act, 1951. Numerous regulations and orders have been made under this Act and probably will continue to be made. The principal regulations are the Dangerous Drugs Regulations, 1953.

One of the most important provisions of the Dangerous Drugs Act is that only certain specified persons are allowed to have these drugs in their possession. Doctors find a place in that group, and while many of the regulations under the Act are not of direct interest to them it is important that they should know their obligations in regard to possessing these drugs, prescribing them, and keeping records of them.

As to the possession of Dangerous Drugs, it is important for the doctor to realize that this is authorized only so far as is necessary for the practice of his profession. The continued supply of drugs to a patient solely for the gratification of addiction is not regarded as a medical need.

These drugs can be dispensed only on a prescription by a registered medical practitioner, registered dentist, or registered veterinary surgeon. The prescription must contain the particulars previously detailed in connexion with Fourth Schedule poisons. The Dangerous Drugs cannot be dispensed more than once on the same prescription unless the prescription so directs, and this is restricted to a total of three times and to the intervals specified on the prescription. Sales of Dangerous Drugs may be made directly to doctors in accordance with the Provisions of the Pharmacy and Poisons Act, 1933, as previously detailed for Schedule Four poisons.

Doctors are required to keep records of the Dangerous Drugs obtained by them and of the Dangerous Drugs supplied by them. Separate registers must be kept for these purposes and separate parts of the registers must be appropriated for each of the drugs. The entries must be made on the day in question or on the following day. The entries must give the date on which the drug was received or supplied, the amount and the form of the drug, and the authority of the person supplied to be in possession of it. However, if a doctor keeps a day-book in which he records particulars of drugs supplied by him to his patients, with the name and address of the patient and the date of supply, he may record in a separate book the date and the appropriate reference to the entry in his day-book.

It is not necessary to enter in the register of supplies particulars of drugs administered to a patient by the doctor personally or by someone acting under the direct personal supervision of the doctor.

All Dangerous Drugs must be kept in a locked receptacle. The courts do not consider a locked car to be a locked receptacle.

The authority of a doctor to possess and supply Dangerous Drugs may be withdrawn from a doctor who:

(1) has been convicted of an offence against the Dangerous Drugs Act; or

(2) has been convicted of an offence against Sections 45, 56, or 304 of the Customs and Excise Act, 1952, in respect of goods being a drug; or

(3) is the subject of a reception order under the Lunacy Act, 1890; or

(4) is the subject of an order deemed to be or having effect as if it were an order under the Lunacy Act, 1890; or

(5) is undergoing treatment as a temporary patient under Section 5 of the Medical Treatment Act, 1930; or

(6) in Scotland, is the subject of a reception and detention order, or is a voluntary boarder under the Lunacy (Scotland) Acts, 1857–1919;

and who in the Secretary of State's opinion cannot properly be allowed to remain an authorized person. Notice of the withdrawal of authority is published in the *London Gazette* and the *Edinburgh Gazette*.

The current list of Dangerous Drugs contained forty-seven items as at June 1, 1958. The most important of these are medicinal opium, morphine, heroin, Indian hemp, cocaine, pethidine, and amidone.

Antibiotics and Corticosteroids

In addition to the regulations regarding poisons and Dangerous Drugs, which have been described, Parliament has also been concerned with the control of the supply of penicillin and such other therapeutic substances as may appear to the Ministers of Health of England and Northern Ireland and the Secretary of State for Scotland after consultation with the Medical Research Council to be capable of causing danger to the health of the community if used without proper safeguards. The main legislation concerning these substances is contained in the Penicillin Act, 1947, and the Therapeutic Substances (Prevention of Misuse Act), 1953. So far as the medical profession is concerned, the principal result of these Acts and the regulations made under them is that the antibiotics and cortisone derivatives can be obtained by the general public only on a prescription signed and dated by a registered medical practitioner.

The control of poisons and Dangerous Drugs in hospital is a special subject and has recently been under investigation by a departmental committee.² Those who are concerned with this problem should study the report of the committee and particularly the summary of recommendations.

The World Federation for Mental Health held its tenth annual meeting at Copenhagen last year, and the papers, together with discussion on them, have now been published as *Growing up in a Changing World* (pp. 238; 15s. net). MARGARET MEAD begins the volume with some contrasts between different cultures in the way infants are cared for, and later S. HERMANN and E. A. KRAFF discuss the work of Unesco and W.H.O. respectively in relation to mental health problems. In a section on the prevention of juvenile delinquency KENNETH SODDY (United Kingdom) draws attention to the limits within which punishment might be effective in keeping children out of delinquent ways. He added, "I think that it requires great qualities of imagination for a child to be deterred from following a delinquent whim by the thought of punishment that he may very well hope to escape." Other themes discussed include problems of puberty, genetics, refugees, and disturbed families. The volume is issued by H. K. Lewis Ltd., of London.

FIRST B.M.A. ANNUAL CLINICAL MEETING SOUTHAMPTON, DECEMBER 4-7

Last week we reported the plenary sessions and panel discussions, the Transatlantic Clinical Conference, the demonstrations of colour television and medical films, and the social events of the first two days of the first B.M.A. Annual Clinical Meeting (*Journal*, December 13, p. 1465). This week we conclude our report with an account of what happened on the last two days. A total of 325 doctors attended the meeting, which was accounted on all sides a great success. The Association plans to hold its second Annual Clinical Meeting next year at Norwich.

PANEL DISCUSSIONS

Saturday, December 6, 9.45 a.m.

Risks of Therapy

As on the Friday, Saturday began with two simultaneous and well-patronized panel discussions. The first was under the chairmanship of Dr. R. M. S. MCCONAGHEY (Dartmouth), who had with him Dr. RICHARD ASHER (London) and Mr. D. F. ELLISON NASH (London). They addressed themselves to the question of "The Risks of Therapy."

Opening the discussion, Dr. MCCONAGHEY remarked that the ancient Egyptians in their "textbooks" had recognized that certain diseases were incurable and "should not be touched." He divided risks of therapy into three kinds—risks to the patient, to the doctor, and to the community.

Dr. ASHER said that one danger to the patient was that therapy could prevent diagnosis. He had been invited to diagnose suspected cases of pernicious anaemia which had already been given vitamin B₁₂, and suspected cases of myxoedema which had been given thyroid. He couldn't do it. An opposite danger was the sudden withdrawal of a treatment which should only be withdrawn gradually, as with adrenal cortical steroids. Withdrawal of therapy could sometimes be very difficult, observed Mr. NASH. Psychiatry, once started, was often hard to stop, as was physiotherapy in cold weather when the patient was getting free transport. He thought that doctors nowadays ran more risks than patients and quoted a report that there were 5,000 complaints a year known to medical defence organizations from patients who considered they had not received proper treatment. Dr. ASHER deplored that the public had got the idea that where there was an illness there was necessarily a remedy. They thought treatments always did good and therefore everyone ought to be getting some. They got this notion from magazines. The community could almost be said to have an addiction to treatment. The unfortunate result was that the doctor gave treatment even if the patient was not ill, because it was expected; and the patient thought that, as he was being treated, he must be ill.

Tests to Impress the Coroner

Dr. K. M. ROBERTSON (Southampton) thought that risks of therapy, especially of new drugs, were overstressed in medical journals, and that this caused doctors to fear to take what should be routine risks. Doctors tended to be frightened unduly by individual catastrophes. He also suspected that hospital doctors might be engaged in trying to keep some new drugs to themselves so as to be one up on the general practitioners. Dr. ASHER retorted that, of course, the consultant must have his mysteries from other doctors—it was gamesmanship. He too thought there might be undue fear of taking risks because of the possibility of being sued. He regretted the use of tests to impress the coroner, if they did not also protect the patient. Weekly blood counts in patients taking thiouracil were an example of this.

Mr. NASH, however, did not think thiouracil a good example of a drug which might be used more freely. It could make patients myxoedematous and possessed of very vascular goitres, altogether unattractive subjects for surgery. He suggested that there was undue fear of using chloramphenicol in urinary infections. When these proved resistant to other drugs chloramphenicol should not be withheld.

On risks of therapy to the community Dr. MCCONAGHEY pointed out that diseased individuals—e.g., epileptics and imbeciles—were being preserved by medicine, and Dr. J. H. BARON (London) reminded the meeting that the population of backward countries was increasing rapidly as a result of medical advances and that this led to immense social problems. Dr. ASHER agreed, but pointed out that it would be quite impossible for a doctor not to treat individual patients, because their survival might present problems to which we could see no solution.

Dr. W. M. DIXON (Fawley) observed that we must not imagine that because drugs are prescribed they are necessarily consumed by the patient, and Dr. ASHER thought that this was an important factor in diminishing the risks of therapy. He thought medical practice was getting needlessly complicated. In his young days blood transfusion was simple. But look at it now! It was terribly complex because of alleged risks. In the old days he used to give blood quite happily.

Mr. NASH drew attention to the virtual abolition of thoracic surgeons' waiting-lists by the advent of effective chemotherapy. (The CHAIRMAN supposed that was a risk of therapy for thoracic surgeons.) Surgeons, continued Mr. NASH, had higher risks of litigation than physicians. Fear of this was not wholly bad. The surgeon must protect himself, of course, but not at the cost of terrifying his patients.

Dr. ASHER spoke of the risk of the patient's finding out what was wrong with him. Patients should not generally be told when they had a hopeless prognosis. In his experience this led to misery and distress. Hope should be given even where there were no grounds for it. Mr. NASH said his opinion and experience on this matter were exactly the reverse of Dr. Asher's.

Other risks discussed were those of self-treatment by patients. Haematemesis from aspirin, renal stone from alkali treatment of peptic ulcer, and impotence from antihistamines were cited. Also the risks of quacks growing rich on patients who had been given a bad prognosis were grave: it was human nature not to give up hope, and human nature to exploit that fact. But the meeting could think of no practicable way of diverting this money to more deserving recipients.

More Geriatric Surgery Advised

Mr. R. P. M. MILES (Chichester) thought surgery in the very old often led to trouble; the patient was often "never the same man again." Mr. NASH disagreed. The more old people operated on the better. In fact they were often anaesthetized more safely, with their breathing being done for them, than they were walking about straining themselves. His advice was to get the hernia or the piles out of the way, so that they would not remain to complicate other diseases—prostatic enlargement, for example—making the patient worse off when he had to be operated upon. An efficient rehabilitation service was, of course, vital in geriatric surgery.

Dr. ASHER agreed. Old people wanted to live, or die; merely to exist in discomfort was useless to them. Surgeons should take more risks and not worry about spoiling a set of good operating figures. Dr. MCCONAGHEY said it was not surgery that did old people in, but hospitalization and being put to bed. Dr. ASHER said he could talk indefinitely about the dangers of bed. He had once even written an article on the subject.

The CHAIRMAN turned the attention of the meeting to diagnostic investigations, unnecessary use of which was condemned. Sometimes they caused more discomfort than the disease. Dr. ASHER said he would rather have pernicious anaemia than undergo a modern full-scale investigation to see if he had. Patients should be given hope and not be over-investigated, he said. But Mr. NASH repeated that they should be told the truth as well as not being over-investigated.

Ocular Emergencies

The other panel, whose subject was ocular emergencies, consisted of Mr. B. W. RYCROFT (East Grinstead) and Mr. A. G. LEIGH (London), under the chairmanship of Mr. E. C. ZORAB (Southampton). They discussed first acute glaucoma.

Mr. RYCROFT reminded the audience that acute glaucoma was a sick eye in a sick body, and that views on its cause were changing. It had been believed to be due to interference with the drainage of fluid from the eye, but now a centre in the mid-brain was thought to be responsible for the tension of the eye. As acute glaucoma could cause very rapid blindness, prompt diagnosis and treatment were imperative. There might be gradual loss of vision or the appearance of a halo round lights. Treatment was the use of eserine drops to contract the pupil, and acetazolamide ("diamox"), 250 mg. thrice daily by mouth, or intravenously if necessary. Mr. LEIGH stressed the importance and the difficulty of the diagnosis, which rested on the recognition of a steamy cornea in a red, tender eye with a dilated pupil. The pain was so severe that it could not be accurately localized and was sometimes wrongly diagnosed as due to abdominal catastrophes, etc. Surgery had now been almost completely supplanted by acetazolamide therapy, and it was very unusual for recovery not to ensue. If acetazolamide failed, then iridectomy was necessary.

Corneal Lesions

The panel then discussed lesions of the cornea. Mr. LEIGH recalled that corneal epithelium is capable of regeneration without scar. In an abrasion some of the epithelium was wiped off; it regenerated partly by pseudopodial migration from the edges of the defect, partly by mitosis. The defect could be covered within hours, but the repair was very delicate and the slightest further injury would remove the new epithelium. Diagnosis was made by instilling 2% fluorescein, which stained the injured part. Treatment was by pad and bandage; cocaine prevented healing. Adherence of the repaired defect to the upper lid caused stripping and recurrence the next day. Antibiotic drops and atropine were then required. To prevent regurgitant infection via the lacrimal ducts, pressure should be applied to the lacrimal sac; infection of a corneal abrasion could lead to loss of the eye.

Mr. RYCROFT said that dendritic ulcer was thought to be due to a virus. It often followed an excessively high fever. Treatment was difficult owing to recurrence and scarring. Cauterization with carbolic was the first line of treatment. Together with atropine, pad, and bandage; local hydrocortisone was definitely contraindicated. The condition usually lasted for three or four weeks. Mr. LEIGH said that, although some dendritic ulcers responded to cortisone, some would develop virus keratitis involving the whole cornea, so destroying sight. Mr. RYCROFT said that after one or two recurrences a deep lamellar graft was useful. Mr. ZORAB said that without a good light, magnification, and fluorescein, dendritic ulcers could easily be missed. They should be looked for in any sore eye.

Retinal Detachment

Mr. LEIGH said detachment of the retina could present as a sudden loss of vision, but usually only a shadow was noticed. Ophthalmoscopy was the only means of diagnosis, but the presence of blood might prevent a clear view. Treatment began with rest in bed. At operation diathermy was used after evacuation of the subretinal fluid. Results were improving because of the introduction of scleral resection and scleral buckling (which took only three hours to do). Mr. RYCROFT mentioned three important symptoms: a "curtain" in the field, flashes of light in one part of the field, and alteration in the quality of vision—for example, a lamp-post would have a kink in it. He suggested vitreous transplantation to push the retina back into place.

Mr. RYCROFT then considered acute infections of the lids and lacrimal apparatus. A red eye was often wrongly put down to conjunctivitis, he said; the one sure sign of conjunctivitis was stickiness of the lids. Itching was often

due to pinguecula, and irrigations used in the treatment of conjunctivitis usually made the irritation of pinguecula worse. Infections of the lacrimal sac in infants due to failure of canalization of the duct were treated by massage of the sac, and 95% would recover in six months. If not, then probing should be undertaken, a procedure possible at that age but more difficult later owing to the change in direction of the duct. In adults, obstruction was due to fractures or to nasal infection. Dacryocystorhinostomy was necessary. Removal of the sac was to be condemned.

Cross-examination of the Panel

Wing Commander E. H. LAMB asked how much retinal detachment made a case hopeless. Mr. LEIGH said that 60% of all cases treated were successful; but, once the macula was detached, visual acuity was never fully restored. Provided a small sector of retina remained attached, a good result could follow treatment.

Dr. J. L. STRUTHERS (Southampton) asked if corneal abrasions from vegetable matter were more serious than those caused by animal or mineral material. Mr. RYCROFT said that the most dangerous substances he had met were caterpillar hairs and cactus spikes. The danger depended upon the subsequent infection. Dr. E. GREY-TURNER (London) asked how long a recurrent corneal abrasion should be allowed to go on for. Mr. LEIGH replied that a lamellar corneal graft was the ideal treatment for the chronic case.

Asked what should put the practitioner on his guard against chronic glaucoma, Mr. RYCROFT said that a patient with failing sight should be examined by an ophthalmic surgeon and not only by an optician. An optician might ascribe the failure of sight to a small cataract, which he could see, but without dilatation of the pupil and examination of the fields the real cause of the reduced vision—namely, chronic glaucoma—could be missed. Mr. ZORAB emphasized that the painlessness of chronic glaucoma made it easily missed.

Using acetazolamide, was it permissible for a G.P. to hold an acute glaucoma for, say, eight hours? Mr. LEIGH said that, if the practitioner was able to judge the response to treatment by noting the cessation of pain, clearing of the cornea and contraction of the pupil, and diminished tension, then it was perfectly justifiable to hold such a case. Mr. ZORAB said it was now no longer necessary for the ophthalmic surgeon to get up in the middle of the night for acute glaucoma, thanks to acetazolamide, but it only gave a breathing-space. Mr. LEIGH mentioned that the chances of glaucoma starting in the second eye were very high, but tests were now available to tell in a given case if that was likely: if so, a preventive operation should be done. Mr. RYCROFT said that sedation was an important adjunct to treatment. The last question concerned vitreous haemorrhages, and Mr. LEIGH said that he found them very difficult to treat. He was doubtful if any treatment was of value.

The remarkable thing about this panel was that all three members were in agreement over everything that was said.

THIRD GENERAL SESSION

Saturday, December 6, 10.45 a.m.

As in the previous general sessions three invited speakers gave short discourses on unrelated topics. For the last of the general sessions, held under the chairmanship of Dr. I. D. GRANT (Glasgow), the speakers were Sir RUSSELL BRAIN (London), Dr. J. T. INGRAM (Leeds),* and Professor E. STENGEL (Sheffield).

Acroparaesthesiae

Sir RUSSELL BRAIN spoke on acroparaesthesiae, illustrating his observations with lantern slides. He said the term implied three things—namely, that the distal parts of one or more of the extremities were involved in a sensory

*Dr. Ingram's appointment to a new chair of dermatology at Durham University was announced last month (*Journal*, November 22, p. 1302).

disturbance which was not a mere lack of feeling but had some positive quality such as tingling which was usually of an unpleasant character. Within this definition there were different forms of acroparaesthesiae characterized by varying degrees of unpleasantness, which in severe cases amounted to pain.

In taking the history of a patient complaining of acroparaesthesiae it was important to get as full an account as possible of the quality of the abnormal feelings and of their distribution, whether the onset was related to any particular posture, whether they occurred only when the patient was lying in bed, and, if so, at what part of the night they came on. Paroxysmal acroparaesthesiae had a different pathogenesis from persistent ones. Their cause was reversible, a vascular factor probably playing an important part. If paroxysmal acroparaesthesiae became persistent, a change which for the time being at least had become irreversible must have taken place. The same was true of acroparaesthesiae which were persistent from the beginning.

All the commonest causes of acroparaesthesiae appeared to involve one or more posterior spinal roots or peripheral nerves in such a way as to lead to their direct compression or an interference with their blood supply, or both. When the pressure operated paroxysmally its effects were reversible, but if it was repeated sufficiently often, or was long-continued, pathological changes were likely to occur in a nerve root or nerve, initially oedema, and later, if the oedema was not relieved, fibrosis. Acroparaesthesiae most commonly occurred in the upper limb, where their three main causes were (1) cervical spondylosis, (2) drooping shoulders, and (3) compression of the median nerve in the carpal tunnel.

Two main types of acroparaesthesiae occurred as a result of cervical spondylosis. Involvement of a single spinal posterior root was likely to cause pain, tingling, and numbness within its cutaneous distribution, which was worse if the patient lay on the affected side in bed, and the numbness was usually constantly present. The other type of acroparaesthesiae consisted of more widespread sensations of painful tingling, numbness, stiffness, and swelling often involving the whole hand. These tended to awaken the patient at night after a few hours' sleep. The acroparaesthesiae associated with drooping shoulders were usually more troublesome during the day than at night, and were specially prone to affect the inner border of the forearm and hand. The low position of the shoulders was evident on examination, especially from behind, and a lateral radiograph of the cervical spine gave a clear view of the body of the first and often, also, the second dorsal vertebra.

When the median nerve was compressed in the carpal tunnel the acroparaesthesiae had the characteristic distribution of the sensory supply of the nerve to the thumb, index, middle finger, and radial side of the ring finger. These acroparaesthesiae were also prone to awaken the patient at night. They soon became associated with objective sensory loss over cutaneous areas of the digits supplied by the median nerve and some wasting and weakness of the outer thenar muscles. Pregnancy sometimes led to acroparaesthesiae arising from either the cervical spine or roots or, less often, the median nerve.

In the lower limb the sensory disturbances in meralgia paraesthetica were not strictly acroparaesthesiae, though they had a similar quality and pathogenesis.

All these benign sensory symptoms needed to be distinguished from paraesthesiae produced by organic disease of the spinal cord, especially disseminated sclerosis, subacute combined degeneration, and atheromatous ischaemia, and from disorders of cerebral origin.

Sir RUSSELL BRAIN, in reply to questions, suggested that rest gave most relief for acroparaesthesiae of pregnancy; there was no specific treatment. Pain from the carpal tunnel syndrome would sometimes affect the arm even to the shoulder. Exceptionally it was possible to have symptoms from cervical spondylosis with normal radiographs. This was due to a moving intervertebral disk. Manipulation of the cervical spine, after heat and without an anaesthetic, might give relief if there was muscle spasm.

"The Restless Skin"

In discussing "The Restless Skin," Dr. JOHN T. INGRAM (Leeds) said it was important for every practitioner to recognize the essentially dynamic nature of the skin. Too often the skin was regarded as something static. Our ideas derived from impressions gained from examining dead material under the microscope. The skin was not an inert envelope enclosing the living organism; it was at least as vital as other parts, if not more vital than most. It certainly participated in and commonly reflected all types of systemic activity, as, for example, the metabolic, endocrine, vascular, and emotional. It was rather like a vast sea, with its unfathomable depths resting upon an unseen bed which might influence its behaviour or erupt to the surface; in addition the surface waters independently might evolve mischievous antics of their own.

These inherent activities, which concerned all the elements of dermis, epidermis, and appendages, often working in harmony, constituted the communications of the individual with the world at large, his life. If we visualized this organ caressed by vascular elements and fine nerve fibrils, it was not difficult to be aware of the restlessness of the skin, and of the significance—and the value and danger—of that restlessness. Injury to the skin and the resulting lesion were important, but we tended to note the insult and too often forgot the sensitive patient and the immediate circumstances.

In local treatment it was rarely necessary to depart from the time-honoured and effective applications that were bland, non-irritating, and non-sensitizing, provided they were dispensed properly and applied properly. The services of a nurse were invaluable.

Where a persistent eruption was limited in extent, the doctor must never tire of seeking a local sensitizing contact. He should not be content with the label allergic unless prepared to find the allergen. Whatever the aetiological balance, however, it was always profitable, from the start, to help to restore general and dermatological calm by prescribing sedatives internally.

In reply to questions, Dr. INGRAM agreed that upon occasion effective treatment of a skin lesion might upset a patient physically or mentally. This was not likely to happen if treatment was directed to the whole patient in relation to his whole environment. He said that applications of hydrocortisone lotions and creams were of particular value in local, irritable, and eczematous affections such as otitis externa, affections of eyelids, and pruritus of the genital and anal regions. They were not of such value in thickened lesions or in widespread eruptions, which was perhaps fortunate, since hydrocortisone was so expensive. Asked about endocrine therapy in acne vulgaris, he said that, though endocrine factors clearly played an important role in its aetiology, treatment with hormones was unsatisfactory and sometimes harmful. Occasionally small doses of oestrogens helped girls, but they were not effective in boys. Gonadotropins had proved disappointing.

Suicide and Attempted Suicide

Professor E. STENGEL (Sheffield) said that there were many common misconceptions about suicide and attempted suicide. It was wrong to believe that people who threatened suicide would not do it. In fact many gave a warning of their intentions, thus allowing their "environment" to intervene.

Attempted suicide was not necessarily unsuccessful suicide; there were not two grades of suicide, the successful and the unsuccessful. That notion presumed that the only motive for the suicidal act was self-destruction. Like most human behaviour the suicidal act reflected the conflict between love and hate—the contact-seeking tendencies on the one hand and the destructive tendencies on the other. The outcome of the suicidal act depended largely on the relative strength of these tendencies. It was generally thought that the outcome of the act depended mainly on the method employed and the

seriousness of the intent. But it also depended on the reaction of the environment and on other imponderable factors. Suicidal acts had the character of a gamble, or rather of an ordeal.

Follow-up studies showed that people who commit suicide and those who attempt suicide form two different though overlapping populations. Only a small proportion of those who attempted suicide killed themselves and only a minority of those who killed themselves had attempted suicide before. Nevertheless the likelihood of suicide amongst those who had attempted it was much greater than in the general population. Suicidal acts were much more frequent in older people than in the young, contrary to a commonly held opinion; and poverty was not an important factor. Depressive illness carried the most serious risk of suicide.

Legislation against those who attempted suicide was a cause of much distress. The incidence of suicide was lower in Scotland, where suicide was not a criminal offence.

In discussion Professor STENGEL agreed that the motive was sometimes veiled aggression, the desire to inflict punishment on others. Considering the incidence of suicide in different Scandinavian countries he felt that prosperity, alcoholism, and industrialization were important influences. The social code of various classes differed and there was often a fear of decline in status. He did not think that referring a depressive patient to hospital was likely to cause attempted suicide; the patient was the best witness to that.

HOSPITAL DEMONSTRATIONS

The afternoon of Saturday was devoted to clinical demonstrations in the various departments of the Southampton hospitals. The demonstrations were illustrated by slides, diagrams, charts, and photographs on whose preparation a great deal of care and hard work had been expended. At the *Southampton General Hospital* thyroid disease was discussed by the physicians, and Crohn's disease in the Surgical Department. A full programme, largely devoted to the general-practitioner aspects of midwifery, was given in the Department of Obstetrics and Gynaecology; whilst the neurologists demonstrated the result of treatment of intracranial angiomas. Members of the Department of Anaesthetics discussed some problems of respiratory insufficiency and presented a case of tetanus under treatment in the Respiratory Unit. The problem of nursing the elderly, the treatment of deafness, and speech training after laryngectomy, as well as demonstrations of laboratory techniques in the Pathological Department, and a film on swallowing in the Department of Radiology, were other items on the programme.

At the *Royal South Hants Hospital*, besides clinical demonstrations in the Departments of Medicine and Surgery on endocarditis and peripheral vascular disease, respectively, the orthopaedic surgeons, the pathologists, and the physiotherapists all discussed problems arising in their specialties. The new rotating caesium telecurie treatment unit was also on show. Particularly well attended sessions were held by the dermatologists and the paediatricians.

At *Southampton Chest Hospital* cases were demonstrated to small groups of visitors, and aspects of thoracic surgery, cardiology, and thoracic medicine were discussed at the bedside. A film on closure of an atrial septal defect under hypothermia was shown. The Department of Anaesthetics held a discussion on the anaesthetist's role in thoracic surgery. The continuous demonstration at the *Southampton Eye Hospital*, which was limited to 30 visitors, was fully attended. The examination and discussion of patients with various ophthalmic conditions were carried out in small groups, and after this three films were shown.

SUNDAY VISITS

On Sunday morning visits were made to five centres of interest in the vicinity. Visitors to the Department of Daily Living at the *Royal Hampshire County Hospital* at

Winchester had the opportunity of first attending Matins in Winchester Cathedral, where places had been reserved for them in the choir. After this Dr. W. RUSSELL GRANT gave a fascinating demonstration of ingenious and simple gadgets and adaptations to the home, whereby those afflicted by disease or injury can lead an active life despite their disabilities. At *Odstock Hospital, Salisbury*, in the Department of Physical Medicine and Plastic Surgery, Dr. HUGH J. GLANVILLE and Mr. J. N. BARRON discoursed on treatment and subsequent rehabilitation after acute injury. This was followed by a visit to the Nuffield Department of Rehabilitation, where patients were seen regaining their working capacity on modified and adapted machinery. Both these demonstrations at Winchester and Odstock were followed by receptions given by the local Divisions of the B.M.A.

Another party visited the *Veterinary Artificial Insemination Centre* of the Hampshire Cattle Breeders' Society at Lyndhurst. The laboratory work undertaken in solving problems of breeding, cross-breeding, fertility, and the treatment and storage of semen was described. Mr. K. G. ELCOATE and Mr. D. H. MADDON included in their demonstration a visit to the bull pens, where semen was collected, and discussed some of the practical problems involved in artificial insemination.

A number of visitors made a tour of the *Port of Southampton*, where after visits to the King George V Graving Dock and the Ocean Terminal Dr. W. P. CARGILL gave a talk on some of the medical problems of a great port. Finally a party were shown round the vast *Esso Refinery at Fawley*, where Mr. COLIN SOUTHALL conducted the visitors on a tour of the various plants. Dr. A. WARD GARDNER described the special problems met with by the Medical Department, and took the party to see the new hospital wing of the Refinery, which is in his charge.

APPROVED NAMES

The last supplement to the consolidated list of "approved names" was published in the *Journal* of September 20 (p. 739). A new supplement, dated December, 1958, is printed below. Communications relating to "approved names" should be addressed to the secretary, British Pharmacopoeia Commission, General Medical Council, 44, Hallam Street, London, W.1.

Approved Name	Chemical and Other Names	Notes
Anisindione ..	2- <i>p</i> -Methoxyphenylindane-1:3-dione "Miradon"	Anticoagulant
Cloquinate ..	Chloroquine di-(8-hydroxy-7-iodo-quinoline-5-sulphonate) "Resotren"	Amoebicide
Dieldrin ..	Product containing 85% of 1:2:3:4:10:10-hexachloro-6:7-epoxy-1:4:4a:5:6:7:8:8a-octa-hydro-exo-1:4-endo-5:8-dimethano-naphthalene	Insecticide
Halopenium chloride	4-Bromobenzyl-3-(4-chloro-5-methyl-2-isopropylphenoxy)-propyl-dimethylammonium chloride	Antibacterial and antifungal agent
Isopropamide iodide	(3-Carbamoyl-3:3-diphenylpropyl)-methyl-diisopropylammonium iodide "Darbid"; "tyrimide"	Anticholinergic agent
Mestanolone ..	17 β -Hydroxy-17-methyl-5 α -androstan-3-one "Androstatone"	Protein anabolizing hormone
Methsuximide	<i>N</i> a-Dimethyl- α -phenylsuccinimide "Celontin"	Anticonvulsant
Noscipine ..	Narcotine "Cocopin"; "nicolane"	Antitussive
Poldine ..	2-Benziloyloxymethyl-1-methylpyrrolidine "Nacton" is the methosulphate	Treatment of peptic ulcer
Prampine ..	<i>O</i> -Propionylatropine "PAMN" is the methonitrate	Anticholinergic agent
Promethazine theoclate	<i>N</i> -(2-Dimethylamino- <i>n</i> -propyl)phenothiazine salt of 8-chlorotheophylline Promethazine chlorotheophyllinate "Avomine"	Antihistamine
Sulphamethoxy-pyridazine	3- <i>p</i> -Aminobenzenesulphonamido-6-methoxypyridazine	Sulphonamide
Sulphatolamide	"Kynex"; "lederkyn"; "midicel" <i>p</i> -Aminobenzenesulphonylthiourea salt of <i>p</i> -sulphamoylbenzylamine "Marbadal C"	"

To-day's Drugs

With the help of expert contributors we publish below notes on a selection of drugs in current use.

Tabs. ethinyloestradiol B.P.
Estigyn (British Drug Houses).
Eticyclin (Ciba).
Lynoral (Organon).

Ethinyloestradiol, a semi-synthetic oestrogen, is the most potent oral oestrogen, being about 20–25 times as active as stilboestrol, but costing more. The justification for the higher cost would be a smaller incidence of intolerance than is shown to stilboestrol; unfortunately this is by no means certainly the case. The indications for ethinyloestradiol are the same as those for other oestrogens: replacement therapy in hypo-ovarianism (dose about 0.1 mg. daily in 20-day interrupted courses) and in the climacteric (about 0.01 mg. or less daily, again in interrupted courses); treatment of menstrual irregularities of functional origin (daily dose about 0.1 mg.); suppression of lactation (no two people seem to have the same views on the precise regime for this, so it probably does not matter); and palliative treatment of prostatic carcinoma (daily dose 0.1 mg. and upwards, according to clinical response), and of some post-menopausal patients with carcinoma of the breast.

In general, it may be said that if stilboestrol is tolerated in doses which are adequate for the purpose there is no reason to use any other oestrogen; if it is not, ethinyloestradiol in equivalent dosage may be tried. Some patients will tolerate it better, but others will not.

N.H.S. basic price: all preparations, 0.01-mg. tablets or linguets (eticyclin), 100 for 1s. 6d.

Injection of cyanocobalamin B.P.
Anacobin (British Drug Houses).
Bitevan (Evans Medical Supplies).
Cobalin (Paines and Byrne).
Cobastab (Boots).
Cytamen (Glaxo).
Distivit B₁₂ (Distillers).
Duodecibin (Woolley).
Fermin (Richter).
Megalovel (Vitamins Ltd.).
Rubramin (Squibb).

Cyanocobalamin is of greatest value in the treatment of pernicious anaemia. In this disease there is a deficiency of it, so that instead of the normoblastic maturation in the bone marrow leading to the formation of normal red blood cells a megaloblastic reaction occurs, and pernicious anaemia develops. This faulty marrow response is corrected within a few days of adequate treatment with cyanocobalamin parenterally. It may be given in doses of: (1) initially, 250 µg. for two or three days in the first week, followed by 250 µg. twice weekly until the blood count is normal and symptoms of posterolateral sclerosis are minimal; then only should the dosage be reduced gradually until (2) a maintenance dose is reached, which may vary in different patients but is usually about 100–250 µg. weekly and then fortnightly. It is usually undesirable for prolonged maintenance therapy to be so infrequent as 50–100 µg. at monthly intervals. Some cases of tropical macrocytic anaemia and a few cases of sprue respond to treatment with cyanocobalamin.

N.H.S. basic price:—Six 1-ml. ampoules for injection, each containing 100 µg. cyanocobalamin: inj. cyanocobalamin. B.P., 2s. 7½d.; anacobin, 2s. 7½d.; bitevan, 2s. 7½d.; cobalin, 2s. 8d.; cobastab "viules," 2s. 7½d.; cytamen, 2s. 7½d.; duodecibin, 3s. 4½d.; fermin, 3s. 4d. Five 1-ml. ampoules of 100 µg.: distivit B₁₂, 2s. 2d.; megalovel, 2s. 6d. Rubramin, 5-ml. vial of 100 µg., 2s. 8d. Ampoules containing doses of different sizes are available.

Correspondence

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

B.M.A. Clinical Meeting

SIR,—“Never a dull moment”—that is how a Southampton colleague described the B.M.A. Clinical Meeting as we came through the swing-doors of the Guildhall after the final general session. What a busy and enlightening experience the three days' meetings have been, especially for a member of an antipodean Branch, as I am.

From such a wealth of splendidly presented items it is hard to select any for special comment, and anyway individual tastes and interests differ. The colour televising of surgical operations from the Southampton General Hospital, the Transatlantic Clinical Conference, the clinical demonstrations at the hospitals—all were evidence of superb planning. And there was so much more.

The Annual Clinical Meeting has been well launched. Developing from this initial triumph, succeeding meetings in years to come will do much to assure the continued advancement of British medicine. All who contributed to this 1958 success have reason to be proud.—I am, etc.,

Adelaide, South Australia.

A. R. SOUTHWOOD.

Antibiotics in Acute Tonsillitis and Otitis Media

SIR,—I must take issue with Dr. Peter A. Walford (*Journal*, November 29, p. 1353) on this subject. To say that the rarity of rheumatic fever warrants the withholding of antibiotics in sore throats is as illogical as to say that because diphtheria is also so rare there is no point in continuing immunization. Incidentally I have yet to hear that the decline in diphtheria is attributed to a waning in virulence of the causative organism. Penicillin is just as specific a therapy for streptococcal sore throat as immunization is a specific prophylactic for diphtheria.

Since it is not refuted that acute nephritis and rheumatic fever follow streptococcal infections, it is logical to treat such infections as early as possible with the specific remedy. To withhold antibiotics for 24 to 48 hours, as Dr. John Fry did in his series of cases (*Journal*, October 11, p. 883), cannot, to my mind, give a true comparison between treated and untreated cases. The most striking results with penicillin in acute tonsillitis and otitis media are observed when the antibiotic is administered early in the infection, as is so often possible in general practice. Dr. Walford quotes a paper by Wilson¹ written in 1946, showing that after penicillin therapy there was some degree of hearing loss in 18% of his series of cases. However, the doses in use at that time would hardly be considered adequate by present-day standards. A more recent survey by Dixon² has shown that, in 114 otitis media infections treated with penicillin without myringotomy, there were only four cases of minimal hearing loss and there were no complications. The author concludes that this is a highly satisfactory result.

Dr. Walford asks for other practitioners' experiences of the incidence of acute nephritis and rheumatic fever. I can only say that in my own practice over eleven years (during which time I have used antibiotics extensively) I have seen no cases of either condition.—I am, etc.,

Twickenham.

DAVID WHEATLEY.

Resistant Staphylococci

SIR,—Dr. Mary Barber and her colleagues are to be congratulated on their efforts to clarify the problems associated with antibiotic-resistant staphylococcal infections (*Journal*, December 6, p. 1377). There are, however, two points on which further clarification might be possible.

DEC. 20, 1958

CORRESPONDENCE

BRITISH
MEDICAL JOURNAL 1531

The first concerns the emergence of erythromycin-resistant strains. There is strong evidence implicating group III staphylococci as the principal offenders. The question remains, however, as to what extent the level and duration of erythromycin administration affected the outcome. Is it possible to compare the treatment of those patients infected with group III organisms and who did not eventually produce resistant organisms with the treatment of a similar group from whom resistant strains were isolated? This point is of particular importance, since erythromycin is probably the least toxic antibiotic in general use at the present time, and therefore increased dosage might be employed if it can be shown that such would prevent resistant strains developing.

My second point relates to their statement that ristocetin (trade name "spontin") has serious toxic effects, "particularly on the eighth nerve." Although this drug has undergone extensive clinical trial, and is used in day-to-day practice in the U.S.A., experience in this country is very limited. To my knowledge, out of several thousands of patients treated with ristocetin, there have been only two instances of deafness, and in neither case could it be definitely stated that the deafness was due to this drug, as other antibiotics were being currently used. If Dr. Barber has additional evidence on this point, I should be most grateful to hear of it.—I am, etc.,

R. F. CRAMPTON.

Hula-hoop Syndrome

SIR,—In recent weeks I have seen an unusual number of children and young adults complaining of pain at the side of the neck associated with a pain in the upper abdomen. Both were aggravated by movement, and in the case of a neck pain it was severe enough to produce torticollis in a few. On examination, there was a varying degree of reduced movement of the cervical spine, especially of rotation, which was limited by pain, and there was spasm and tenderness in one or both sternomastoids, the cervical portion of the trapezius, and the paravertebral muscles in the cervical region. Abdominal examination revealed tenderness in the epigastric region and immediately below the costal margin. Pain was also produced in this region by straight-leg raising.

Having noticed the present fashion of the hula hoop in this area I started making inquiries from the parents of the sufferers, and so far in each case the attack followed a first indulgence in this sport. My diagnosis was confirmed the other day when a lady of 68 presented herself with this classical picture. Whilst thinking of a possible alternative diagnosis I made the remark that had she been a little younger I would have asked her whether she had been hula-hooping yesterday. To my surprise she replied, "As a matter of fact I did have a go yesterday at young Willie's birthday party."—I am, etc.,

Stevenage.

J. O. NEWMAN.

SIR,—The widespread popularity of the pastime recently introduced to this side of the Atlantic from America prompts me to report briefly the following case history.

A girl aged 7 years complained of feeling off colour and some frequency of micturition on November 28. By November 30 the frequency had gone, but she complained of pains all over and could not walk. When seen on December 1 her temperature was 102° F. (38.9° C.). Normally a very active child, she lay perfectly still in the bed. She had moderate neck rigidity, was unable to sit up unsupported, and her lower-limb movements were slow and painful. Her lower-limb tendon reflexes were diminished, but skin reflexes were normal. Her back muscles were tender especially in the mid-dorsal region.

She was admitted to hospital as a possible case of poliomyelitis. In hospital she was provisionally diagnosed as a case of benign lymphocytic meningitis. Both these were proved wrong by a normal cerebrospinal fluid, pathological centrifuged deposit in the urine, and a rapid recovery by the patient.

The reason for the "meningeal" signs was that the patient was given a hula hoop on November 29 and proved to be

very proficient with it, at both neck and waist level. It is tempting to postulate that the waist level activity may have converted a cystitis into a pyelitis.—I am, etc.,

Castleknock, Co. Dublin.

HALDANE G. NELSON.

Potassium Perchlorate Sensitivity

SIR,—We thought that there might be some general interest in what appears to be an unusual case of potassium perchlorate sensitivity.

In 1952 Wyngaarden *et al.*¹ demonstrated the inhibitory action of this drug on thyroid function. Since then it has been used effectively in the treatment of hyperthyroidism with minimal toxic reactions. Morgans and Trotter² treated 198 cases for periods of one to ten months, the side-effects noted being gastro-intestinal irritation in two patients. Godley and Stanbury³ treated 24 patients with doses between 600 mg. and 1,200 mg. daily with good effect. Perforation of a duodenal ulcer occurred in one patient whilst on potassium perchlorate and a further patient developed dyspeptic symptoms, but no other side-effects were seen. Smellie⁴ treated six thyrotoxic children effectively with the same drug and no side-effects occurred. In the case reported here potassium perchlorate appears to have been responsible for a drug reaction.

Mr. L. P., aged 37 years, first attended at our clinic on June 24 this year, when a diagnosis of moderate thyrotoxicosis was made on clinical examination. Treatment was begun with potassium perchlorate, 300 mg. thrice daily, with the intention of proceeding to thyroidectomy later. On July 14 he began to feel unwell and developed some bowel frequency. On the same evening he felt tight about the throat, had swellings on his neck, and an extensive macular rash. He was admitted to another hospital on July 17, when he was found to have a partially confluent macular rash over the whole of his body and a generalized, fleshy lymphadenopathy. A soft spleen could be felt about an inch (2.5 cm.) below the costal margin, and his throat and mouth were raw, with small areas of superficial ulceration. Apart from a pyrexia of 103° F. (39.4° C.), there were no other abnormal findings in a systematic general examination.

The rash began to desquamate and his temperature remained between 101 and 103° F. (38.9–39.4° C.) for four days, but then settled. On the tenth day after admission it rose again to 100° F. (37.8° C.) and reached this daily during the following week. Simultaneously he became oedematous in his arms, legs, and scrotum; and the skin of these regions became very fiery. Slowly the desquamation ceased and the other conditions settled.

Laboratory results were as follows: Paul-Bunnell test was negative. White cell count varied between 3,600 and 6,600/c.mm., with slight neutrophilia. E.S.R. 2 mm. in one hour. Stools showed no pathogens. Urine was normal. Serum proteins were 4.8 g./100 ml., with normal electrophoresis.

A skin test (superficial) with potassium perchlorate solution gave a positive vesicular eruption.

This man, therefore, seems to have exhibited an unusual sensitivity to this apparently innocuous drug.—We are, etc.,

B. J. FAIRHURST.

A. L. M. HOLLINGWORTH.

Prevention of Lung Cancer

SIR,—It seems clear that those doctors who refer cases of carcinoma of the bronchus in heavy cigarette-smokers to the coroner do so in the hope that the general public will be warned of the danger of the habit. Such notifications are perfectly proper, but it appears that some coroners do not know what should be done. Thus, Dr. Ian Milne, one of the coroners for the County of London, held an inquest on such a case, in which a verdict of "natural death" was returned. Dr. Milne now writes (*Journal*, November 22, p. 1292) to say that "A verdict of accidental death is, clearly, inappropriate where the incidents are repetitive.

frequent, and undated, as in the case of the cigarette addict." But, as Dr. J. Shackleton Bailey points out on the same page, Sir Bentley Purchase recorded a verdict of "accidental death" in the case of a man who died of multiple skin carcinomata, after working with arsenical sheep dip for 40 years: here the incidents must have been repetitive, frequent, and undated.

These divergent views seem to support Dr. G. B. Forbes's doubts (November 1, p. 1104) as to whether the coroner's court is the proper platform for propaganda. Indeed, if doctors acquired the habit of referring similar cases to coroners, there might be some very comical results. One can imagine a conscientious practitioner referring a case of carcinoma of the penis to the coroner, stating that it was due to a persistent prepuce. It might then be difficult for an inquest verdict to avoid stating that the death was due to inattention in infancy, although, doubtless, the negligent parents will have passed out of the jurisdiction of earthly tribunals. Again, one can imagine a death certificate which stated that the immediate cause of death was carcinoma of the cervix, due to multiparity due to careless copulation. Could the (probably) ignorant husband be charged with having caused his wife's death? Such cases are just as silly as were the manslaughter charges against Christian Scientists and other anti-medical cranks. It is indisputable that an anti-smoking campaign is overdue, but it is equally certain that coroners, many of whom are not doctors, are among the least suitable propagandists.—I am, etc.,

London, W.1.

A. PINEY.

SIR,—We are grateful to Dr. R. Ian Milne (*Journal*, November 22, p. 1292) for confirming our view that a doctor who believes his patient has died from cancer of the lung, due to smoking, has the legal right to assert this belief on the death certificate, provided he is prepared to testify to this knowledge and belief on oath, and listen to contrary evidence in court. We also believe it is an ethical duty to do so.

We should like to clarify what we meant in our original letter (*Journal*, October 18, p. 980) by "in the appropriate case." Of the three main types of bronchial carcinoma, one, the adenocarcinoma, has no proved association with smoking and therefore we would not incriminate it, even if the patient were a heavy smoker. In the oat-cell or squamous type we would state that it was "due to smoking" only if there were no occupational risk from asbestos, arsenic, chromates, nickel or coal distillation. The elimination of these groups, however, would still leave the vast bulk—at least four-fifths—as being attributable. While clearly it is better to know beforehand the nature of the growth, lack of this knowledge need not prevent certification of a lung cancer death as due to smoking, for the coroner can order a post-mortem examination, as a result of which the exact histology would be established.

Atmospheric pollution is the other factor which can reasonably be incriminated, but the gross sex differences in incidence and the small variation between deaths in non-smokers in town and country strongly suggest that its role is not a major one nor comparable in importance to that of cigarette-smoking. In the heavy smoker with an oat-cell or squamous growth who has no particular occupational risk, it is reasonable to attribute the development of lung cancer to cigarettes. We consider it not only reasonable but necessary in the public interest to say so.

One further point requires attention—the feelings of the relatives of the dead patient. Naturally, due consideration should be given to these, and it is necessary to warn the relatives that the coroner may decide to have a post-mortem examination and an inquest may follow. Some will be upset; others will no doubt welcome the opportunity to establish the truth; but in neither case should their attitude be a factor which influences what the doctor will do as regards the death certificate; this has to be completed in accordance with the facts as he understands them to the best of his knowledge and belief.

Finally, we should like to endorse the view put forward by Dr. H. J. Pratap (*Journal*, November 8, p. 1165) that the psychiatric approach as to why people smoke is of prime

importance. More attention will have to be given to helping those who wish to give up smoking; for this we must obtain more information and study the various aetiological factors in their social context.—We are, etc.,

Stanmore, Middlesex.
London, W.1.NORMAN MACDONALD.
WILFRED LESTER.

SIR,—With respect to Dr. R. Ian Milne I do not think his letter (*Journal*, November 22, p. 1292) has altogether explained the logic of his quarrel with a doctor's use of the term "excessive" in relation to a smoking habit of 40 or 50 cigarettes a day. His objection to the term on a death certificate appears to be that it has no legal significance because it only amounts to a reason for the doctor's opinion that death from carcinoma of the bronchus was due to smoking. But surely we cannot omit consideration of degree where it is the determining factor in a cause of death. "Excessive" here is the operative word, and it would have been implied even if it had not been used at all. One might more easily sustain an objection to the word on the grounds that it was redundant. Obviously for heroin, alcohol, barbiturates, or radiation to cause death they must have been met with in excess of a safe amount whether this was over a long period or in the nature of a single lethal dose.

One cannot but agree with Dr. Milne that it was unfortunate that the use of the word "excessive" by the certifying doctor was trailed as a red herring across a case that has raised the really important question of the legal recognition of smoking as a cause of "accidental death." This especially when the medical evidence relating to causation was as conclusive as it is likely to be in any case of carcinoma of the bronchus until the correlation of smoking and cancer is less dependent upon statistical data. As I pointed out in my own letter printed below that of Dr. Milne, the real difficulty is that, whereas this correlation approaches something like certainty in the mass, the significance of the smoking habit in any specific death is entirely a question of probability based upon the excessiveness and nature of the indulgence in that instance. Whilst one could not quarrel with the opinion that 40 or 50 cigarettes a day were causative, what is one going to do about 20 or 30 or less? Similarly, where does the degree of probability cease to be significant in relation to pipe- or cigar-smoking?

Coroners are accustomed to accepting a balance of probability, as illustrated in my letter (*Journal*, November 22, p. 1293) by the case in which Sir Bentley Purchase returned a verdict of "accidental death" with no more than a statistical probability to prove that prolonged exposure to arsenic had been a cause of death from cancer. The exposure here of 40 years could be considered excessive by any standard, although I have no doubt that Sir Bentley appreciates how awkward it would be to be called upon to state exactly how many years less than 40 he would have been prepared to accept as sufficient to justify his verdict. Fortunately we medical coroners when in difficulties of that sort can always fall back upon the legal element in our calling which allows of a purely intuitive wisdom that cannot be questioned in this way. Nevertheless one does wonder when the increasing pressure of science and statistics will compel a more scientific and uniform outlook amongst us all.

Even in cases where contributory causes of death can be stated in terms of statistical probability there still remains the decision as to what degree of probability should suffice. One can hardly be content with the coroner's hunch as to what amounts to excessive exposure to arsenic, smoke, or radiation, even if he is well advised and versed in the general and particular scientific evidence relating to the case. Surely it is time that some official decision was taken in relation to death from diseases such as cancer and leukaemia which can be attributed at all to exposure to harmful environmental factors. This is not a purely academic matter with no practical significance. In the meantime, whilst it is bound to become more confused under the purely arbitrary authority that exists at present, I rather join with your third

correspondent, Mr. Leslie J. Temple (*Journal*, November 22, p. 1293), in hoping that, at least in cases where really excessive smoking has preceded cancer of the lung, we shall have some verdicts of "accidental death." Then, as usual in this country, pressure will come from the public and eventually official inquiry and guidance might lead to a wiser and more orderly attitude to this smoke menace to life and health.—I am, etc.,

J. SHACKLETON BAILEY,
H.M. Coroner, County of Norfolk (Diss District).

Medicine on Television

SIR,—Professor Roger Warwick's interesting letter about medical television programmes (*Journal*, November 29, p. 1354) draws attention to what is really a very important subject. Television, like radio, reaches a vast audience and its influence on the general public is tremendous, and is bound to become even greater in the future, whether we like it or not. It is therefore most important that both we of the medical profession and the B.B.C. make up our minds as soon as possible how future television programmes of this nature are to be handled. Discussions such as the one at the College of Surgeons recently (*Journal*, November 29, p. 1351) are merely scratching the surface of the problem.

What is needed is a proper committee appointed by the B.M.A. to thrash it out thoroughly and recommend a policy for the guidance of the producers. If properly handled it could be a golden opportunity for us to educate the public in health matters and help them to take a more sensible attitude to physical fitness and the prevention of disease. At present hypochondriasis is so widespread that it is almost universal. Patients are morbidly fascinated by disease and seem pathetically ignorant about how to keep themselves healthy. And why? Because they have never been educated in the simple elementary facts of healthy living.

If these future programmes concentrate too much on disease and not enough on health they will inevitably do harm. Cynics have dubbed the N.H.S. the National Disease Service—and with good cause; for we still devote most of our energies to curative medicine instead of adopting the more positive attitude that disease can and should be prevented by healthy living.

It must be confessed the recent pronouncement of Sir Ian Jacob that the B.B.C. has no intention of elevating its present standards and means to continue providing light entertainment most of the time is not very encouraging. Are the ideals of culture and education now to be taboo to the B.B.C.? If so, as a citizen I protest, and as a doctor I see little hope for future medical programmes. The I see little hope for future medical programmes. The hours of dreary drivel churned out by the B.B.C. sound programmes every day are the despair of those of us who like something interesting to listen to. Let us hope that the television will at least try to rise above such puerile mediocrity and not pander to those who merely look for sensationalism and gruesomeness in the future when medical subjects are being dealt with.—I am, etc.,

Merioneth.

CLAUD C. M. WATSON.

Fishbone Furunculosis

SIR,—In the *Journal* of October 18 (p. 978) Dr. Ian Martin-Scott referred to Dr. Peter Cook's letter regarding "fishbone furunculosis" (*Journal*, September 27, p. 797) and wondered if the condition described might be an atypical erysipelas. May I add to this interesting discussion that many North American fishermen themselves recognize two distinct clinical entities?—(1) the furunculosis type of infection, which they call "Bait Sores," and (2) the erysipelas type, which they call "Seal Finger," "Red-fish Finger," or "Mackerel Finger," because this type is more frequently seen in seal-hunters, bait fishermen using frozen mackerel bait, or fishermen or fish-handlers who prick their fingers on Red-fish bones.

The experienced port surgeon can usually clear up the furunculosis type quickly and then concentrate on the erysipelas. A streptococcal secondary infection causing

pronounced lymphangitis and axillary adenitis is not uncommon in the "Bait Sore" type of infection, but rather rare in the erysipelas.

The "Bait Sore" type, like basal-celled carcinoma, is quite easy to handle when superficial, but when it invades bone it is rapidly destructive. In the days when fishing schooners did not have engines, a Banks fisherman making port against a head wind would sometimes bring in a man with a late furunculosis type of infection which had penetrated to bone, which necessitated a rather grievous amputation. This, fortunately, is practically unheard of to-day.—I am, etc.,

Lunenburg,
Nova Scotia.

H. A. CREIGHTON.

Chloroquine in Rheumatoid Arthritis

SIR,—In "To-day's Drugs" in the *Journal* of November 8 (p. 1160) there is a note on chloroquine phosphate and its use in the treatment of rheumatoid arthritis and other diseases. A word of caution is added because of the risk of corneal deposits when using large doses. From the inquiries I have made I understand that this risk is very small, and I am hoping that this possibility will not have an adverse effect on research and the subsequent use of this valuable drug.

In my experience as a general practitioner I have had greater success in early cases of rheumatoid arthritis using chloroquine than with any other form of treatment. Two of my patients have been taking chloroquine sulphate for a year and have become almost free of pain, stiffness, and joint swelling, and in both cases the E.S.R. has fallen dramatically. I had previously watched a gradual deterioration in each one in spite of treatment with sodium aurothiomalate, phenylbutazone, and salicylates. The only evidence I have had so far of any toxicity has been nausea, with occasional diarrhoea. In cases where this occurs I now use hydroxychloroquine, and have found it to be well tolerated.

In dealing with a tragic and disheartening disease like rheumatoid arthritis, any remedy suggesting a possibility of relief is a ray of hope. Reports so far seem to suggest that this drug is safer than corticosteroids, less toxic than phenylbutazone and gold salts, and it is relatively cheap.—I am, etc.,

Kettering.

W. L. OGLE.

Drug Treatment of Parkinsonism

SIR,—Dr. Macdonald Critchley in his excellent article on the use of drugs for Parkinsonism (*Journal*, November 15, p. 1214) refers to those of the solanaceous group—i.e., atropine, hyoscine, and stramonium. He reminds us that these drugs may well be used when the more recent drugs are found unsuitable.

The visual disabilities which the former may cause can be largely overcome.¹ Often 10 times the pharmacopoeial dose of stramonium is given, resulting in very marked improvement in the Parkinsonian rigidity.² Many of the patients, however, complain greatly of their inability to read, and of being worried by bright lights, due to paresis of accommodation and dilatation of the pupils. Roughly speaking, the stramonium effect as regards accommodation for reading distance is counteracted by a +1.50 to 1.75 lens, and eserine and pilocarpine applied to the conjunctival sac seem to counteract the effect to the extent of 1½ dioptres. Thus those with normal refraction, who do not want to read much, can have their visual disabilities removed by miotics. Presbyopes and hypermetropes need glasses, the latter for constant wear. In children, or myopes, the use of miotics to prevent dazzle is found the best procedure. The problem is a definite one, as sometimes Parkinsonian patients have to continue with stramonium for the rest of their lives.—I am, etc.,

London, W.1.

Insomnia

SIR,—Dr. A. H. Douthwaite's article on insomnia in the series "Drug Treatment of Disease" (*Journal*, November 29, p. 1347) is most helpful. Like many brainworkers who write and study too late, I have, during 40 years, endured many bouts of sleepless nights. For these I tried many drugs as well as methods of relaxation. Of all drugs chloral hydrate was the best. It acted rapidly and left no hangover as did the various barbiturates which were formerly prescribed to be taken every night. In my dermatological practice I met many patients who complained bitterly about the depression following these drugs.

During the 1914-18 war I was in France, and found how far in advance of us the Paris physicians were in ability to treat with electricity. I learned how to apply galvanism through the brain, and to this day I resort to that when the brain is worn and weary; sound sleep is certain to come that night. I have administered it to sleepless patients for many years with success. To-day, owing to the ease of applying diathermy in hospital clinics, the modern physiotherapist does not learn how to give galvanism from a portable battery. Like many other old and tried remedies, it has unfortunately gone out of fashion.—I am, etc.,

London, W. I.

AGNES SAVILL.

Physically Handicapped Children

SIR,—In the survey of pupils in schools for physically handicapped in London by Mr. W. T. Palmer and Dr. Denis Pirrie (*Journal*, November 29, p. 1326) there lies buried a fact which tends to be overlooked. Among the 1,325 children whose conditions are analysed there appear to be only 37 cases of spina bifida, and 24 cases of progressive muscular dystrophy. Those of us who are associated with residential schools for the physically handicapped supported by independent organizations are only too well aware of the fact that these two most handicapped groups have largely passed into the care of the voluntary societies, as indeed the survey points out. It is appropriate to call attention to the fundamentally greater difficulties facing those in charge of the residential schools. Running costs must necessarily be very much greater, and staffing arrangements need to be more closely related to those of hospitals.

I wonder whether the picture for London could be completed by the publication of figures showing the incidence of those "too severely handicapped for the special schools of the London County Council"? Presumably the existence and location of these children are known to the council, and it would give some indication of the trend of disability.—I am, etc.,

D. F. ELLISON NASH.

London, S.E.19.

Haemolytic Disease of the Newborn

SIR,—In the article by Dr. G. A. Kelsall and Mr. G. H. Vos and Mr. R. L. Kirk, entitled "Case for Induction of Labour in Treatment of Haemolytic Disease of the Newborn" (*Journal*, August 23, p. 468), certain conclusions are reached which do not seem justified by the evidence presented.

It would appear that the authors have been able to demonstrate a correlation between the titre of the maternal Rh antibodies, as determined by the indirect anti-globulin test, and the severity of the disease in the infant when born (see their Table I). It is, however, difficult to reconcile this apparent relationship with the fact that, using this method to prognosticate in 43 Rh-negative infants, 17 were thought to have a one-in-four chance of not surviving and five a three-in-five chance of dying. Moreover, "most of" these Rh-negative cases were induced, with one death occurring; it is difficult not to attribute this death to the method of treatment, and it should be included in the overall mortality rate.

The foetal loss rate occurring in those cases which the authors were able to treat as they wished is surely of

fundamental importance, but it is not possible to arrive at this figure from the data presented. The series is divided into two groups which are obviously not comparable; the "spontaneous" group is loaded with the great majority of the stillbirths, most of which, as the authors state, could not have been saved by their method of treatment (or indeed by any form of treatment). This "spontaneous" group also contains those less severe cases allowed to proceed to term. The induced group appears to consist of cases of intermediate severity. The overall foetal loss rate in the series (excluding the death of the Rh-negative infant) was 99 in 373 cases—i.e., approximately 26%. Thus, although a considerable number of cases in the series were treated by the authors' method (179+x, where x=the number allowed by design to proceed to term), the overall foetal loss rate does not differ significantly from that of the spontaneous series of Mollison.¹ This figure of the overall foetal loss appears to be the only one on which data is available in the article for comparison with other series.

If an attempt is made to construct the group treated by the author's method by adding to the induced group both the more severe cases (the stillbirths, which are called spontaneous) and the less severe cases—i.e., those with a titre of 1/128 or lower (spontaneous group, their Table IV) then the following figures are obtained:

Group	Stillbirths	Died	Survived	Total
Induced	4	19	156	179
Stillborn	48	—	13*	61
Spontaneous	2	1	62	65
Totals	54	20	231	305

* The number the authors thought might have been saved by their method.

This gives a foetal loss rate of 24% (not including the Rh-negative death), which is not better than the spontaneous series of Mollison. This artificially constructed foetal loss rate may not be correct, but is the nearest we can deduce from the available data. It seems difficult to find in the article, therefore, evidence supporting the view that artificial induction of labour and resultant premature delivery has favourably affected the foetal loss rate. Moreover, maternal complications of this method of treatment are not mentioned.—I am, etc.,

Royal Newcastle Hospital,
Newcastle, New South Wales.

Excision of Atrial Myxoma

SIR,—Mr. J. R. Belcher (*Journal*, September 20, p. 742) says that a myxoma may be so friable that pieces may break off during its removal if pushed up from below. I tried in the article by Dr. F. R. Reid and myself (*Journal*, August 30, p. 531) to make it clear that this could not happen because the whole manipulation was so gentle. May I emphasize that the tumour during its removal is subjected to no more stress than before the operation? Its separation from the intra-atrial wall exerts no pressure on the tumour: the upper finger-nail cuts the pedicle across very much like peeling the skin of a banana, because the pedicle is composed only of endocardium and a thin layer of fibrous tissue. (A thick hard pedicle might cause difficulty in peeling off the tumour from the atrial wall: but such a tumour would not break up.) The myxoma then passes up into the auricle against the blood flow, but is held in the auricular incision mainly by the intra-atrial pressure and is only steadied by the lower finger. Its exit from the auricle occurs only when the auricular muscle is opened enough for it to slide out, most of the pressure coming from the blood itself, which, if anything, tends to blow fragments outwards.

In my own case, though the removal was relatively roughly performed, there was no evidence then or later of fragmentation.—I am, etc.,

Johannesburg,
South Africa.

L. FATTI.

Aspirin and Gastro-intestinal Haemorrhage

SIR,—Dr. L. Th. F. L. Stubbé, in his article on alimentary bleeding following aspirin therapy (*Journal*, November 1, p. 1062), seems to contradict himself in some of his statements. Using every means available to minimize the irritant effect of aspirin tablets on the gastric mucosa—giving them diluted with milk or water after meals, insisting that they be chewed or allowed to disintegrate in the mouth before swallowing, yet excluding in his main group any patient who suffered from dyspepsia—he still showed that approximately 70% had alimentary bleeding as judged by faecal occult blood tests applied with the most stringent precautions. Moreover, in 20 healthy volunteers one woman previously completely free of dyspepsia developed a gastric ulcer with severe indigestion within three weeks of taking 3 g. of aspirin per day, the symptoms abating completely within a few days of stopping it. Finally, he assessed the average blood loss in these patients who had aspirin bleeding (70% of those who took them) to be in the region of 120 ml. per month and possibly more—a greater loss than that occurring during normal menstruation.

In spite of this, he says that gastric haemorrhage and other complications "despite the frequent use of this drug have been rare," and "It is known that bleeding may occur in the stomach after a person has taken aspirin. But, considering the enormous quantities of this drug which are consumed and the frequency with which it is taken, such an occurrence may be regarded as an exception." We find it difficult to reconcile his findings and his opinions. If he meant by "gastric haemorrhage" frank haematemesis or melaena, then he is possibly on firmer ground, but even this seems unlikely.

In such an excellently controlled investigation as Dr. Stubbé's, we feel that it is a pity he did not include soluble calcium aspirin and aspirin substitutes such as N-acetyl-p-aminophenol ("panadol"), which we have found to have little irritant effect on gastric mucosa. On the other hand, buffered aspirin containing either glycine or alkali we have found, in common with other observers, to be just as irritant as ordinary aspirin.—We are, etc.,

Malarial Chemoprophylaxis in Indigenous Populations

SIR,—The paper by Drs. L. J. Bruce-Chwatt and D. W. Horn (*Journal*, October 11, p. 869) raises several related questions of vital importance to the indigenous populations of areas like West Africa where malaria is endemic. These questions concern: (a) The propriety of advising anti-malarial prophylaxis for individual families in endemic areas. (b) The effects of chemoprophylaxis on malarial immunity. (c) The correct dosages and toxicity of potent antimalarials like chloroquine and mepacrine.

It has long been held by many that the institution of drug prophylaxis among indigenes of endemic areas is dangerous, because the loss of acquired tolerance to malaria which may result might ultimately encourage cerebral malaria in defaulters. This belief has been responsible for the hesitation of the medical profession in the past to advise the public in endemic areas unequivocally on the subject. Such a view assumes

(i) that once chemoprophylaxis is instituted it will have to be continued indefinitely;

(ii) that no build-up of immunity is possible where even limited drug prophylaxis is in progress, and that in fact what immunity was originally present is lost during chemoprophylaxis;

(iii) that most families in endemic areas are unlikely to follow instructions regarding prolonged chemoprophylaxis which has proved to be of such great value in expatriates.

Assumption (i) seems reasonable in the light of our present knowledge, but (ii) is far from proved, while (iii) it takes no notice of contemporary developments in the fields of education and health consciousness, especially in urban communities in

endemic areas, and minimizes the vast power of newspapers, radio, and other methods of mass education introduced into most of these areas in the past decade.

People who live in endemic areas know that there is no such thing as absolute immunity to malaria, because they suffer from overt attacks of malaria throughout their lives. The value of the immunity lies in preventing fatal complications of malaria, particularly cerebral malaria in the "immune" populations. This immunity is dearly bought with human lives, and at the fatal illness the blood of the child is literally packed with malaria parasites. Most of these lives might have been saved if the overwhelming malarial infections which lead to fatal complications could be prevented, without necessarily aiming at complete suppression.

The crucial questions are:

Is it possible by limited chemoprophylaxis to reduce drastically the incidence of overwhelming malarial infections (with their dangerous complications) without complete suppression of malaria? Is it possible for immunity to develop while limited chemoprophylaxis is in progress?

I believe that the answer to both questions is Yes. This idea has also occurred to others. For instance, Jelliffe,¹ after stating the other side to the case, says, "alternatively, it is possible to conceive of a new drug or one in current use but with a modified dosage which could act as a semi-suppressive preventing serious ill-effects, but permitting the development of immunity."

Here it is necessary to recall some known facts which may be relevant to the problem. First, there is the clinical phenomenon of the "break-through" when a person taking antimalarials develops an attack of malaria. This is recorded as a fact by Bruce-Chwatt and Horn and also Nicol.² Whatever the mechanism is, the attacks are usually relatively mild, fatal results are uncommon, and the blood often shows only scanty parasites. Break-throughs can usually be prevented by complete suppression of malaria by increasing the dose of the antimalarials, and insisting on their being taken regularly.

Another important fact is that, as recorded by Bruce-Chwatt and Horn, an increasing number of indigenes of endemic areas are taking prophylactic antimalarials. One point which they did not mention, however, is that many of us find that we need only a fraction of the recommended prophylactic dosage of antimalarials to keep away clinical attacks of malaria—e.g., 2 to 3 tablets of proguanil per week. If this limited chemoprophylaxis interfered with the level of immunity, we should have found that we need increasing doses of antimalarials over the years to keep away clinical malaria, which is not so. The inference is that this limited chemoprophylaxis is effective in preventing only severe attacks of clinical malaria, but, presumably, not subclinical parasitaemia, which helps to keep up the level of immunity.

Now there is evidence that babies born in endemic areas inherit some degree of immunity from their mothers. Their spleens are 50% heavier than those of expatriate babies.³ I believe that they too can be protected from overwhelming and fatal malaria by limited chemoprophylaxis (e.g., 1½ tablets of proguanil a week) without complete suppression. Such a dose might still permit some build-up of immunity while preventing overwhelming infection.

A possible objection to this form of prophylaxis would be that such doses might encourage resistant strains of malaria parasites. The answer to this is that in spite of the widespread and haphazard use of antimalarials resistance has not become a clinical problem in West Africa, and has shown no signs of increasing. This contrasts sharply with the ready development of resistance to penicillin, sulphonamides, and other widely used antibiotics by certain organisms in West Africa.

Even if further experience should show such limited prophylaxis to fall below expectation, there is still a strong case for the encouragement of routine malarial chemoprophylaxis in individual families in endemic areas in the towns and the increasing numbers in the rural areas who live near hospitals, provided that the possible drawbacks of the practice are explained to them. Much can be achieved through the midwives in maternity centres, who are in regular contact with the mothers in the towns and in many rural areas.

Malaria undermines health in West Africa from the cradle to the grave and is responsible for much ill-health, high infant mortality, prematurity, anaemia, and much lowering of resistance to other diseases. The justifiable jubilation over the health of expatriates is not paralleled in indigenous vital

statistics. Yesterday the alleged ignorance of these families made the advances in malarial prophylaxis seem like a mixed blessing. To-day, however, although much remains to be done, an ever-increasing proportion of the people are wide awake and will heed instructions given in matters pertaining to health. They should no longer be denied the proved benefits of malarial chemoprophylaxis.

Finally, I agree with Bruce-Chwatt and Horn that intramuscular mepacrine and chloroquine could be dangerous, but the danger is relatively small if attention is paid to dosages. For instance, the 100-150 mg. of mepacrine musonate given by the doctors cited by Bruce-Chwatt and Horn to children under 3 is in my opinion an overdose. They should receive 50 mg., which may be repeated in 2-3 hours if necessary. The corresponding dose of chloroquine is 30 to 50 mg. of the base, which is repeatable in 1 to 2 hours.—I am, etc.,

General Hospital
Enugu, Nigeria.

Hypothermic Myxoedema Coma

SIR.—The therapeutic programme of the three cases of hypothermic myxoedema coma reported by Dr. Donald W. Macdonald (*Journal*, November 8, p. 1144) included penicillin intramuscularly. Two died. I have for long been under the impression that allergic phenomena are more likely in people with low basal metabolic rates. Some 15 cases of hypothermic myxoedema coma have been reported in the last five years—that is, within the antibiotic era—and the mortality is high. Is it possible that a penicillin allergy is a cause of death in such cases, and might not an antibiotic with a less notorious allergic reputation be advisable in these instances?—I am, etc.,

Cape Town, South Africa.

Australian War Experience

SIR.—I have just read with interest the review by Dr. J. C. A. Dowse of the third medical volume *The Island Campaigns*, by Allan S. Walker, dealing with the Australian Medical Services in the war of 1939-45 (*Journal*, August 16, p. 432). I say with interest, particularly, because it emphasizes a criticism of this work which I had published in the *Medical Journal of Australia*.¹ You will note that the reviewer's remarks are correctly and interestingly written in accordance with what this volume contained, and thus his opening sentence, naming only the mosquito as a more deadly enemy than the conventional weapons of war, gives a very inaccurate (through no fault of the reviewer) overall picture of the medical hazards of the campaigns in question. Further along, the reviewer rightly states, "Much is told of the work of individuals in field ambulances and sections of those units; little of the work of the casualty clearing stations or general hospitals."

In order to place the medical hazards encountered in the South-west Pacific Islands in their proper perspective, may I refer your readers to my communication to the *Medical Journal of Australia* already mentioned? There they will see that, through unfortunate and unavoidable circumstances, practically all reference to skin diseases was omitted. Here I would again refer your readers to chapter 55, page 619, in the first volume of this series, *Clinical Problems of War* (also by Allan S. Walker), where it will be seen that for a long period skin diseases were a greater cause of manpower wastage than any other condition, including malaria. I have made a number of attempts to get the over-all Australian war historian to publish a short addendum to the third volume, to correct the very erroneous impression it gives in its present form as to the relative importance of the

various causes of manpower wastage, in case such wastage should ever become important at some future date. However, my efforts have, so far as I am aware, produced no constructive results.—I am, etc.,

Faculty of Medicine,
University of Sydney.

Foreign Body in Endotracheal Tube

SIR.—I note a letter from Dr. K. A. Stewart (*Journal*, November 15, p. 1226) describing obstruction of an endotracheal tube by a cork. I have always advocated routine inspection of the tube to be used, thereby on one occasion avoiding using a tube blocked by a piece of cotton-wool.—I am, etc.,

Newport, Monmouthshire.

K. S. THOM.

SIR.—The letter in the *Journal* of November 29 (p. 1357) by Mr. E. H. Rainer is one of several reporting blocked endotracheal tubes. No further letters need be written, thus saving valuable space, if a curved metal introducer is inserted into the tube before oral intubation.—I am, etc.,

London, W.3.

E. V. SLAUGHTER.

Fermented Liquors and Disulfiram

SIR.—Alcoholics on disulfiram ("antabuse") do occasionally accidentally ingest alcohol with the resultant toxic symptoms. This is usually the result of misguided friends "spiking" a soft drink. The following incident is unusual, and so far as I know has not been reported in the literature.

A middle-aged and co-operative female alcoholic had been in hospital for three weeks and had been on disulfiram for six days. She had had no side-effects, but one morning complained of nausea, vomiting, flushing of the face, palpitations, and of oppression in the chest. There was a distinct smell of acetaldehyde on her breath. Naturally, it was assumed that she had obtained alcohol in some form from a visitor. This was strongly and tearfully denied, and the searching of her locker failed to reveal any alcohol.

As well as the usual vitamin therapy she had expressed a wish for one of the proprietary malt preparations which she had been taking three times daily for about a week. On opening the jar of malt it was obvious that fermentation had taken place, and subsequent analysis confirmed the presence of alcohol.

This may be a hazard peculiar to hot countries, but it certainly indicates how careful patients on disulfiram must be to avoid accidental contact with alcohol.—I am, etc.,

Ndola, Northern Rhodesia.

DONALD WHITFIELD.

Rational Use of Drugs

SIR.—In common with other medical practitioners I have received a copy of the very helpful booklet¹ which sets out the relative cost of proprietary preparations and their equivalents. Recently, when wishing to prescribe a suitable preparation for threadworm infestation, I referred to the booklet to see whether there was any difference in cost between "elixir antepar" and the B.N.F. equivalent, elixir piperazine citrate. Discovering that the latter is considerably cheaper, I duly ordered that. However, the dispenser actually issued the proprietary, as that was the only preparation in stock. As a result, my earnest endeavour to play a part in the much-needed drive for economy was frustrated. What is the answer to this? I imagine that this is by no means an isolated example.—I am, etc.,

Halifax, Yorks.

MALCOLM B. BUTLER.

Pharmaceutical Houses and the Doctor

SIR.—I am reluctant to contradict one of my respected teachers, but Professor S. J. Hartfall (*Journal*, December 6, p. 1411) is wrong when he says that the *British National Formulary* contains all that we require for our sick patients.

The *Formulary* is deficient in children's remedies. There is no liquid preparation of penicillin V, tetracyclines, or antihistamines, nor is there any oral streptomycin for gastroenteritis. Perhaps there are technical reasons for these omissions, but it is certainly in treating children that I use most proprietary medicines.—I am, etc.,

Bradford, 5.

G. B. HILL.

SIR.—While hesitating to criticize the opinions (*Journal*, December 6, p. 1411) of a member of the Joint Formulary Committee, I would like to put forward a point of view which other general practitioners may share. The *British National Formulary* is a first-class book, and 90% of my prescribing is based on it. Its amendments, however, are clumsy, and even the most recent one does not include, for example, tab. chlorothiazide, tab. mecamlamine, or a mist. kaolin. et neomycin. pro inf. We must be much more up to date than that, not only for our own prescribing, but to keep pace with the consultant who suggests that we use a proprietary drug previously unknown to us. *Prescribers' Notes* are no help here, and most doctors exercise enough judgment to be able to do without *Proprietary Medicines*. "To-day's Drugs," while written in a suitably critical manner, is difficult to file for easy reference, and "Drug Treatment in Disease" is out of date as soon as a new drug of proved value is produced.

Most of the pharmaceutical firms are doing a good job, as Dr. S. Bradshaw (p. 1411) says, and it is mainly in the method of distributing information that some of them fail us. The solution offered by Dr. J. A. Frai (p. 1412) is a nutcracking sledge-hammer. No, the whole answer has already been provided by Dr. J. D. W. Whitney in his article "Modern Pharmaceutical Advertising" (*Supplement*, July 13, 1957, p. 7). His scheme could be operated at far less than the cost estimated by Dr. J. Phillips (p. 1413). Although about 25 firms have already taken his remarks to heart, I am sure that quicker results could be obtained if the B.M.A., the Association of British Pharmaceutical Industry, and the Ministry of Health would discuss the matter together.—I am, etc.,

Walsall.

J. P. LESTER.

SIR.—May I reply to the letters on "Pharmaceutical Houses and the Doctor" in the *Journal* of December 6? I would like to inform Professor S. J. Hartfall (p. 1411) that the questionnaire I completed was in the form of a postcard brought into my surgery by a cheerful representative. I placed a few ticks in appropriate squares "for research purposes." As for writing letters to the *British Medical Journal*, the letter published on November 22 (p. 1291) was the first letter I have ever written in my life to any publishing body. I was writing merely as a general practitioner whose surgeries get more like commercial television every day. This week, on Wednesday morning, my surgery was interrupted four times by representatives who entered when I rang for the next patient. There I am—trapped—while my patients cool their heels and I champ at the bit. I know I could ease my lot by throwing all the literature unopened into the waste-paper basket and hang a "keep out reps" notice on the door—but is this really the right solution? Professor Hartfall says my patients will not suffer if I do this. Dr. S. Bradshaw (p. 1411) tells me that useful life-saving drugs will remain unrecognized for periods of time varying from 12 to 40 years. Who am I to believe? Yes, I repeat, I am "a simple family doctor," with an innate sense of courtesy, not a churlish, disagreeable cynic, an analytical scientist, a combine harvester made for sifting proprietary products . . . nor yet a social butterfly, flitting from cocktail parties to dances at the expense of time spent

in the surgery. (I have been to nine dances since 1945 and fewer cocktail parties, and on no occasion have I had a medical representative as an escort, charming though they may be!)

Of course, I use the *British National Formulary*. I am fortunate enough to receive every new edition gratis from the executive council. It is my best friend; I have a current copy on my desk, one in my case, one at the hospital, and another at the treatment centre. However, this does not stop the continual bombardment to which I am subject. I receive *Prescribers' Notes* too, but new drugs come out much faster than either of these.

My own experience tells me that if I prescribe certain products that are "freely prescribable on E.C.10s," according to the representatives, I would receive a letter from the executive council informing me that I shall have to pay the cost of the drugs out of my own pocket. Each locum I have engaged has unknowingly left me a legacy of such chitties and I am responsible for their payment. It is therefore with relief that I hear that final-year medical students are encouraged to write prescriptions and are to be proud possessors of a good pharmacopoeia. Whether it is *Martindale*, the *British National Formulary*, a special hospital pharmacopoeia, or a personal one compiled from one's own experience, it is invaluable and, I maintain, will contain much valuable material so neglected nowadays in the *British Pharmacopoeia*. I do not deplore the fact that G.P.s do not use the B.P. *per se*. I deplore the fact that we are being bogged by firms who change the name of the rose, wrap it in cellophane, and charge more for it.

As for Dr. Bradshaw's attack, I have already answered some points in his letter. I am not discussing my own remuneration or the price I have to pay for drugs. That is entirely irrelevant. My worry is that I am acutely aware of the fact that every single time I write a prescription I am spending other people's money, not my own. It is a heavy responsibility and I must not be too gullible or be misled by the glossy advertisements. (I object to the glossiness because it limits its domestic uses. They are more difficult to dispose of: some of them will not even burn.)

Advertisement psychologists are people who earn about four times as much as the average general practitioner, so I am told. They are used for increasing the sales of products.

Yes, I am in favour of research, but if you cannot afford to do all the vital research you desire, do not give so much away to charities or spend so much on advertising material or sending representatives so frequently to sit in our waiting-rooms. I am in agreement with exporting, but from my ever-increasing collection of foreign stamps I am wondering how many millions of pounds worth of drugs we are importing.

Finally, Dr. Bradshaw, my Utopias are dreamt up in my car in between the visits which are sometimes delayed by sorting through a heavy post or listening to the properties of a new wonder drug.

I agree with Mr. R. Merryweather Shaw (p. 1413). hospital pharmacists and local chemists are an invaluable boon to the busy doctor. They are not riding a hobby horse to increase the sales of any particular firm. They are keen on dispensing, not being shop assistants.

Dr. Geoffrey F. Baines (p. 1413) is right. It is difficult to sort out problems. I discovered that several proprietary products were cheaper than the *British National Formulary* equivalents. As a result I prescribed these preparations in an attempt to save national expenditure. When my drug bill was analysed, I was asked why I had prescribed proprietary products instead of *British National Formulary* equivalents. Professor Hartfall may be astonished to learn that I was also asked whether I always prescribed the drugs advised by hospital consultants when I have asked for a second opinion. General practitioners are working under difficult and exacting conditions; all we want is understanding, honest co-operation.—I am, etc.,

Birmingham, 30.

MARY M. RAYNER.

* * This correspondence is now closed.—ED., B.M.J.

Proper Use of Words

SIR.—Recently, in a Very Important weekly medical journal, a Very Important Cardiologist stated that a patient collapsed "following a large haemoptysis."

I remember a colonel who collapsed following a large tiger and a South American band-leader (obese and no

longer young) who collapsed following a large blonde. But why, I asked myself, should anyone follow a large haemoptysis? My first thought was that he was a "time-expired registrar" who intended to write a paper about haemoptysis: my second that "haemoptysis" was a misprint for "hippopotamus." Dr. H. M. Sinclair's letter (*Journal*, November 29, p. 1559) provides an alternative explanation. Could the Very Important Cardiologist have meant that his patient collapsed after a large haemoptysis? What a dull solution of a fascinating problem!—I am, etc.,

London, S.W.3.

RAYMOND GREENE.

SIR,—My old friend, Dr. Hugh Sinclair, very properly criticizes my style (*Journal*, November 29, p. 1559). However, not everyone would agree with him. My friend Lord Cohen has pointed out that Fowler¹ says:

"Firstly, secondly, lastly. The preference for *first* over *firstly* in formal enumerations is one of the harmless pedantries in which those who like oddities because they are odd are free to indulge, provided that they abstain from censuring those who do not share the liking. It is true that *firstly* is not in Johnson; it is true that De Quincey labels it 'your ridiculous and most pedantic neologism of *firstly*'; the boot is on the other leg now; it is the pedant that begins his list with *first*; no-one does so by the light of nature; it is an artificialism. Idioms grow old like other things, and the idiom-book of a century hence will probably not even mention *first*, *secondly*."

Dr. Sinclair ends his letter with an admonition in Greek which I fear few of your readers will understand, which is a pity, because the function of language is to convey meaning. "Physician heal thyself" is not easily achieved. A writer cannot remedy his own defects of style unless he himself recognizes them, or they are pointed out by others. Nowadays it is difficult to find the time to read meticulously what one has written. It is no criticism of you, Sir, to say that the Editor who unfailingly notes the kinds of faults which Dr. Sinclair notes is now, from similar causes, almost extinct. Good writing is not something whose decay one watches with equanimity. I bow my head to Dr. Sinclair's strictures. Would that the physician could heal himself.—I am, etc.,

University of Oxford.

G. W. PICKERING.

REFERENCE

¹ Fowler, H. W., *A Dictionary of Modern English Usage*, 1926. Oxford.

SIR,—In your issue of November 29 (p. 1359) Dr. H. M. Sinclair takes the Oxford regius professor of medicine to task for the misuse of words and lack of clarity in a recent address (*Journal*, November 8, p. 1117). The letter ends with this observation, "In the singular opinion of a former student of Sir George's who admires his addresses, we should all avoid unnecessary jargon and the improper use of words." Does this sentence mean that Sir George admires Dr. Sinclair's addresses or vice versa?—I am, etc.,

West Malvern.

W. G. SHAKESPEARE.

Women Police Surgeons

SIR,—Dr. Nesta H. Wells's account of her 27 years' service as a Manchester City police surgeon (*Journal*, December 6, p. 1404) is both interesting and informative. But I do not follow her reasons for supposing that women doctors (*per se*) are better suited for dealing with children. I have heard similar postulations applied in other branches of medicine—for example, in gynaecology—and I think the idea is both retrograde and old-fashioned. Surely the sex of a doctor is not so important as the innate qualities of kindness, patience, and understanding. Does Dr. Wells feel that male doctors are lacking in these?

Regarding the cases she describes, I submit that our chief concern should be in their prevention (rather than after-treatment or punishment), and that this starts in the home—for adults, as well as children.—I am, etc.,

Knowle, Warwickshire.

N. W. SARGENT.

Obituary

ERNEST SACHS, M.D., F.A.C.S.

Dr. Ernest Sachs, the eminent American neurosurgeon, died in hospital at New Haven, Conn., on December 2. He was in his eightieth year and had been ill for only a short time.

Having been professor of clinical neurological surgery at Washington University, St. Louis, from 1919 to 1946, Ernest Sachs went to Yale at the age of 70 as research fellow in physiology, and it was at New Haven he completed his *History and Development of Neurological Surgery*. Well known as a neurosurgeon, teacher, and writer on both sides of the Atlantic, he had many friends in Britain, for which, as one who had sat at the feet of Sir Victor Horsley, he had a particular affection. When the centenary of Sir Victor Horsley's birth was celebrated last year, Dr. Sachs contributed to this *Journal* some "Reminiscences of an American Student" (April 20, 1957, p. 916), paying this tribute to his mentor: "As I look back upon the years I spent with Victor Horsley, I feel he gave me the best possible insight into the life of a broadminded, generous scientist of his generation." Dr. Sachs's own students felt much the same about him.

Sir GEOFFREY JEFFERSON, F.R.S., writes: The death of Dr. Ernest Sachs means to many engaged in neurosurgery and neurology the passing of a warm and loyal friend. He has told the story of his life in a recent book, *Fifty Years of Neurosurgery—A Personal Story* (1958), and an important document it is, because it covers the whole period of the rise and development of the surgery of the nervous system from Horsley's day onward. Born in New York, the nephew of the famous neurologist Bernard Sachs, he graduated from Harvard and from the Johns Hopkins Medical School, where he was a pupil of Halsted and Osler and came to know Cushing. Ernest Sachs worked with Sir Victor Horsley for a twelvemonth 1907-08 at Queen Square and in his laboratory at University College on the structure and function of the optic thalamus. Sachs became the friend of the Horsley family and a permanent and devoted admirer of Sir Victor, of whom he has written generously.

Sachs will be remembered as a pioneer because, declining an offer to join Cushing, he accepted an invitation in 1911 to go out to the mid-West, to the newly founded Washington University in St. Louis, Mo. This was a courageous move, for at that date there was little specialized neurosurgery anywhere except in Baltimore, Philadelphia, and New York. When he was young there were scarcely a dozen neurological surgeons in the world; now there are over a thousand in the U.S.A. alone. Sachs's tremendous energy, his frank and attractively dynamic personality and complete scientific integrity ensured the success that came his way in plenty. It is impossible in a few words to convey a proper impression of the bubbling warmth of his abundant personality. He was a member of all and had been president of most of the important neurosurgical societies of America and of the American Neurological Association. He was a valued honorary member of our own British Neurological Society and of the Neurological Section of the Royal Society of Medicine.

After his retirement he moved to New Haven, where he helped with the teaching of Yale undergraduates. Sachs wrote several books which had a wide public: one arising from his famous clinical demonstrations to the students at St. Louis is very wise. All those who knew Ernest Sachs well—and if one knew him at all one was sure quickly to want to know him better—will feel sorrow now and sympathy with his charming wife, Maisie, his constant companion.

J. M. C. SPEER, M.D., D.P.M.

Dr. J. M. C. Speer, formerly medical superintendent of Roundway Hospital, Devizes, died in Dublin on October 20. He was 56 years of age.

James Millar Craig Speer was born in Co. Donegal on November 17, 1901. He proceeded from Foyle College, Londonderry, to the Queen's University, Belfast, where he graduated M.B., B.Ch. in 1924. In 1925 he was appointed an assistant medical officer at the Wilts County Mental Hospital, as it then was, and devoted himself to psychological medicine, taking his D.P.M. in 1928. He became deputy medical superintendent in 1934, and in the following year proceeded to the M.D. with a thesis on dysentery in mental hospitals. In 1947 he succeeded the late Dr. J. F. W. Leech as medical superintendent of Roundway Hospital. Four years earlier he was appointed to the commission of the peace for the borough of Devizes, and on the bench his special knowledge was highly valued. He was chairman of the Trowbridge Division of the British Medical Association in 1948-9.

J. O. D. writes: Millar Speer brought high professional abilities and personal qualities to all his life and work. He kept abreast of advances in psychological medicine and introduced new methods of treatment of mental illness. He undertook with quiet efficiency the heavy increase in both administrative and therapeutical work occasioned by the inauguration of the National Health Service. To all his work he brought knowledge and diligence, good judgment and imagination. Above all else he was a doctor, happier in a ward than in an office. He retired to Blackrock, Dublin, with his wife in 1957, to enjoy only eighteen months of quieter life. At Roundway Hospital his memory is cherished for the personal qualities that marked his relationship with staff and patients. Speer was a man of flawless integrity and an imperturbable temper. Essentially humble-minded, he was infinitely patient and gentle in manner. With his imaginative understanding and quiet humour he won the confidence and regard of everyone. In Millar Speer the injunction was abundantly fulfilled—"He that is chief among you, let him be as he that serves."

A. D. WALL, M.B., F.R.C.S.

Mr. A. D. Wall, senior surgeon at the Paignton and District Hospital, died at Paignton on November 25, aged 62.
