Halothane Concentration

SIR.—We have followed with great interest the correspondence in your columns on halothane concentration and hope that a view in perspective on this important problem might not be amiss. Our use of the Rowbotham's bottle in a circle absorber was part of a phased plan to demonstrate the safety and economy of vaporizing halothane in a circle system; this particular phase is now over,^{1,2} and it was never denied that the use of the bottle or indeed any vaporizer for this purpose offered some slight resistance to inspiration. Dr. H. C. Newman's statement (*Journal*, June 14, p. 1417) succinctly and authoritatively puts it: "Whereas I agree that the vaporizer might be modified to possess bigger ports and pathways, the matter is not quite as alarming as has been made out." We accept this appraisal as being based on accurate measurement, and at realistic flow rates. Even if flow rates of 80 litres a minute or more do occur, they can only be momentarily sustained.

Dr. John Bullough in his latest letter (*Journal*, August 23, p. 510) has not only attempted to restate his case but has ingeniously inserted a number of red herrings which may confuse the issue further and possibly trap the unwary. Coughing and straining (which in our practice with halothane is practically nonexistent) are largely a matter of forced expiration, and therefore as such are mainly a concern of the expiratory valve and not the Rowbotham's bottle, which is situated on the inspiratory side of the circuit.

The experiment mentioned of endeavouring to reproduce conditions involving low minute volumes, quoted by one of us (F. R. G.) (*Journal*, June 7, p. 1356) was unsound if only for the reason that a Coxeter-Mushin Mark I unit was used. This machine, as is well known, has been superseded by the Boyle Circle II (used by both of us) because of the former's relatively large areas of dead space, and we are only surprised that the large areas of dead space, and we are only surprised that the figure given of 2% carbon dioxide was not greater. Work is in progress which will demonstrate clearly, by means of rapid infra-red analysis, that, in a true circle system with halothane, carbon dioxide build-up with low minute volumes is very slight and is of no clinical significance.

We are perturbed at the suggestion that an anaesthetist might be content these days to use an unknown concentration of halothane; surely we have reached a stage in the evolution of this anaesthetic agent that it is imperative to know that we are delivering continuously a safe concentration to the patient? The tendency for halothane to ruin the ether vaporizer of a B.O.C.

circle unit has now been shown to be a certainty,³ and in addition the method carries the great danger of sudden increases in concentration.

Finally, lest it be said that we are unable to see the wood for the trees, a near to resistance-free vaporizer, capable of delivering safe concentrations of halothane in a circle system at theatre temperatures for up to two hours, will be available in a short time.—We are, etc.,

Buzzers for Bed-wetters

SIR.—Surely the electrical buzzer is the most expensive and troublesome way of curing bed-wetting (*Journal*, August 23, p. 499). There is another and simpler way which does not seem sufficiently well known. At the Dreadnought Seamen's Hospital I see a large number of young men who wish to go to sea but who are prevented by bed-wetting. They are easily cured by pituitary snuff and strong suggestion. Pituitary snuff inhibits the secretion of urine so that if the patient empties his bladder before going to bed and takes a sniff of snuff he cannot wet the bed because he has no urine left to do so. He is told that bed-wetting is merely a childish habit he has never grown out of, but if he takes the snuff for a few months he will. It is surprising how many cases are successful with this simple routine. No doubt not so dramatic as bells ringing and rising at night to pass water, but much cheaper, simpler, and comfortable. —I am, etc.,

CLIFFORD ALLEN.

Mass Casualties from Nuclear War

SIR.—In the concluding remarks of his presidential address to the Bath, Bristol, and West Somerset Branch of the B.M.A., "Nuclear Warfare and the Treatment of Mass Casualties" (*Journal*, August 9, p. 379), Dr. G. D. Kersley suggests that information must be given to the public to reduce panic about the unknown effects of a nuclear explosion; that people must understand the "stay put" policy; and that the population as a whole must learn some first-aid, home nursing, and self-help. It may not be sufficiently well known that the Women's Voluntary Service is giving information now on these lines to one in five of the women in the country under the W.V.S. "One-in-Five" scheme. Specially schooled W.V.S. speakers give the first two short talks, based on information contained in the Civil Defence manual, and drawn up in full consultation with the Home Office: "How to Protect Your Home and Family," explaining simply and clearly about the after-effects of a nuclear explosion and how they could be lessened by simple precautions; and "How You Would be Cared for—How to Try to be Independent," explaining the extent of the help which the Civil Defence Corps could give, and how by applying their own practical knowledge women could provide much of this help for themselves. It also impresses upon them the importance of "staying put" in their homes, if asked to do so, however damaged those homes might be.

The third talk, "How to Care for a Sick Person at Home," is given by trained nurses and specially nominated members of the St. John Ambulance Brigade, or St. Andrew's Ambulance Association, and the British Red Cross Society. It was drawn up by W.V.S. with the help of St. John Ambulance Brigade, the British Red Cross Society, Queen's Institute of District Nursing, and the Ministry of Health, and explains very simply how it is possible to care for someone sick in a badly damaged home, how to improvise where necessary, and how to do the best under any circumstances until skilled help arrives.

The talks are primarily designed for the ordinary housewife who does not belong to any special organization. It

is hoped that the practical knowledge which is contained in them would give her some measure of assurance in a nuclear disaster. Small groups of women are meeting in their own homes, at their work, in village halls, and other convenient places to hear the talks, which each lasts about half an hour and which are followed by time for questions. There is nothing to pay, and women are not asked to join any organization, although those wishing for more information are advised to join the Civil Defence Corps.—I am, etc.,

London, S.W.1.

MARGUERITE M. HAMMOND,
Joint Head, "One-in-Five" Department,
Women's Voluntary Service for Civil Defence.

SIR,—Dr. G. D. Kersley's paper on this subject (*Journal*, August 9, p. 379) is illuminating, but I suspect it will not produce the effect he apparently desires. The author claims that, with proper preparation, much could be done to alleviate the effects of nuclear warfare on Britain. However, careful examination of his proposals forces one to the following conclusions:

(1) *The schemes proposed are based on impossible estimates of what can be done by one doctor in 24 hours.*—Ahern¹ is quoted as authority for the statement that a filter unit with 10 doctors can sort 6,000 patients and perform urgent surgery on 1,200 of these in 24 hours, allowing 2 minutes per examination and 9 minutes per operation. Now $2 \times 6,000 + 9 \times 1,200$ minutes adds up to 380 hours; that is, each doctor will have to work 38 hours in the 24, which is nonsense. In the same paper Ahern says that one surgeon can categorize 3-4,000 patients in 36 hours. This can only mean that this surgeon examines patients at the rate of one every 30-40 seconds for 36 hours, without pause.

(2) *Our medical services will be disrupted if these schemes are put into effect fully.*—A 10-megaton bomb is stated to produce 110,000 untrapped casualties in a city of a million inhabitants. Of these, 50,000 are serious and two-thirds of them will need hospitalization. Let us accept Ahern's claim that a unit with 10 doctors can "filter" 6,000 casualties in 24 hours and Drummond's statement² that three doctors can cope with 100 serious surgical cases in hospital. A simple calculation shows that, to deal with the effects of one H-bomb on such a city, 1,183 doctors will be required. Suppose we follow this estimate to its logical conclusion. We may regard as a potential target any town with a population of over 100,000, and there are 20 million people living in such towns in this country. Since the blow delivered is likely to be adapted to the size of the target, we can assume that the number of casualties in each town will be roughly proportional to the population and that the medical services required will be similarly proportional. We therefore need $20 \times 1,183$, or 23,660, doctors to be ready to deal with the initial onslaught. Since there will be no time to locate and evacuate 23,000 doctors to their action stations in the brief hour or so left to us after we are warned that the missiles are on their way (and this is the first we shall hear of hostilities), it follows that half the medical profession must leave our large towns in the near future, and the sooner the better, and wait indefinitely at sites 20-30 miles (32-48 km.) away. Since, as we have seen, Ahern's estimate is hardly reliable, we shall need a correspondingly larger proportion of the medical profession to be so evacuated. The effect on our medical services can be imagined.

(3) *Even if they could be put into effect, these schemes would do little good.*—We are not told how many dead to expect, but there will be 150,000 serious casualties per million of population attacked. Of these, 100,000 will be trapped and presumably abandoned. Of the 50,000 untrapped, a third will be abandoned because under these conditions there will be no facilities to treat their injuries. Two-thirds will be sent to hospital requiring surgery. Now from Whitney's estimates³ it is seen that 50,000 serious casualties will need over 10,000 pints (5,700 litres) of blood in the first three days, so we can assume that any surgery undertaken will be effectively without the aid of blood. Anaesthesia will necessarily be of the sort which can be undertaken by medical personnel without special training or by nurses. Asepsis will be of the most primitive kind. It would not be pessimistic to expect a 30% death rate in these circumstances. The net survival, then, of the 150,000 serious casualties will be about 22,000, or one in seven. This is hardly reassuring and does not justify Kersley's optimistic outlook.

(4) *The schemes ignore major factors almost inevitable in a nuclear war and which will prevent them from being carried out.*—No allowance has been made for further waves of assault with nuclear weapons. No allowance has been made for devastation

by extensive fall-out, and that this is likely is suggested by the American admission⁴ that nuclear weapons have been altered in a way that would increase local fall-out. No allowance is made for breakdown of transport, communication, electricity, or water supply, and none for epidemics or panic. Even the possibility that the rescue services might be unexpectedly efficacious is not envisaged, since the medical services would then be overwhelmed with some of the two-thirds of the casualties who would otherwise have remained trapped.

Many of us are put in a dilemma by such schemes. If we reject them as so much nonsense, we may be accused of refusing to plan to help the victims of an approaching disaster. On the other hand, if they are accepted by any large section of the medical profession and there was extensive participation by the profession in Civil Defence organization, this would certainly revive the illusion now held by few that an effective answer exists to nuclear weapons, that such a war would not be so terrible after all, and that the individual citizen has a good chance of surviving. Such beliefs are false, and to help to spread them is irresponsible, to say the least. Widespread appreciation of the realities of nuclear warfare is the surest safeguard against such a war. We must be on our guard, therefore, against being led by humanitarian considerations to approve of schemes which will blunt this appreciation and thereby bring about the very thing we most wish to avoid. If there is an answer to this threat, it cannot lie in plans which bear no relation to reality. If, for reasons of their own, statesmen wish to foster this illusion, let them take the responsibility for it and let them do it without help from us.—I am, etc.,

Harrow.

Hypno-anaesthesia

SIR,—We have read with great interest the leading article in the *Journal* of September 13 (p. 682) which reviews the role of hypnosis in medicine and surgery and recommends a more extended employment. The point that we noted with particular attention was the suggestion that clinics could be formed in the larger hospitals to use and study hypnotic techniques in suitable cases.

The two hypnosis societies which we have the honour to represent were founded about six years ago, and together now have a membership of over a thousand medical and dental practitioners, the great majority of whom have attended specially organized courses of instruction in hypnotic techniques. Regular meetings have been held by both bodies at which papers have been read on hypnosis by authorities in various branches of medicine and surgery. Recently we have felt that further progress could best be advanced by the organization of a clinic specializing in hypnotic techniques, and a joint committee of both societies has been exploring the possibilities. Contact has been made with public bodies, the representatives of which have received us with sympathetic interest. The ideal is, as your leading article suggests, to work under the aegis of a large hospital, but a great practical difficulty has been to secure the necessary accommodation. If any such hospital can give us the necessary accommodation we are prepared to furnish the appropriate medical and dental staff from our members, who would be prepared to work on a voluntary basis, at least in the early stages until the value of hypnotic techniques had been amply demonstrated. In this connexion it is important for the practitioner to recognize the limitations as well as the possibilities of hypnosis. An alternative method would be to open a clinic in a central area of London, and, although this presents some financial problems, they are not incapable of solution: nevertheless direct attachment to a hospital represents the method of choice.

There is no doubt at all that a knowledge of hypnotic techniques is essential to a properly equipped doctor or

dentist. Probably for practical reasons (e.g., the congested curriculum) postgraduate instruction in the pre-registration period would be most suitable for the medical practitioner, and some similar method could be devised for the dental surgeon.—We are, etc.,

"Sytron"

SIR,—In the note on sytron under the heading "To-day's Drugs" (*Journal*, August 30, p. 562) it is stated, "This substance produces diarrhoea in about 25% of patients treated with it." If this is based on Dr. C. F. Herridge's comparative study of ferric chelate and other iron preparations (*Journal*, July 19, p. 140) I should like to point out that he used a preparation of sodium ironedetate containing 71 mg. elemental iron per 8 ml. (2 teaspoonfuls) and administered this dose b.d. or t.d.s. to 10 children. He reported diarrhoea in 3 of these patients—2 transitory and 1 possibly not entirely due to the drug—but expressed the opinion that his dosage could probably be reduced and still give adequate haematological response, with fewer side-effects. The preparation which has been made generally available (sytron) contains sodium ironedetate equivalent to 55 mg. iron in 8 ml. and the dosage recommended for children is $\frac{1}{2}$ –1 teaspoonful t.d.s.; experience has shown that this dosage produces adequate response and is better tolerated than the much larger one used by Dr. Herridge.—I am, etc.,

Deluge of Advertisements

SIR,—Dr. B. J. Maxwell's figure of seven and two-thirds pieces of pharmaceutical literature per practitioner in one day is far from being a record (*Journal*, August 2, p. 329). Were it a matter for pride, I should boast of the 30 delivered one day to my home in Sussex. Many had to be redirected for the second time, having been sent to the wrong address in Malaya, some for the third time. Since one hospital complained that my "correspondents" had not been notified of my change of address, I sent out 37 circulars of my own requesting pharmaceutical firms not to bother me with preparations which had no use in anaesthesia. I received five replies, expressing all degrees of concern at my annoyance, and one Swiss firm was frank enough to explain they worked on the "all-or-none" principle. When I firmly declined to receive their advertisements, they discovered it was after all possible to oblige a potential customer.

I have no figures to show accurately the result of my campaign, but I should say the "flow rate" has decreased about 50%. One or two firms appeared to attack me with renewed vigour when they learned my latest address, and I should be delighted to co-operate with other members of the profession in compiling a black list of these people. On the other hand, it gives me pleasure to record the outstanding courtesy of Messrs. May and Baker, both here and in England.—I am, etc.,

Malaya.

A. S. GARDINER.

"Flying Ambulance"

SIR,—The portrayal of medical practice on television will remain, no doubt, a controversial subject. Let us give the B.B.C. full marks, however, for a really commendable production, "Flying Ambulance," which portrayed with tact and accuracy some of the problems of general practice in an isolated community off the West Coast of Scotland. It was a most moving tribute to all our colleagues—medical and non-medical—who undertake such service. I hope there will be an early repeat of this programme, because, in common with many others, a "call" prevented my seeing part of it.—I am, etc.,

London, N.18.

S. A. HALL.

Electrified

SIR,—Dr. Robert McCurdy's letter (*Journal*, September 13, p. 691) is a reminder that electrification is no new phenomenon. We have in the R.A.M.C. Historical Museum a massive manuscript autobiography of one Surgeon-General William Cattell (1829–1919). In the 1880's he was serving in Canada and writes as follows:

"The air here and in the States is thought to be more electrical than in Europe, and the dry winter is especially attended by evidences of such, as by sliding the feet on the carpet to charge the body, so you can light a gas jet by the spark from one's finger. Blanche can do this at any time by taking off her shoes and gliding along the carpet for frictional excitement, and she thinks there is nothing uncommon in the power."

Blanche certainly cannot have been wearing nylons in those days!—I am, etc.,

Crookham, Hants.

R. E. BARNSEY.

SIR,—We in Canada are acquainted with Mr. L. H. Pimm's startling electrical experience (*Journal*, August 9, p. 390), though we are not afflicted during the summer months. In winter, when the temperature on a crispish January morning may be to 10 to 20° F. below zero and the humidity low, nylon snow-suited infants in their fur-clad mother's arms present the human equivalent of cat's fur and ebony rod, so that paediatricians develop a Pavlovian reluctance to pat them affectionately on the head. I suppose the answer would be to earth all babies as soon as they entered the waiting-room, but, so far, guile in persuading someone else to touch the loaded baby first has been my most effective prophylactic.

Incidentally, I have no idea why Mr. Pimm should have been afflicted during an English midsummer.—I am, etc.,

Fort William, Ontario.

PATRICK C. MACGILLIVRAY.

Gray's Anatomy

SIR,—I have read your recent references to *Gray's Anatomy* and its centenary (*Journal*, September 6, pp. 598 and 610) and I have wondered if the following will be of interest to you. Although it has nothing to do with the book it does refer to two of its former editors. My father was the originator of the anatomical tip, "Timothy doth vex all very nervous pupils," and he once told me that Timothy Holmes was not pleased. It does seem remarkable to me that a phrase of no literary merit should have survived for so long (it must be more than 80 years since it was first coined) and have become so widely known; I understand that it is still in use by students of the present day.—I am, etc.,

Sherborne, Dorset.

B. PICKERING PICK.

POINTS FROM LETTERS

Orthopaedic Medicine

Dr. R. T. D. FITZGERALD (Brampton) writes: Dr. T. Logan's comments (*Journal*, August 9, p. 390) on Professor J. H. Kellgren's review of Dr. J. H. Cyriax's *Textbook of Orthopaedic Medicine* are most appropriate. I would remind Professor Kellgren that in his own admirable researches into pain he made most of his deductions following injections. Dr. Cyriax has done exactly the same, and I am sure that his total of more than 20,000 epidural anaesthetics given both diagnostically and therapeutically gives him at least some claim to know what he is talking about. I am not aware that Dr. Cyriax anywhere ignores morbid anatomical studies. On the subject of disk lesions in particular Dr. Cyriax has been in advance of many of the morbid anatomists and surgeons, both in the medical and veterinary world. . . . The method of manipulation advocated by Dr. Cyriax for cervical and lumbar spines is completely foolproof, and is performed by all St. Thomas's Hospital physiotherapists with no harm to any patient (myself included), the reason being that no anaesthetic is used for this painless procedure. The danger of spinal cord lesions arises only in the work of ignorant osteopaths or in the hands of orthopaedic surgeons who manipulate under anaesthesia. . . . Dr. Cyriax's book is of great value to all general practitioners and students particularly in that it teaches diagnosis with a precision and nicety not elsewhere to be found.

Obituary

W. J. A. WEBSTER, M.B., Ch.B., F.R.C.S.Ed.

Dr. William Webster, who had practised in the village and environs of Cradley, in Herefordshire, until his retirement in 1952, died on August 10 in his 83rd year.

William John Alexander Webster received his medical education at Glasgow University, graduating M.B., Ch.B. in 1898. After holding a resident post at the Western Infirmary and a period of general practice in the Lake District, he went to New Zealand to study conditions existing there in the treatment of mental disorder. On his return he decided to take up surgery and was admitted to the F.R.C.S.Ed. in 1910. He became house-surgeon at the West Norfolk and Lynn Hospital and later was appointed honorary surgeon in charge of out-patients at the North Staffordshire Royal Infirmary, Stoke-on-Trent. During this time he was actively associated with Freemasonry in the town and was a justice of the peace and a town councillor at Newcastle under Lyme. It was a surprise and disappointment to his colleagues on the staff at the Infirmary when he announced that he was leaving surgery for a post in the Ministry of Health of an administrative character. At the Infirmary at that time he was regarded as the best diagnostician, medical or surgical, in the hospital. His erudition was very exceptional, and there was no branch of medicine on which he was not well informed. In 1933, after spending some years in retirement at Milverton, in Somerset, he decided to resume the practice of medicine as a general practitioner. He took over a small practice at Cradley, on the borders of Herefordshire and Worcestershire, and for the next twenty years he worked with vigour and enthusiasm to build up a thriving practice.

Dr. C. S. GLASS writes : In the passing of Dr. William Webster we have lost the last of the all-round, first-class doctors. Trained with Sir William Macewen, he was the complete doctor, unknown in these days of specialization. When he was on the staff of the North Staffordshire Infirmary he used to do all his own pathology and bacteriology. The mantelpiece of his room was festooned with culture tubes, and the long table held his two first-class microscopes and all the necessary requisites. He performed all his own surgery either in the patient's home or in his own house, assisted by his wife, and very occasionally in a nursing-home. Many times I have gone over to Newcastle and given an anaesthetic for him while he did mastectomies, gangrenous appendices, prostates, and what have you. He was rather a slow operator, but a very careful and thorough one. He always said that he had seen more patients killed by speed than by being slow and careful. He was indeed an all-rounder. He did the pathology for the North Staffs Royal Infirmary for a time and the eye work at another time when the only eye surgeon was ill during the first world war. He never used the infirmary dressings and instruments, preferring always to prepare his own. I remember on one occasion I got him far out into the country to see a woman with a suspected meningitis. A lumbar puncture was done by candle-light, and we went back and hunted bugs till 3 a.m. As a diagnostician he was splendid : he often spent twenty minutes in getting a history, and if anyone at the North Staffordshire Royal Infirmary was stumped Webster was always asked to see the case and usually had some very useful suggestion to make. I think of the days when we did hernias, appendices, and hysterectomies in the kitchen on a portable operating table and the anaesthetic was by rag and bottle. To the young surgeon he was ever kindly and helpful. He always said that you must operate under supervision, and was always willing to let a houseman have a go while he stood by. To me, as a young doctor, he was an inspiration, guide, philosopher, and friend. I took all my difficulties to him and never in vain. To his colleagues he was very loyal, and he certainly maintained the highest traditions of the medical profession.

G. E. R. B. writes: I was privileged to be associated with Dr. Webster only in the last decade of his life. As a young man entering general practice I considered myself most fortunate to be working with a man of such vast experience and wide knowledge and one who still preserved his truly remarkable flair for diagnosis. He had a prodigious memory, and I have listened on many occasions to him reciting case histories in minute detail dating back to the beginning of the century. His singleness of purpose in pursuing a problem was an inspiration to me, as was also the faith and confidence that he inspired in his patients. When he had his surgery built at Cradley just before the second world war, he incorporated into it what was virtually a one-man pathological department, and spent many hours at the microscope and the bench. He still practised surgery when he could, and on a number of occasions since 1948 I have not only given anaesthetics in patients' homes but helped him to load up his car with all the equipment and instruments, including a portable operating table. He and his wife, who predeceased him in 1956, were held in great esteem throughout the surrounding countryside. To the end, through many months of suffering, he maintained his interest not only in the many medical problems that I could take him but also in the stocking and cultivation of his garden, which he loved so much.

J. W. BROWN, M.D., F.R.C.P.

Dr. J. W. Brown, who was a regional cardiologist with headquarters at the City General Hospital, Sheffield, died at Mount Vernon Hospital, Middlesex, on September 16. He was 61 years of age.

James William Brown was born at Gloucester on January 23, 1897. After serving with the French Red Cross from 1915 to 1918 during the first world war he enrolled as a medical student at the Middlesex Hospital, and qualified M.R.C.S., L.R.C.P. in 1923. He obtained the London degrees of M.B., B.S. in 1924 and proceeded to the M.D. four years later. In 1930 he was elected a Member of the Royal College of Physicians of London, becoming a Fellow of the College in 1942. After qualification he held the appointment of casualty medical officer at the Middlesex Hospital. He was in general practice at Cleethorpes from 1924 to 1931 and at Grimsby from 1931 to 1938, when he became a consultant physician with a particular interest in congenital heart disease. Physician for many years to the Grimsby and Scunthorpe hospitals, he subsequently became cardiologist to both hospitals and to the Lincoln County Hospital. In 1952 he was appointed a part-time lecturer and clinical teacher in medicine in Sheffield University. A member of the British Medical Association for 35 years, he was chairman of the Grimsby Division in 1932-3 and he represented his Division at the Annual Representative Meetings in 1928, 1929, and 1931. He also served on the Consultants and Specialist Committee from 1946 to 1948. He was the author of *Congenital Heart Disease*, a book first published in 1939 and of which a second edition appeared in 1950.

F. M. writes: Dr. J. W. Brown, "Jim" to many of us, died at a comparatively early age, but few have lived a life with more activity and a wider range of interests. His boyhood in Gloucestershire gave him a knowledge of and an interest in all aspects of rural life. Had he not from an early age always been attracted by medicine he would surely have become a great naturalist. This interest in bird, animal, and plant life persisted, and it was always a joy to be with him on a country walk or to show him around one's garden. His zest in these aspects of life was apparent in his photographic work and in his engravings on wood and lino. He had a great appreciation of graphic and decorative arts, and keen critical faculties with books, cinema, and stage. But there was little time for these aspects of life, since medicine always had first call. With himself he was merciless when medical work was concerned. The highest standard was all that he would consider, and he expected others in his profession to be similarly minded.

SEPT. 27, 1958

The fact that he was forthright, outspoken, and confident of his own knowledge did, on occasion, lead to pronouncements that could hurt and were sometimes unforgiven. But to most he will be remembered as a delightful, lovable man, free from any form of affectation and with little time for the outward pomp of this life, cherishing his profession and an active supporter of the B.M.A. In the sphere within which he worked he has left his mark, one that will persist. In the wider sphere of medicine his pioneer work on congenital heart disease culminating in the publication of his book, *Congenital Heart Disease*, brought him an international reputation and will assure him a place among those who lived and worked in the highest traditions of the medical profession.

H. MURTAGH, M.B., B.Ch.

Dr. Harold Murtagh, who had been in practice in Ripponden, Yorkshire, for nearly thirty years, died suddenly on August 29 while on holiday in Cornwall. He was 58.

Harold Murtagh was born on August 20, 1900, and studied medicine at Queen's University, Belfast, graduating M.B., B.Ch., B.A.O. in 1927. Through a family friendship with the late Mr. John Hodgson, who was a surgeon on the staff of the Royal Halifax Infirmary, Harold Murtagh joined the resident staff of that hospital, where he was successively house-physician, house-surgeon, and resident surgical officer. When he had completed these appointments in 1929 he joined the late Dr. J. M. Wingham in practice in the village of Ripponden in the rural Ryburn valley, where he remained for the rest of his life. Keenly interested in his work as a general practitioner, he held the posts of police surgeon and appointed factory doctor for the valley and was medical officer to Rishworth School. His leisure was devoted largely to fly-fishing and gardening.

N. H. writes: Harold Murtagh was a true rural general practitioner, beloved by all in the wide area he served, where his equable temperament made allowances for the oddities of human nature, and his cheerfulness played no small part in his successful therapy. A patient recently declared that to visit him was in itself a tonic. He was a man of great energy, and his arrival was invariably announced by a cheery whistle, but he wasted no time in the completion of his duties. No wonder that his loss is most keenly felt by all his patients and by his partner. He leaves a widow and a daughter, who is a medical student, and in their loss they will have the sympathy of all his friends and colleagues.

D. JUSTIN DAVIES, M.B., B.S., F.F.A. R.C.S.

Dr. D. Justin Davies, consultant anaesthetist in Leicester, died with tragic suddenness on September 7, when he collapsed during a game at the Leicestershire Golf Club. He was 61 years of age.

David Justin Davies was born on July 26, 1897, the son of the Rev. D. C. Davies. Educated at the University Colleges of Aberystwyth and Cardiff, he completed his clinical training at the Middlesex Hospital, qualifying in 1920. After holding resident posts at the Middlesex, he became an assistant medical officer at one of the Metropolitan Asylums Board hospitals in London. Having graduated M.B., B.S. at London University in 1924, he came to Leicester Royal Infirmary as house-surgeon in that year. Later he married Dr. Lucy Simpson, a daughter of the late Councillor Herbert Simpson, a former Lord Mayor of Leicester, and they set up in joint practice in that city. Becoming interested in anaesthetics, he decided to make that his specialty, and was appointed visiting anaesthetist to Leicester Royal Infirmary in 1933. He gained his D.A. in 1935 and was elected F.F.A. R.C.S. in 1953. He soon became recognized as an anaesthetist of outstanding ability and enjoyed an extensive hospital and private practice. Maintaining a keen interest in clinical matters, he was a most regular attendee at meetings of the Leicester Medical Society, of which he had been

OBITUARY

a vice-president. He was an ex-president of the Sheffield and East Midland Society of Anaesthetists. A keen Territorial, he held the rank of lieutenant-colonel in the R.A.M.C., commanding the No. 9 C.C.S., which went to France in 1939, but he was invalided out of the Service after Dunkirk.

R. McD. C. writes : Dr. D. Justin Davies was a most likable man and extremely popular with all with whom he came in contact ; in consequence he had a very wide circle of friends, all of whom will miss very much his genial and engaging personality. The loss of his wife in 1947 was a very great blow, but he was devoted to his daughter, who is now in her final year in medicine, and his interest in her career and well-being came to be the outstanding object in his life. To her is extended the sincere sympathy of his many friends and colleagues in the loss of a loving father. Recently Dr. Davies had been in failing health, but fully realized the import of his physical handicaps. Himself a son of the manse, he took a deep interest in the affairs of the Presbyterian Church in Leicester, of which he was an elder. He developed a most admirable philosophical attitude to life, and was determined to carry on with his work. Nothing gave him more pleasure than a quiet game of golf with his friends, and one cannot help feeling that the end, coming as it did, might well have been the one he himself would have chosen.

J. CATHCART, M.B., Ch.B., D.P.H.

Dr. John Cathcart, who was formerly in practice in Bootle, died suddenly at his home at Chorley, in Lancashire, on August 26. He was 72.

John Cathcart was born on March 29, 1886, in Kells, in Northern Ireland, and studied medicine at Edinburgh, where he graduated M.B., Ch.B. in 1910, taking the D.P.H. in the following year. After holding resident appointments at Stockport Infirmary, the Royal Victoria Hospital, Belfast, and the Barnes Convalescent Home of Manchester Royal Infirmary, he decided to specialize in tuberculosis and became a medical officer at Whiteabbey Sanatorium in Co. Antrim. During the first world war he served in France in the R.A.M.C., being attached for much of the time to the Black Watch. On return to civilian life he held a resident post at Lord Mayor Treloar Cripples' Hospital, Alton, and then joined the staff of the Lancashire County Council as assistant tuberculosis officer, remaining in that employment for twelve years. After further sanatorium appointments he decided to go into general practice and eventually settled at Bootle, where he took part in establishing a group practice. During the second world war his house was destroyed by a bomb, but he continued to practise until three years ago. He leaves a widow.

C. H. BURGESS, M.B., Ch.B.

Dr. C. H. Burgess, who practised for many years in Hoylake, died there on September 1 at the age of 75 years.

Charles Herbert Burgess was born on August 26, 1883, the third son of Dr. Robert Burgess, of Coagh, Co. Tyrone. Educated at the Royal School, Dungannon, and at the University of Edinburgh, he graduated M.B., Ch.B. in 1906. After a period of practice in Doncaster he moved to Hoylake in 1911. During the first world war he served in the R.A.M.C. from 1914 to 1918, mainly in Egypt and Palestine. Returning to Hoylake, he remained in practice there until he retired last March.

In 1908 Dr. Burgess married Meta Jeanette Leitch, who died not long ago. He is survived by a daughter and by a son, who is surgeon on the staff of the Southport General Infirmary.

We are indebted to Dr. J. A. ELLIOT for the following appreciation: Charles Burgess was a perfect example of the

best type of family practitioner—wise, calm, patient, and inspiring. He was a retiring person, and I knew him for years before I knew him well. Thereafter I was privileged to enjoy his friendship and to share work with him. He was a wise and far-seeing person and occasionally gave me remarkably valuable advice, ranging in subject from the value of tinned hams in the summer of 1939 to that of a new car in the following year—just before such a thing disappeared off the market. I learned much from him and found the process entertaining as well as educative. It would be impossible for his friends to forget what he was like. His last illness was borne with stoical and matter-of-fact calm which was not only characteristic but deeply impressive.

T. I. ROWLAND, M.B., B.S.

The death of Dr. Trevor I. Rowland at the age of 31 has been reported from the Solomon Islands. A medical officer of the South Pacific Health Service, he was travelling, accompanied by his wife, on board the Government ship R.C.S. *Melanesian* to pay a routine visit to the isolated Polynesian atoll of Sikiana, when the ship was lost, on or about July 10, with all 60 or so souls on board. So far the body of only one crew member has been recovered.

Trevor Ingman Rowland was born on August 15, 1926, and studied medicine at Guy's Hospital, graduating M.B., B.S. in 1950. After holding the posts of house-physician at the Southern Hospital, Dartford, and to the radiological department at Charing Cross Hospital, he served for two years in the R.A.M.C. Entering the Oversea Civil Service in 1956, he worked for a year in Fiji and was then transferred to the British Solomon Islands Protectorate, being stationed as medical officer on the island of Malaita.

J.D.M. writes: Although his short service in the Solomons was fated to be terminated so abruptly, Dr. Rowland's pleasing personality, his professional competence, and the unstinted hospitality of a home managed more than capably by his charming wife endeared him to his colleagues and friends, and not least to the Solomon Islanders in whose service he lost his life.

R. R. MACNICOL, M.B., Ch.B.

Dr. Roderick R. Macnicol, who died at his home in Edinburgh on September 4 at the age of 87, practised at Taynuilt for fifty years and was well known in the West Highlands.

Roderick Reid Macnicol was born on March 15, 1871, and received his early education at the village school at Dalmally, where his father was in practice, having moved some years before from North Uist. Going on from Glasgow High School to the University, he graduated M.A., M.B., Ch.B. in 1898. After working as an assistant in Oban and then in Blantyre, he was appointed parish medical officer in Taynuilt, and for fifty years he practised in this widely scattered district, which extended from his home far beyond the head of Loch Etive on the one side to the shores of Crevan in the north and over difficult roads to Kilchrenan and Dalavich on Loch Awe.

J.A.C.G. writes: During all his years in Taynuilt Dr. Macnicol looked after his patients both far and near with zeal and skill. Many a time he had to travel for miles in an open boat or on foot and often on horseback. These journeys had to be undertaken in summer and winter, by day and by night, often in wind and rain. He always seemed to enjoy the walking, which he said contributed to his good health. He came to Taynuilt at a time when there were no telephones and the motor-car was unheard of in the Western Highlands. He was a man of even temperament, never perturbed by anything. A fluent Gaelic speaker, he was a great upholder of the language and was a life

member of An Comunn Gaidhealach. A good pianist he was always ready to help, and his talent was much appreciated by everyone.

He never seemed to grow old, and remained young-looking and active to the day of his retirement. Some years after he retired, when he was over 80 years of age, he attended a meeting of the Argyll Division of the B.M.A., of which he was a former chairman, and his colleagues were amazed to find that he had not changed in any way, and was still the same quiet, knowledgeable colleague we had all liked so much when he was in practice in Taynuilt. During the first world war he served for four years in the R.A.M.C. After the war he acquired his first motor-car, to use, as he said, "when there were roads available."

Dr. Macnicol was a real Highland gentleman, with an individuality and a charming personality all his own. He enjoyed his work to the full and never spared himself in fulfilling his arduous duties in the scattered West Highland district which he liked so much. He will long be remembered by his colleagues and his patients and by everyone in the community he served so well.

His wife died many years ago, and he is survived by his daughter, to whom our sympathy is extended in her sad bereavement.

Medico-Legal

CHIVERS CANCER ASSOCIATION IN LOTTERY TROUBLE

[FROM OUR LEGAL CORRESPONDENT]

With certain statutory exceptions lotteries are illegal in England. A lottery is any scheme for the distribution of prizes by the operation of chance, and a raffle is a typical example. The statutory exceptions are not designed to make the path of the lottery promoter smooth.

The Betting and Lotteries Act, 1956, created a new exception in favour of lotteries promoted on behalf of registered societies established for charitable and certain other purposes to allow them to raise money for the purposes of the society. The principal thorn on this rose is that the total value of the tickets sold must not exceed £750, but a branch of a society for the purposes of the Act counts as a separate society.

On September 16 Harold Chivers and the Chivers Cancer Association Ltd., of Southchurch Road, Southend, pleaded guilty at Southend Quarter Sessions to five charges of promoting lotteries on behalf of the Chivers Cancer Association Ltd., with, in each lottery, tickets on sale exceeding £750 (*Manchester Guardian*, September 17). For the prosecution it was said that the association, a company limited by guarantee with the object of raising funds by any lawful means for cancer research and treatment, had registered a number of non-existent branches from which to run lotteries simultaneously. The Act required, however, that to be treated as a separate society the branch must be a bona-fide one, and not just attached to the name of someone who as in this case had only to sign two documents. It was stressed by the prosecution that Mr. Chivers had an excellent character. There was no question of fraud. For the defence it was said that Mr. Chivers had collected £10,000 between 1952 and 1956 for cancer research. Neither he nor Mrs. Chivers had benefited in any way from the lotteries, the prizes for which had been Premium Bonds.

Fines of £50 each were imposed on Mr. Chivers and the company and each was ordered to pay £25 costs, two months being allowed for payment. This case should serve as a warning that, however excellent the object, the promotion of lotteries for the purpose of raising money is beset by very stringent restrictions, the infringement of which carries heavy penalties. It is dangerous to attempt to run a raffle without legal advice.

Vital Statistics

Week Ending September 13

The largest fluctuations in the number of notifications of infectious diseases in England and Wales during the week ending September 13 were decreases of 374 for measles, from 1,977 to 1,603, and 45 for whooping-cough, from 791 to 746, and an increase of 27 for food-poisoning, from 275 to 302.

A further decline in the incidence of measles was recorded throughout the country; the largest falls in the number of notifications were 89 in Lancashire, from 315 to 226, and 66 in Sussex, from 112 to 46. The number of notifications of scarlet fever, 296, were 8 fewer than in the preceding week, and there were no large fluctuations in the local returns. The trends of whooping-cough showed very little change, with the exception of a fall of 50 in the number of notifications in Lancashire, from 119 to 69. 3 cases of diphtheria, the same number as in the preceding week, were notified, and 2 of these cases were notified in Plymouth C.B., where 2 cases were also notified in the preceding week.

The number of notifications of acute poliomyelitis numbered 62, and these cases were 20 fewer for paralytic and 2 more for non-paralytic cases than in the preceding week. The largest returns were Yorkshire West Riding 13 (Leeds C.B. 4, Bradford C.B. 2), Lancashire 12 (Manchester C.B. 5, Liverpool C.B. 3), and Yorkshire North Riding 5 (Middlesbrough C.B. 2).

The number of notifications of dysentery, 329, was 13 more than in the preceding week. The largest centres of infection were Yorkshire West Riding 55 (Leeds C.B. 21), London 54 (Bermondsey 13), Lancashire 44 (Liverpool C.B. 18), Nottinghamshire 19 (Basford R.D. 10), and Warwickshire 19 (Birmingham C.B. 10).

The largest outbreak of food-poisoning was 20 cases in the metropolitan borough of St. Pancras.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the years 1949-57 are shown thus ----, the figures for 1958 thus ———. Except for the curves showing notifications in 1958, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

X-rays in industry

At the end of 1957 about 400 factories in Britain were using radioactive isotopes, and over 100 were operating x-ray apparatus, according to the Annual Report of the Chief Inspector of Factories for the year.¹ The chief hazard to health at present is thought to be when sealed sources such as strontium-90 and thallium-204 are used to emit beta rays. The hazard occurs mainly when the machine is being dismantled for maintenance or to remove the source. Isotopes used for radiography are thought to be a greater hazard than x rays. In most cases when x-ray operators have received an overdose it has been an accidental and isolated occurrence. Luminizing factories pose special problems. One is that the luminizer may often be a young woman who has had no scientific education, and therefore "it is difficult for her to grasp the real nature of the hazard." The following example is recorded of how badly a luminizing shop can become contaminated:

"The linoleum top of the desk was found to have surface contamination 60 times greater than the recommended maximum; the facing edge of the luminizer's bench 150 times; the lampshade 80 times; the seat of the luminizer's chair 60 times; the back of the seat 40 times; and the cover of the log book 60 times."

At most establishments the employees are highly skilled technicians aware of the hazards, "although even among these workers dangerous practices sometimes occur."

¹ Annual Report of the Chief Inspector of Factories for the Year 1957, cmd. 521. H.M.S.O., 5s.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending September 6 (No. 36) and corresponding week 1957.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the whole of England and Wales (London included). London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenza pneumonia.

‡ Includes puerperal pyrexia.

Medical News

Travelling Fellowships.—The Medical Research Council invites applications for travelling fellowships in medicine and medical science, to be awarded for the academic year 1959-60. These fellowships are intended for graduates resident in Britain who have had some training in research work in clinical medicine or surgery, or in some other branch of medical science, and who are likely to profit by a period of work at a centre in the United States or elsewhere abroad before taking up appointments for higher teaching or research in the United Kingdom. Fellowships held in the United States will provide maintenance allowances at rates varying from \$3,000 to \$5,000 per annum, according to individual circumstances, and travelling expenses will also be supplied. Further particulars of these fellowships and forms of application may be obtained from the secretary, Medical Research Council, 38, Old Queen Street, Westminster, S.W.1, to whom the completed form should be returned not later than October 31.

Parkes Weber Collection.—Dr. F. PARKES WEBER has presented to the Wellcome Historical Medical Library, London, the remarkable collection of manuscript notes, reprints, and case reports of rare diseases which he has brought together in the course of his long and distinguished career as a physician and medical writer. Dr. Parkes Weber was born in 1863, and his books, *Rare Diseases and Some Debatable Subjects* (2nd ed., 1947) and *Further Rare Diseases* (1949), were based on a selection of this material. A general index to the "Parkes Weber Collection," as it is to be known, will be prepared by the Wellcome Library, where in due course it may be consulted, together with the original records and reports.

"Gray's Anatomy."—On September 18 at the Stationers' Hall, London, the directors of Messrs. Longmans, Green, and Company, the publishers of *Gray's Anatomy*, gave a dinner to celebrate the centenary of this famous textbook's first appearance. The guest of honour was Professor T. B. JOHNSTON, senior editor of the centenary edition. The company which assembled in the finely restored Stationers' Hall was a judicious mixture of anatomists and other medical folk, and of those concerned with the book's production. Mr. WILLIAM LONGMAN, who proposed the toast to *Gray's Anatomy* and its editors, said the occasion was not so much the centenary of a book as the centenary of the birth of an idea of a book. Longmans had always been interested in medical books; in their 1725 book list 44 of the 520 titles were medical, three of them works on anatomy, including Cheselden's, which saw 13 editions between 1713 and 1792. Professor JOHNSTON, replying on behalf of himself and his fellow editors, Professor D. V. DAVIES, of St. Thomas's, and Professor F. DAVIES, of Sheffield, sketched the origins and later progress of *Gray's Anatomy*. It was a wonder it had survived, he said. It had to weather a damaging first review; its first publishers went out of business after the second edition; and Gray himself died of smallpox in 1861 at the early age of 34. Credit for its survival was due to Timothy Holmes, who edited the next seven editions between 1863 and 1880. Professor JOHNSTON ended by thanking all those who had contributed to the present centenary edition.

Guy's Hospital.—On September 19 LORD NUFFIELD, president of Guy's Hospital, laid the foundation stone of the hospital's new surgical block (see *Journal*, September 28, 1957, p. 773). The block is an eleven-story building, designed by Mr. A. S. GRAY, F.R.I.B.A., with the help of Mr. PAUL G. BURT, of Chicago. Its cost is put at about £2.25m., and it is expected to be finished in two years' time. Speaking at the foundation ceremony, the MINISTER OF HEALTH, Mr. Derck Walker-Smith, paid tribute to Lord Nuffield's great generosity to Guy's. The new building, he went on, was a striking manifestation of the steady

growth and acceleration of the Government's hospital building programme. These projects represented in terms of money £10m. in 1955, £13m. in 1956, £18m. last year, £20m. this year, and £22m. next year.

Medical Society of London.—Sir CECIL WAKELEY, president of the Medical Society of London, appeals on behalf of the society for the loan of portraits of former presidents so that they may be photographed for permanent record. The society has an almost complete list of its presidents since its foundation in 1773, and would be glad to hear of portraits of any of the following:

John Millar, M.D., 1773	Theophilus Thompson, M.D., F.R.S., 1844
George Edwards, M.D., 1779	Walter Cooper Dendy, 1846
George Pinckard, M.D., 1811	Edward Headland, 1854
Thomas Walshman, M.D., 1817	Francis Hird, 1857
David Unwins, M.D., 1821	William Hughes Willshire, M.D., 1858
William Shearman, M.D., 1823	Francis Sibson, M.D., F.R.S., 1862
John Burne, M.D., 1831	Peter Marshall, 1869
John Whiting, M.D., 1835	John Cockle, M.D., 1879
Thomas Egerton Bryant, 1837	
Leonard Stewart, M.D., 1839	
George Pilcher, 1842	

Information about portraits of these past presidents should be sent to Sir Cecil Wakeley at the Medical Society of London, 11, Chandos Street, Cavendish Square, London, W.1.

Medical Photography.—The ninth annual conference of the Medical Group of the Institute of British Photographers was held at the Royal College of Surgeons, Lincoln's Inn Fields, from September 18 to 21. Sir JAMES PATERSON ROSS, P.R.C.S., opened the conference, which then proceeded to discuss such topics as the routine production of colour prints, the design of hospital photographic departments, the relationship between the medical photographer and his medical colleagues, and the presentation of demonstration panels. During the conference the Group held its annual meeting, under the chairmanship of Mr. NORMAN K. HARRISON. On the last day there were demonstrations of the Land polaroid camera and of the photography of dermatological and orthopaedic conditions.

Changes at the Ministry.—Dr. G. A. CLARK, one of the two deputy chief medical officers at the Ministry of Health, is retiring on September 30. He will be succeeded by Dr. DANIEL THOMSON.

COMING EVENTS

Institute of Dermatology.—Semi-permanent exhibition, October 1-28, on "The Sweat-retention Syndrome."

Casualties Union Day.—Casualties Union is holding a civil rescue contest (starting 11 a.m.) and the finals of its annual open competition in first aid and diagnosis (starting at 2 p.m.) on October 5 at the George Cohen 600 Group Depot, Wood Lane, London, W.12. Tickets (2s. 6d.) are obtainable from Miss E. E. JOHNSON, 8, Woodcote Park Avenue, Purley, Surrey.

London Hospital.—Old Students' dinner, October 9, at the Trocadero. Tickets 37s. 6d. (27s. 6d. for those qualified less than five years) from Dr. R. R. BOMFORD, London Hospital, E.1.

Glasgow Graduates in Yorkshire.—Annual dinner, October 17, in the senior common room, Leeds University. Details from Mr. JAMES WISHART, 33, Manor Row, Bradford, 1.

Leeds School of Medicine.—Annual dinner of past and present students, October 31, at the Griffin Hotel, Leeds. Details from the hon. secretary to the medical dinner, Leeds Medical School, Leeds, 2.

Hand Clubs.—The Hand Club of Great Britain and the Second Hand Club are holding a meeting on November 22, from 10 a.m. to 4 p.m., at the Royal College of Surgeons. Any surgeon interested who would like to speak or attend should write to Mr. GRAHAM STACK, 150, Harley Street, London, W.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, September 29

● ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Mr. H. J. B. Atkins: Fibroadenosis of the Breast; 6.30 p.m., Mr. R. F. Guymer: Surgeon and the Injured Worker.

Tuesday, September 30

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor C. J. Kaplan: An Appraisal of Conservative Therapy in Skeletal Tuberculosis.

● ROYAL COLLEGE OF SURGEONS OF ENGLAND.—6.30 p.m., Mr. R. Belsey: Carcinoma of the Oesophagus.

ROYAL STATISTICAL SOCIETY.—At New Small Lecture Theatre, London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. J. Tizard: Prevalence of Mental Defect.

WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Dr. G. F. Swann: Vertebral Arteriography.

Wednesday, October 1

FOUNTAIN HOSPITAL.—5.30 p.m., subject: Care of the Mentally Retarded Child. Dr. S. Yudkin: Paediatric Aspects of the Care of Mentally Retarded Children; Miss Jacqueline Grad: Home Care of the Mentally Retarded Child.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. W. Riddell: Fungi as Saprophytes and Parasites.

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Sir Russell Brock: Surgical Treatment of Pulmonary Stenosis.

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—5.30 p.m., Dr. I. Friedmann, Dr. D. A. Osborn, and Dr. A. Jeanes: clinico-pathological conference.

INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Dr. W. N. Mascall: Gonococcal Urethritis.

MANCHESTER MEDICAL SOCIETY: SECTION OF MEDICINE.—At Large Anatomy Theatre, Medical School, Manchester University, 4.30 for 5 p.m., "Hashimoto's Disease." Dr. R. W. Luxton: Clinical Aspects. Dr. Deborah Doniach: Immunological Aspects.

● ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Dr. Wilfrid Oakley: Surgery in Relation to Diabetes; 6.30 p.m., Mr. D. J. Waterston: Surgery in the Newborn.

YORKSHIRE SOCIETY OF ANAESTHETISTS.—At General Infirmary at Leeds, 8.30 p.m., Dr. Michael Johnstone: Respiratory Function During Halothane Anaesthesia.

Thursday, October 2

● ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Mr. H. R. S. Harley: Subphrenic Abscess.

ROYAL SOCIETY OF HEALTH.—At Town Hall, Colchester, 10 a.m., Dr. J. D. Kershaw: Practical Integration of Health Services; Mr. W. A. Rapier: New Houses for Old: An Experiment in the Modernization of Ancient Houses.

● ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Mr. R. B. Welbourn: Surgery of the Adrenal Glands.

WHIPPS CROSS HOSPITAL MEDICAL SOCIETY.—8.30 p.m., Dr. George Somerville: Changes in Psychiatric Disorders During the Past 25 Years.

Friday, October 3

● INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. G. B. Dowling: clinical demonstration.

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. E. H. Hudson: clinical demonstration.

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—3.30 p.m., clinical discussion for general practitioners by Dr. Norman Hulbert: Blood Disorders in Association with Ear, Nose, and Throat Diseases.

● ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Mr. R. B. Welbourn: Surgery of the Adrenal Glands.

WHIPPS CROSS HOSPITAL MEDICAL SOCIETY.—8.30 p.m., Dr. George Somerville: Changes in Psychiatric Disorders During the Past 25 Years.

Saturday, October 4

ASSOCIATION OF CLINICAL BIOCHEMISTS.—At Royal College of Surgeons of England, 9.30 a.m. and 2 p.m., scientific meeting (with Association of Clinical Pathologists) including symposium on quantitative paper chromatography; 5 p.m., annual general meeting.

NORTH OF ENGLAND OTOLARYNGOLOGICAL SOCIETY.—At Preston, 2 p.m., annual general meeting.

Sunday, October 5

UNIVERSITY COLLEGE HOSPITAL.—10.15 a.m., meet in Front Hall of main hospital building, lecture-demonstration for general practitioners. Clinical demonstration by Professor C. E. Dent: Dwarfism. An Obvious Feature Sometimes of Diagnostic Importance.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Armitt.—On September 11, 1958, at Farley House, Farnborough, Hants, to Dr. Marion (formerly Jenkins) and Dr. J. M. Armitt, a sister for Gillian—Rosemary Ann.

Clements.—On September 15, 1958, at Poole, Dorset, to Sheila Mayer, wife of Dr. P. W. Clements, a brother for Gillian and Stephen—Christopher.

DEATHS

Ker.—On September 3, 1958, at Halstead, Essex, William Perceval Ker, M.R.C.S., L.R.C.P., aged 83.

Laslett.—On September 6, 1958, at 1, Albert Road, Farnworth, Bolton, Lancs, William Henry Laslett, M.C., M.B., Ch.B.

Mackenzie.—On September 8, 1958, at the Royal Infirmary, Edinburgh, John Cosserat Mackenzie, M.B., Ch.B., of 67, Mountcastle Drive South, Portobello, Midlothian.

Macnicol.—On September 4, 1958, at 97, Greenbank Road, Edinburgh, Roderick Reid Macnicol, M.B., Ch.B., late of Tynmilt, Argyllshire, aged 87.

Rutherford.—On September 2, 1958, Henry Ireland Gascoyne Rutherford, M.B., B.Ch., of 100, Widdicombe Way, Moulsecoomb, Brighton, Sussex, aged 73.

Schonberger.—On August 12, 1958, Elisabeth Schonberger, M.D., of Greenbanks, Springwell Road, Durham.

Webster.—On August 10, 1958, in a nursing-home, William John Alexander Webster, M.B., F.R.C.S.Ed., of Redbrook Gate, Cradley, near Malvern, Worcs, aged 82.

Wilson.—On August 27, 1958, Fergus Falconer Wilson, M.B., Ch.B.

Any Questions ?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Toxic Effects of Mersalyl

Q.—What are the toxic effects of mersalyl therapy, and how should they be treated ?

A.—The most serious toxic effect of mersalyl therapy is heart failure. Mersalyl is a compound of mercury, and mercury has long been known to combine with sulphhydryl groups. Compounds containing sulphhydryl groups indeed are known as mercaptans because they capture mercury. Mersalyl can combine with sulphhydryl groups in the heart and cause arrest. Mersalyl is given by intravenous injection or by intramuscular injection. The risk of causing cardiac arrest is much greater when the intravenous route is used, and for this reason mersalyl should always be given intramuscularly. Dimercaprol is of value in treating the toxic action on the heart, but it must be given immediately there are signs of failure. For example, in the heart-lung preparation of the dog it is possible to cause cardiac arrest by injecting mersalyl and then to restore the beat by injecting dimercaprol. Dimercaprol contains sulphhydryl groups which dislodge the mercury from its attachment to the heart. To-day, however, the newer diuretics, particularly chlorothiazide, should be used in preference to mersalyl, for they are much less toxic.

E.C.G. in Angina of Effort

Q.—What further information may be gained from an E.C.G. in a patient who gives a clear-cut history of angina of effort ?

A.—The electrocardiogram varies in the presence of a clear-cut history of angina of effort. Sometimes definite evidence of myocardial infarction with deep muscle damage is seen, while in other cases the electrocardiogram shows the damage to the muscle to be less serious. Another group of patients shows slight or no evidence of cardiac damage in the resting electrocardiogram, and an electrocardiogram with exercise is necessary to demonstrate the lesion. If the electrocardiogram is normal, both at rest and on effort also, the diagnosis should be questioned. In general, therefore, the electrocardiogram confirms the clinical diagnosis and amplifies it by indicating the degree of muscle damage and also its anatomical site.

The crux of the question, however, lies in the interpretation of the words "clear-cut." Angina of effort is perhaps the most pathognomonic of all cardiac symptoms ; it is certainly more so than the isolated pain of cardiac infarction, which may be simulated by pulmonary embolus, dissection of the aorta, and other conditions. In the anxious patient, however, it may sometimes be difficult to disentangle the organic from the functional symptoms suggesting angina of effort, and it is here that the electrocardiogram is of special value.

Inadequate Personality

Q.—What is the definition of an inadequate or immature personality ? Is this a permanent disability, or is it possible to help an adult affected by this handicap ?

A.—An inadequate or immature personality characterizes the individual who is unable (or unwilling) to adapt himself to the everyday demands of his setting in life. The disability is usually due to a mixture of constitutional and environmental influences. Nevertheless, it is seldom easy to lay down the precise responsibility of nature or nurture. It is possible to help the condition and often to help substantially. Much depends upon the patient's age, his capacity for co-operation, his circumstances and general

health, and also upon the opportunities for obtaining the requisite professional advice and treatment.

The first step is to find out the nature of the disability. There may be intellectual inadequacy and consequent difficulties in education, or social maladaptation because of personal anxieties and complexes. The immature person is prone to develop neurosis ; he compares the achievements of his contemporaries with his own efforts and becomes discouraged. Psychological treatment can relieve this situation and at any rate prevent the spread of the trouble by the accumulation of new symptoms. The patient should be seen by a psychiatrist. He will make a tentative diagnosis, probably using one of the many personality tests, and assess the situation. If he succeeds in establishing a good contact with the patient on a human and personal level, the outlook for later treatment will be much improved.

Glucose Tolerance in Pregnancy

Q.—(1) Does pregnancy affect the glucose tolerance test ; and (2) does the E.S.R. rise in pregnancy ?

A.—(1) Pregnancy does not affect the glucose tolerance test. The finding of reducing substances in the urine in the presence of a normal glucose tolerance test is due either to a lowered renal threshold for glucose or to lactose. (2) The E.S.R. may rise markedly in pregnancy, presumably owing to a decrease in the viscosity of the plasma.

NOTES AND COMMENTS

Tennis Elbow.—Mr. A. H. G. MURLEY (London, W.1) writes : Your expert in the answer to the question on tennis elbow ("Any Questions ?" August 16, p. 461) mentions the efficacy of injection of hydrocortisone acetate in this condition. He says that it is useless to expect a satisfactory result unless the injection causes agony. This agony, I feel, is quite unnecessary, as equally satisfactory results can be obtained after local analgesic infiltration of the tender area, provided the hydrocortisone is injected into the area which is tender. Because of the comparatively superficial situation of this area, this is technically quite easy, and by this method the patient is saved a good deal of pain.

OUR EXPERT replies : My experience does not lead me to support Mr. Murley's view. In my hands the preliminary infiltration of a local analgesic makes the subsequent injection of hydrocortisone a less accurate method of giving the patient relief, but, as I stated in my previous answer to the original question, very many different varieties of treatment and of techniques are credited with success in this condition.

Correction.—In the report of Dr. J. Joseph's address at the B.M.A.'s Annual Meeting (July 26, p. 231) the subjects on whom he performed electromyographic studies were described as having "the hands clasped tightly behind the back." This should have read "lightly."

Collected Articles from the "British Medical Journal"

THE EPIDEMIOLOGY OF Q FEVER IN GREAT BRITAIN

AN ANALYSIS OF THE FINDINGS AND SOME CONCLUSIONS*

BY

B. P. MARMION, M.D.†

Consultant Bacteriologist, Public Health Laboratory Service

AND

M. G. P. STOKER, M.D.

Huddersfield Lecturer in Special Pathology, University of Cambridge

From the Department of Pathology, University of Cambridge

Perhaps the most lasting impression left by a survey of the literature of Q fever is of the remarkable diversity of the ecology of *Rickettsia burneti*. Its pattern of maintenance in animal or insect hosts differs strikingly from one part of the world to another, and the particular local variant which has evolved may have much significance for the infection of man. Thus, for example, the infection of sheep in the central valley of California or in southern Europe is accompanied by an appreciable morbidity among the human beings in contact, whereas the presence of the organism in the rabbits and ticks (Hyalomma excavatum) of the Nefik forest, Casa-blanca, is an inapparent infection of seemingly little consequence to the visitors to this popular holiday resort (Blanc and Bruneau, 1956).

The extensive information about Q fever has been reviewed in detail many times (Derrick, 1953 ; Berge and Lennette, 1953 ; Kaplan and Bertagna, 1955 ; Stoker and Marmion, 1955a) and attempts have been made to form a unified view of the ecology of the rickettsia from a unified view of the ecology of the rickettsia (Derrick, 1944 ; Marmion, 1954). These have not, perhaps, been particularly successful, but they do serve at least to indicate those ecological problems which need further exploration—for example, that of the relation between the cycle of maintenance of the rickettsia in ticks and small animals in various parts of the world and in the larger domestic animals, such as cattle, sheep, and goats.

Sporadic cases or outbreaks of the human disease have often been found in areas of intensive cattle or sheep farming, and the work of the Californian investigators (Huebner and Bell, 1951 ; Lennette and Clark, 1951) in particular has done much to unravel the way in which infection spreads from these animals to man. However, methods of animal husbandry in California have some unusual features, and the experience there cannot necessarily be used as a model for other countries. Q fever appears to be rare or entirely absent in certain agricultural countries such as Denmark, Finland, Norway, the Netherlands, and New Zealand. This may possibly be related to the infrequent importation of cattle and sheep into these countries (Kaplan and Bertagna, 1955), but the factors responsible may be more

complex, as the prevalence of the disease in cattle has been found to vary quite strikingly within the boundaries of a single county in England.

The work of Giroud and his colleagues in the Belgian Congo and French Equatorial Africa suggests that the ecology of the rickettsia and the epidemiology of the human disease may differ both qualitatively and quantitatively in tropical as compared with the temperate areas of the world.

Italian workers (Babudieri and Moscovici, 1952) found that pigeons and geese may be naturally infected with *R. burneti*, and Czechoslovakian workers (Brezina and Táborská, 1956 ; Raska *et al.*, 1956 ; Syruček and Raska, 1956) have extended our knowledge in this field by demonstrating natural infection in certain wild and domestic birds as well as in various rodents. The former finding is of some interest in view of a Russian report (Zhmaeva *et al.*, 1955) that *R. burneti* has been isolated from nestling field sparrows and two species of bird mites in an endemic focus of infection in Central Asia. The mites, it appears, were of a variety which sometimes attacks man and were collected from some of the numerous sparrows nesting near a village where human cases of Q fever had occurred.

These examples of the more unusual geographical variants of the ecology of the organism have been chosen deliberately to give point to Derrick's (1953) statement that "the history of 'Q' fever is full of paradoxes and surprises and changes of emphasis" and to make it clear that our understanding of the ecology of *R. burneti* is still incomplete.

There are therefore good general grounds for investigating Q fever in each country where it has been detected—quite apart from the need for public health workers to know about the local reservoirs of infection for man.

The investigation of the disease in England started in 1949, when Stoker found serological evidence of infection in two patients with pneumonia. Later in the same year the organism was isolated from patients in a small outbreak of Q fever at a hospital in London (Harman, 1949 ; MacCallum *et al.*, 1949). The epidemiological investigation of this outbreak (Marmion and Stoker, 1950) established that cattle in this country were infected and that the human cases were not the result of isolated importations of the disease.

*Based on a report to the Medical Research Council.

†Now at the Public Health Laboratory, Bridle Path, Leeds, 15.

Subsequent epidemiological investigations fell into two stages. In the first, conducted from Colindale and Cambridge, patients with Q fever in many parts of the country were followed up to find out how they had been infected. This approach to the problem yielded some information, summarized in the paper by Marmion *et al.* (1953). However, the retrospective investigation of sporadic cases or outbreaks has limitations—due principally to the absence of epidemiological information about control groups of uninfected human beings or animals. In the second stage, therefore, certain areas and groups of the population were studied in a controlled way so as to assess the significance of various possible sources or modes of spread of infection to man which had been uncovered in the earlier investigation. This work was carried out from Cambridge as a joint responsibility of the authors and with support from the Medical Research Council and Cambridge University. Attention was concentrated on Kent and East Anglia—areas of high and low prevalence of the disease. Systematic surveys of possible animal reservoirs of Q fever in these two areas were undertaken and three main epidemiological investigations were carried out. For the sake of brevity the latter will subsequently be called the “survey of healthy adults,” the “rural area investigation,” and the “urban area investigation.”

In the first of these the epidemiological histories of blood donors with Q fever antibody who were living in Kent or East Anglia were compared with the histories of randomly selected and negative donors living in the same areas (Marmion *et al.*, 1956). In the second a comparison was made of the prevalence of Q fever in a sheep-raising area, the Romney Marsh, and in a geographically similar area of Fenland—Chatteris-Witchford R.D.—with few sheep (Marmion and Stoker, 1956). In the third, the residents of two towns in north-east Kent were studied to determine the part played by cows' milk as a vehicle of Q fever infection (Marmion and Harvey, 1956).

In other parts of the country and about the same time, surveys of Q fever infection in cattle and cows' milk were undertaken by Dr. Slavin, of the Weybridge laboratory of the Ministry of Agriculture and Fisheries (Slavin, 1952). The disease in human beings and animals was also investigated by Drs. A. D. Evans, W. F. Lane, and J. C. Walker at the Public Health Laboratories in, respectively, Cardiff, Bedford, and Luton, and also by Dr. N. R. Grist at the Virus Laboratory, Ruchill Hospital, Glasgow.

It is the purpose of this paper to assemble the results of all these studies and to present them, together with some fresh information, in an effort to provide a composite picture of our national epidemiology.

The reservoirs of infection in this country and their possible interrelationships are described first of all, then the ways in which infection spreads from them to man.

1. NATURAL HOSTS OF *R. BURNETI* IN GREAT BRITAIN AND MAINTENANCE OF THE ORGANISM

Cattle

R. burneti has been isolated on numerous occasions from the pooled milk of herds of cattle kept in many parts of England, Wales, and Scotland (Marmion and Stoker, 1950; Slavin, 1952; Marmion *et al.*, 1953; Evans, 1956; Grist, 1956). The survey by Slavin was the most comprehensive, and covered 3,374 herds, of which 6.9% in England, 2%,

in Wales, and 0.8% in Scotland were infected as judged by the isolation of the rickettsia from the herd milk. The intensity of infection appeared to vary from county to county, doubtless owing mainly to uneven sampling, but nevertheless it was probably a valid observation that herds in East Anglia were much less often infected than those, for example, in Kent, Devon, Stafford, or Cheshire.

Few observations have been made on the distribution and progress of infection within herds of cattle in this country. The scanty information available suggests that the number of cows in a herd which are excreting rickettsiae in the milk may be small and that the infection may smoulder in the herd in an undramatic way. Thus in six infected herds in Kent and East Anglia 12 (10%) of 116 cows were shedding the rickettsia in the milk, and 24 (21%) of 114 cows had serological evidence of infection. Infection was found to persist for at least as long as two years in some Kentish herds which were sampled repeatedly.

Serological surveys of cattle at large—carried out mainly by testing sera submitted to veterinary laboratories for other diagnostic purposes—suggested low rates of infection; only 2 of 446 cattle in Kent and none of 609 cattle in East Anglia had Q fever antibody. Slavin found rather higher rates—12 (2.3%) of reactors among 509 sera collected from cattle in the country as a whole. When it is remembered that *R. burneti* was isolated from 8 to 12% of herd milks in Kent it is clear that surveys of bovine sera are an insensitive method of detecting or excluding the presence of Q fever in countries with a prevalence of infection at levels such as ours.

The rates of infection found by Huebner and his colleagues in Californian cattle were much higher than those just described—the milk from two-thirds of 63 dairies in Los Angeles contained the rickettsia (Huebner and Bell, 1951) and over 15% of 120,000 dairy cattle at large had serological evidence of infection (Luoto *et al.*, 1952). Such frequencies of infection seem to be of a different order of magnitude to those in British cattle. This might be due either to the less intensive methods of dairy farming in this country or it might represent a fundamental difference in the modes of spread of infection among the cattle. Presumably *R. burneti* is excreted in the placenta of English cattle as in Californian (Luoto and Huebner, 1950), but in a small series of tests we failed to isolate the organism from 32 placentas collected from cattle in herds with evidence of infection.

Sheep

Serological evidence of infection with *R. burneti* has been found in sheep in several parts of Great Britain. Fifteen (1.6%) of 906 sera from sheep killed in Kent slaughterhouses were found to have antibody, and higher rates of infection were found in certain flocks associated with cases of Q fever in the Romney Marsh area of the county (Marmion *et al.*, 1954). Eleven (3.5%) of 317 sheep in a rural area of Cardiganshire about 12 miles from Aberystwyth were found to have Q fever antibodies (Report to the P.H.L.S., 1956). Further south in Wales it was found that 2.7% of nearly 2,000 sera from sheep in 13 sanitary districts had Q fever antibody (Evans, 1956). Grist (1956) found a few positives among sheep coming to the Glasgow abattoir.

The significance of these serological observations was confirmed and enhanced by the isolation of *R. burneti* from 2 of 96 placentas collected from ewes in a flock with serological evidence of infection and kept in the Romney Marsh (Stoker *et al.*, 1955). The rickettsia was also isolated from pieces of wool collected from around the vulva of some ewes in the same flock. The frequency of serological positives and of the isolation of the organism from the placenta suggests a less intense infection than that found for example in North Californian or Italian sheep (Lennette and Clark, 1951; Davoli and Signorini, 1951).

We do not know how infection commonly spreads among sheep in this country—whether it is by the respiratory tract

after inhalation of infected aerosols, or by the digestive tract after the ingestion of water or pasture contaminated with the rickettsia, or even by arthropod vectors. Although *R. burneti* was found in the ticks (*Haemaphysalis punctata*) which heavily parasitized one infected flock in the Romney Marsh, infection was also found in another flock which was virtually free from ticks.

Spread of Infection from Sheep to Cattle

Early in the investigation of Q fever in Kent it was noted that the herd milks from cattle in the sheep-rearing areas of the county were more often infected than those elsewhere. A detailed survey of herds in two parts of the county was undertaken, therefore, to explore this lead. The parts chosen were agricultural census areas 8, 9, and 10 on the one hand and area 2 on the other. (See Fig. 1 (a).) Samples of the herd milks from the cattle in these areas were inoculated into guinea-pigs by Dr. E. R. Jones, of the County Pathological Laboratory, Maidstone, and the sera from the guinea-pigs, collected some six weeks after inoculation, were tested for Q fever antibody in our laboratory. In addition, samples of milk were obtained for us by medical officers of health in the two areas and tested in guinea-pigs at Cambridge. It will be seen from Table I that

TABLE I. Isolation of *Rickettsia burneti* from Herd Milks of Cattle in Various Areas of Kent with Differing Populations of Sheep

Agricultural Census Area	Animals per 100 Acres of Crops or Grass			Cattle: herds with		Total
	Cattle	Sheep	Pigs	Positive Milk	Negative Milk	
2	26.8	14.9	16.8	0	82	82
8, 9, 10	21.3	57.3	22.2	12	91	103

the two test areas were roughly similar in their numbers of cattle and pigs but differed strikingly in their number of sheep. It is clear that the proportion of herd milks which contained *R. burneti* was much higher in agricultural census areas 8, 9, and 10 than in area 2.

This difference in the rates of infection in the herds of cattle in the two areas could, of course, be due to other factors unrelated to exposure to sheep. Consequently an attempt was also made to find out whether the herds in the two areas differed in their size, methods of maintenance and replacement, exposure to sheep, infestation with ticks, and so on. This was done by sending a questionnaire to the farmers whose herds had been sampled. An analysis of the results is shown in Table II. The herds in the two areas were similar in respect of size, methods of maintenance, and grazing practice, but those in areas 8, 9, and 10 were more

TABLE II.—Analysis of the Answers to a Questionnaire Sent to 35 Farms in Area 2 and 63 Farms in Areas 8, 9, and 10

	Agricultural Census Areas			
	2		8, 9, and 10	
	No.	%	No.	%

FIG. 1.—Sketch maps of Kent, divided into agricultural census areas (1 to 9 and the Romney Marsh) and showing (a) the number of sheep per 100 acres of crops and grass in the various areas of the county, (b) the number of cattle per 100 acres of crops and grass, (c) the distribution of sporadic cases, and outbreaks of Q fever (the numbers in the squares), and (d) the proportion of blood donors with Q fever antibody in the various areas.

commonly found on farms where there was a flock of breeding ewes—either at the time of replying to the questionnaire or in the past—and the farmers also reported that ticks were more often found on the cattle or sheep.

There is thus some evidence for an association between the infection of cattle and the presence of sheep or sheep ticks, or both, in this region of Kent. This conclusion is also supported by the findings in East Anglia, where the sheep population is low and the cattle are infrequently infected (Marmion *et al.*, 1953; Marmion and Stoker, 1956).

Goats and Pigs

Slavin (1952) isolated *Rickettsia burneti* from the pooled milk of a herd of goats in Devon. More recently we have failed to isolate the organism from the milk of five of the larger herds of goats in Kent.

So far as we are aware, there is no substantial evidence that pigs can act as a source of Q fever, although some workers (Giroud and Jadin, 1951; Giroud and Goulon, 1952; Davoli and Signorini, 1951; Monaci and Nuvolone, 1953) have found antibody in their sera. The epidemiology of an outbreak of Q fever on a farm in Kent (Stoker and Thompson, 1953) suggested that farrowing sows might be a source of infection for man. This conclusion stimulated a search for more certain evidence of infection among pigs in this country. As a preliminary some pigs were inoculated artificially to determine the nature of their serological response to infection with *R. burneti*. Both complement-fixing and agglutinating antibody were formed, but the rickettsia was not excreted in the placenta of a sow inoculated during pregnancy (Stoker and Betts, 1953). Tests for these two types of antibody were then carried out on the sera from 106 bacon pigs and 401 sows slaughtered in bacon factories and abattoirs serving a wide area of the country, but the results were negative. In addition placentas were collected from 101 sows, mostly on dairy farms in Kent, but *R. burneti* was not isolated by guinea-pig inoculation. Other material which was tested and proved to be negative included post-mortem specimens from four sows coming from farms where infection was known to be present either in human beings or in dairy cattle.

Rabbits

Bengtson (1941) and Fiset (1957) have shown that rabbits artificially inoculated with *R. burneti* form agglutinating and complement-fixing antibodies, and other workers have shown that infection sometimes occurs in Nature (Davoli and Signorini, 1951; Blanc and Bruneau, 1956).

The organs from 229 rabbits, mostly trapped in the Romney Marsh, were examined by guinea-pig inoculation, but *R. burneti* was not isolated. Professor C. P. Beattie, of the Department of Bacteriology, University of Sheffield, kindly provided 172 rabbit sera which had been collected during a survey of the distribution of *Toxoplasma*. These showed neither agglutinating nor complement-fixing antibody to *R. burneti*.

Birds

Chickens

Our colleagues Drs. Fiset and Barber have examined sera from domestic hens which were obtained through the courtesy of Miss M. J. B. Wheatley and Mr. John Edwardson, of the Veterinary Inspection Service in Kent and of the Director of the Houghton Poultry Research Station in East Anglia. The method of indirect complement-fixation (Rice, 1948) was used to test for Q fever antibody and with an antigen made from the Nine Mile strain of *R. burneti*.

Sera from 390 birds were tested and 46 (11.8%) gave a positive inhibition test at titres of 1/10 or more. A comparison of sera collected from Kent, where Q fever is endemic, and East Anglia, where infection is rare, showed that 46 (13.5%) of 341 Kentish fowl sera were positive (some with titres of 1/80) but none of 49 sera from East Anglian fowls. There was also an indication that the

proportion of positives in Kent was the highest in flocks of hens running on pastures used by sheep.

The serological infection rate in Kentish fowls was of the same order as that—15%—found by Syruček and Raska (1956), who, however, used the direct complement-fixation test on fowl sera from Czechoslovakian farms where Q fever had occurred in man and domestic animals. These authors, and Sobeslavsky, also studied the excretion of the rickettsia and antibody formation in experimentally infected fowls. *R. burneti* was recovered from the droppings of one bird during the period from the 7th to the 40th day after inoculation. Complement-fixing antibody formation as measured by the direct test was rather irregular: only 3 out of 12 hens developed antibody, and even then not until six weeks after infection.

Wild Birds

The organs of 166 wild birds of various species taken in the Romney Marsh were examined, but *R. burneti* was not isolated.

Ticks

R. burneti was isolated from two batches of *Haemaphysalis punctata* collected from the flock of sheep in the Romney Marsh which had provided the infected placentas and wool clippings (Stoker and Marmion, 1955b). Ticks collected at the same time from other flocks in the Romney Marsh were negative, but an equivocal isolation was made some years before from *H. punctata* collected on the northern Kent marshes. Large batches of *Ixodes ricinus* from Cumberland and Scotland and a small number of *Dermacentor reticulatus* from Devon were negative (Marmion *et al.*, 1953).

Miscellaneous Animals and Ectoparasites

The organs from 30 assorted small animals—mice, rats, shrews, moles—and several pools of rabbit fleas, mostly collected in the Romney Marsh, were examined by guinea-pig inoculation with negative results.

2. TRANSMISSION OF INFECTION TO MAN

General Epidemiology of Human Q Fever

Geographical Distribution of Cases

Patients with Q fever have been detected in most parts of the Midlands and southern England. Relatively few cases have been reported in the north, and they appear to be especially rare in Lancashire, Westmorland, Cumberland, and the North and East Ridings of Yorkshire (Stoker, 1949; Manderson, 1949; Crofton *et al.*, 1951; Cameron, 1951; Marmion *et al.*, 1953, and unpublished data; Erooga and Shaw, 1956). The absence of Q fever in these northern counties, which are agricultural areas with large numbers of sheep, is most probably due to the fact that a systematic search has not been made. On the other hand, there are certain areas in East Anglia where, despite a rigorous search for patients with Q fever, only one or two have been found. This fact and the relatively infrequent finding of Q fever antibody in healthy members of the local population make it certain that the disease is genuinely absent and not merely undetected (Marmion *et al.*, 1953, 1956; Marmion and Stoker, 1956). In fact, the disease may have a patchy distribution even within the boundaries of a single county. Thus in Kent most of the patients with Q fever were found in the eastern half of the county, although admittedly the distribution is weighted by the inclusion of patients in the "urban" and Romney Marsh areas, which were the subject of special study. Despite this, the results of a serological survey of healthy adults (blood donors) throughout the county does support the idea of an irregular distribution of infection which more or less coincides with the case distribution. (See Fig. 1 (c) and (d).)

Sporadic cases or outbreaks of Q fever have also been found in many parts of Wales (Forbes, 1950; Evans, 1956; Report to the P.H.L.S., 1956). Little evidence of human

infection has yet been obtained in Scotland in spite of finding infected cattle in Dumfries, Clydebank, and Aberdeen (Grist, 1956; Slavin, 1952).

Age and Sex Distribution of Sporadic Cases

An analysis of the first 69 patients with Q fever showed that 58 were males and only 11 females. Of the patients, 92% were between 20 and 60 years old—that is, of working age (Marmion *et al.*, 1953). An analysis of cases since 1953 shows similar trends. The youngest patient in our records was aged 6.

Seasonal Prevalence of Cases

Fig. 2 shows the distribution of 104 patients with Q fever in England and Wales by their month of onset of illness. Over half of these had been found in Kent—an area of intensive study. It will be seen that cases occurred all the year round, but that there was a sharp increase in the spring (April and May) and another peak in September and October. Fig. 3 (a, b, c) gives the results of a detailed analysis of the 57 patients in Kent. Fig. 3 (a), "all cases," shows once again the prevalence of infection in the spring. Three out of the four outbreaks in the county occurred at this time of the year. Fig. 3 (b) shows that the vernal increase

FIG. 2.—Seasonal distribution of 104 sporadic cases of Q fever in England and Wales. Those in Kent are represented by black squares and those elsewhere by open squares.

was predominantly among those supplied with pasteurized milk at home, so that infection from a source other than raw milk must be postulated. Lastly, Fig. 3 (c) shows that the vernal prevalence of infection was most striking in the Romney Marsh area of Kent, where sheep were almost certainly the source of infection. On the other hand, cases in the urban area in the north-east of Kent, where milk was the most probable source of infection (see below), occurred all the year round.

Modes of Spread of Infection from Animals to Man

Occupational Q Fever

Classically, Q fever is a disease of those working with the domestic ruminants, but in fact only 8 (11.6%) out of the original series of 69 sporadic cases of Q fever in this country had such exposure. Nevertheless, in accord with the pattern of the disease elsewhere, patients with Q fever have been found among farmers and farm workers, shepherds, slaughterhouse workers, and veterinary surgeons. The herds, slaughterhouse workers, and veterinary surgeons. The serological survey of healthy adults in Kent and East Anglia showed that antibody was almost twice as common in persons who were occupationally exposed to cattle and sheep (or materials from them) as in those who were not. The low incidence of the clinical disease among those most closely exposed was probably due to pre-existing immunity—a point more fully explored in the discussion.

Residence Near Sources of Infection

Elsewhere in the world, in Los Angeles or Italy for example, it has been found that people living near certain sources of infection (cattle, sheep, or goats, particularly when giving birth to their young) have an increased risk of

getting Q fever. In England, however, there is little evidence from the investigation of Q fever patients in general that such "residential" contact plays a significant part in the epidemiology of the disease. This conclusion is supported by the finding that healthy adults in Kent and East Anglia who had lived within 200 yards (183 m.) of farm stock did not have Q fever antibody any more frequently than those not so exposed. This divergence from the experience in Los Angeles and elsewhere is probably accounted for by our wetter and less dusty atmosphere, the generally low incidence of Q fever in English cattle and sheep, and the less intensive and concentrated dairy farming.

There was, however, one group of 10 patients with Q fever in a small town in north Kent (Fig. 1 (c), area 6) where a form of "residential" exposure probably did play a part. Investigation of these patients showed that they had probably not been infected from milk or the local cattle and sheep, and the only remaining source seemed to be a large glue and fertilizer factory, around which most of the cases of Q fever either lived or worked. The factory received, among other materials, the offal from animals slaughtered in abattoirs in various parts of Kent and Sussex—bones, horns and hooves, intestines, and parts of the genital and urinary tracts. Some of this material—namely, the udder, the uterus with placenta and birth fluids, and the intestines—may have contained *R. burneti* from time to time, or indeed any of it may have been contaminated with the excreta of the rats which were inevitably to be found in the area.

If the factory was the source of infection then it is far from clear how infection was disseminated to the local inhabitants. Simple wind-borne carriage of infected dust from the factory during the processing of various tissues seems hardly credible, as some of the patients lived or worked more than half a mile (0.8 km.) away. Some interesting conclusions about the distance which infected aerosols can

FIG. 3.—Seasonal distribution of sporadic cases and outbreaks of Q fever in Kent: (a) all cases, (b) showing the household milk supply at the time of illness, and (c) showing the area of the county from which the cases were drawn.

spread from a rendering and fertilizer factory have recently been given by Spendlove (1957). After an outbreak of psittacosis had occurred at a factory which processed infected turkeys it was found that "tracer" bacteria placed on the material being macerated could be recovered in small numbers in an air sampler placed on a road skirting the factory and some 100 feet (30 m.) down-wind from the factory chimney. A more credible if quite unproved explanation would suggest that infected dust was carried out of the factory on the floors of transport vehicles or on the clothing or hair of the factory workers and subsequently liberated into the air of places at a distance—for example, the packing bays of adjoining factories, or in local shops, public houses, or cafés, and so on. Presumably the intensity of such infection would be greatest in the vicinity of the factory but would diminish much more slowly with the distance from the source than would simple wind-borne carriage of infected dust.

Direct Contact with Infected Cattle and the Use of Infected Raw Milk

Although there have been one or two episodes in which bystanders other than the herdsman or veterinary surgeon have been infected at the birth of a calf, the main vehicle by which Q fever comes from cattle to man in England appears to be the milk. The part played by milk in causing Q fever was shown in two towns in area 8 of Kent. (See Fig. 1 (c).) In these towns it was found that there was a preponderance of users of raw milk among Q fever patients when compared with a control group of patients suffering from other forms of fever or pneumonia. The majority of the cases of Q fever, and also the highest proportion of healthy adults with serological evidence of infection, were found among the customers of five particular retail dairies out of a total of 16 or 17 selling milk in the two towns. The rickettsia was demonstrated in the milk supplied to two of the five dairies.

Infection from sources other than milk seemed improbable in these two towns because a history of occupational or any other form of contact with animals or animal products, or of regular contact with persons working in trades with animals, was no commoner among the Q fever patients than among the controls.

The results of the survey of healthy adults in all parts of Kent and several counties of East Anglia provided an independent confirmation of the importance of milk-borne infection. In both areas it was found that after due allowance had been made for exposure in other ways the proportion of healthy adults with Q fever antibody was significantly higher among those who had used raw milk at home for all or part of the period 1942–53 than among those who had used only pasteurized milk.

Sheep as a Source of Infection for Man

The part played by sheep in the epidemiology of human Q fever in England was explored in the Romney Marsh area of Kent, which has a very large sheep population. As already mentioned, several flocks with serological evidence of infection were found in this area and the rickettsia was isolated from placental and wool samples collected from the sheep in one such flock. A serological survey of patients in the Romney Marsh who had suffered from pneumonia or undiagnosed fever during the period 1949–54 showed that some 14% of them had probably had Q fever. The majority of the patients with Q fever became ill in April, May, and June—that is, at a time when lambing, shearing, and other work with the sheep is at its height. (See Fig. 3 (c).) Several of the patients with Q fever were farm labourers or shepherds in close contact with sheep, and in at least three episodes it seemed very probable that the patients had been infected from the lambing ewes. The other Q fever patients in the area were not working with sheep, but some were in contact with shepherds or other persons handling sheep or materials from them. An investigation of the milk supplies of the cases of Q fever showed that some were using

pasteurized milk, while others were using supplies of raw milk and that one of these was infected with *R. burneti*. This last supply may have been the source of infection for a few of the cases (Marmion *et al.*, 1954; Marmion and Stoker, 1956).

The investigation of a small outbreak of 15 cases of Q fever in a sheep-rearing area of Cardiganshire (Report to the P.H.L.S., 1956) provided additional evidence that sheep may be responsible for human infection in Great Britain. As with the series of Q fever patients in the Romney Marsh only a proportion, 10 of the 15 patients, had obvious occupational exposure to animals. The remaining patients—a salesman in a mobile clothing-shop, a physician, a newspaper reporter, a carpenter, and a domestic worker—had either visited farms or had some contact in their spare time with persons who were engaged in sheep farming. It seems probable that they were exposed to infection in some undefined way during these activities.

The epidemiological pattern of the Welsh outbreak and that of some of the Romney Marsh cases resembles that found in the outbreak at Colusa, North California, by Clark *et al.* (1951). These workers considered that some persons who were not directly exposed to sheep may have been infected by the inhalation of dust containing *R. burneti* which was carried into town on the clothing of sheep farmers or other fomites. We have recovered *R. burneti* from the dust taken from the clothing of a Romney Marsh shepherd in charge of an infected flock (Marmion and Stoker, 1956), and it is easy to imagine how such persons dressed in their working clothes could carry infection into local shops, cafés, hairdressers, or public houses, or to any other place at some distance from the infected sheep.

Possibility of Infection from Other Domestic Animals, Birds, and Arthropods

Goats.—These animals are known to play a part in the epidemiology of Q fever in some parts of the world. Although infection has been demonstrated in goats in England (Slavin, 1952) their small number probably makes them of little importance as a cause of human Q fever in this country. Reliable statistics of the goat population are difficult to obtain, as many goats are kept on holdings of less than an acre, which are not included in the agricultural returns. In the 1951 census 995 goats were recorded in Kent—a trifling number compared with some 120,000 cattle and 400,000 sheep. Goats are sometimes kept instead of cows to provide milk for farm households in the Fenland areas of Cambridgeshire, and are probably commoner there than in Kent. It is significant, therefore, that the Fens are largely free from Q fever. The survey of healthy adults in Kent and East Anglia revealed that only 5% of the sample of nearly 400 persons who were interviewed had bought or consumed goat's milk during the period from 1942 to 1953. Those who had done so did not have Q fever antibody more frequently than the remainder of the sample.

Pigs.—The survey of healthy adults in Kent and East Anglia did not show any increased frequency of Q fever antibody in human beings in contact with pigs. In fact, those persons living in areas of Kent and East Anglia with the largest populations of pigs showed the lowest rates of serological infection. These findings, together with the failure to demonstrate infection in pigs (see above), indicate that the pig is at best a very infrequent source of infection for man in this country.

Miscellaneous Animals, Birds, and Insects.—There was no increased frequency of Q fever antibody among the healthy adults in Kent or East Anglia who had kept dogs, cats, rabbits, chickens, or various psittacine birds at or near their homes during the survey period from 1942 to 1953. Similarly infestation (generally slight) of the house or outbuildings with mice, rats, or mosquitoes was without significance. A history of tickbite was very uncommon among both the healthy adults and the patients with Q fever, and there is no good evidence of the infection of man by this means. There were a few reports of the presence of ticks on dogs,

cats, or ferrets, and it is possible that an occasional patient might be infected while removing them—as in the incident with dogs and *Ixodes ricinus* described by Hengel *et al.* (1950).

DISCUSSION

It is difficult to make an accurate estimate of the prevalence of clinical Q fever and the size of the problem it presents in this country. This is partly because of the indefinite clinical picture and partly because there is considerable variation in the frequency of the disease from area to area (for example, in Kent and East Anglia) and also between town and country. It is not altogether surprising, therefore, that figures derived from the central examination of the sera from patients with pneumonia or unexplained fever (mostly from urban areas) show low rates of infection (MacCallum, 1954). In some well-studied areas such as the Romney Marsh, or the small urban area in Kent, some 14% of patients with pneumonia probably had Q fever, and it is significant that the local medical practitioners at first did not distinguish the sporadic cases of Q fever from the bulk of those with pneumonia or fever due to other causes. Evans (1956) draws attention to the discrepancy between, on the one hand, the evidence of infection in cattle and sheep in South Wales and the frequency of antibody in the healthy residents of the area, and, on the other hand, the infrequent detection of clinical Q fever (15 (0.6%) of 2,482 cases of non-bacterial pneumonia). These findings might mean either that human infection was occurring at the time of the survey but was almost entirely subclinical in nature, or, as antibody may persist for six or more years after infection, that the antibody in the healthy population was from past infection and that the rickettsia was no longer spreading from cattle (or sheep) to man in this area. A recent change to the use of pasteurized milk could, for example, bring about such a dissociation between serological and clinical evidence of infection.

In general terms the finding of antibody in a population with no clinical Q fever might indicate a past acquisition of immunity and resistance to present exposure to infection. Relatively few of the Kentish cases of Q fever occurred among persons occupationally exposed to animals, although antibody was commonly found among such workers. In both the urban area and the Romney Marsh investigations it was noted that the newcomer to the area bore the brunt of the clinical Q fever—an observation most easily explained by postulating an immunity in residents of longer standing. Such an immunity might be the result of childhood exposure and acquired from infected milk—which appears to produce a high ratio of subclinical to clinical infections. An analogous situation appears to exist in South Africa, where most of the adult population are apparently immune and patients with Q fever are seen mostly among newly arrived immigrants from overseas or in South-African-born children (Report, 1954; cited by Kaplan and Bertagna, 1955).

The main conclusion from the investigations in Great Britain is that human beings in the areas studied were infected primarily from cattle and to a less extent from sheep. Although a few persons may have been directly or indirectly infected at the birth of a calf, the chief way in which the rickettsia spread from cattle to man appeared to be in the milk—at least in the sporadic cases of Q fever. No epidemiological evidence was obtained that goats, pigs, dogs, cats, rats, mice, domestic fowl, psittacine or other birds, ticks or other insects were a significant source of infection.

Although there is convincing evidence that Q fever can be contracted from the use or consumption of infected raw milk from cows—not only from the pioneer observations of Huebner and his colleagues in Los Angeles (Huebner *et al.*, 1948; Beck *et al.*, 1949; Bell *et al.*, 1950), but also from our own experience with the survey of healthy adults and the urban area investigation—the situation has nevertheless some puzzling features.

Infected milk may contain large numbers of rickettsiae—5 to 500 guinea-pig-infective doses per ml., and sometimes even more. Superficially it might be thought that drinking infected milk would be more dangerous, in terms of concentrations of organisms in contact with the oropharynx, than inhaling an infected aerosol. Yet the consumption of infected milk appears to be responsible for sporadic cases of Q fever at most. It is often assumed, possibly correctly, that this low incidence of clinical Q fever in drinkers of raw milk is due in some way to the greater resistance to infection of the oropharynx or intestinal tract as compared with the lower reaches of the respiratory tract. The recent demonstration (Abinanti and Marmion, 1957) of the protective or neutralizing properties of whey antibody in infected milk offers another possible explanation—namely, that contact with the antibody-coated rickettsiae leads to subclinical rather than clinical infection as with the guinea-pig inoculated with a mixture of rickettsiae and immune serum.

The ratio of subclinical (antibody-forming) to clinical infections among the users of an infected milk supply is a matter of some interest. In the absence of much-needed and accurate data from an institutional population supplied with infected milk we can only make a very rough estimate of the proportion of clinical cases of Q fever to persons with antibody for the customers of dairies A and B of the urban-area investigation. Probably about 7,000 to 8,000 people were getting milk from these two dairies. It can be estimated that during the period 1948–54 there were some 94 cases of pneumonia in this group and that of these about 30 were probably due to Q fever. From the results of antibody tests on the samples of healthy adults using milk from dairies A and B it can be calculated that some 1,070 persons among the customers had antibody—a proportion of one patient with Q fever for every 35 persons with antibody.

There have been several experimental investigations of the effects of pasteurization on infected raw milk (Huebner *et al.*, 1949; Marmion *et al.*, 1951). Essentially these have shown that treatment of the milk at 161° F. (71.7° C.) for 15 seconds in the high-temperature-short-time (H.T.S.T.) process and 145° F. (62.8° C.) for 30 minutes in the vat-holding process is generally sufficient to destroy the rickettsiae in naturally infected milk. A recent reinvestigation of the problem (Enright *et al.*, 1957) has confirmed these findings. Examination of milk purchased in the open market and pasteurized by the H.T.S.T. or vat-holding process has revealed a few samples in which the rickettsia has survived (Huebner *et al.*, 1949; Lennette *et al.*, 1952; Evans, 1956). This is probably of little practical significance, for the results of our investigations show clearly that persons using pasteurized milk have a lower probability of contracting Q fever or of exhibiting antibody than those in the same area who use raw milk. The great increase in the pasteurization of milk which has taken place during the last ten years in this country should substantially reduce the number of sporadic cases of Q fever in urban dwellers who are not otherwise exposed, although unpasteurized tuberculin-tested milk will presumably still remain as a potential source of infection.

Although the sporadic cases of Q fever may be brought under control the outbreaks of the disease may well continue, as they appear to be part of a different epidemiological problem. The source and occasion of infection has only been determined with certainty in one of the seven British outbreaks investigated—that at the Royal Cancer Hospital in London. Four of the outbreaks occurred in the spring and at the time of lambing and shearing, but the remaining two were at quite different times of year. Perhaps the most puzzling of all was that among the students at the College of Arts, Canterbury, where no obvious contact with domestic animals, rodents, or birds could be demonstrated (Harvey *et al.*, 1951).

A number of the students at this college came from the farming community and a few from sheep farms on the edge of the Romney Marsh. In view of the recovery of

R. burneti from air-borne dust by the Northern Californian workers (DeLay *et al.*, 1950) and their suggestions about fomites-borne infection (see Welsh, 1951), and also of our own isolation of *R. burneti* from dust collected from the clothing of a Romney Marsh shepherd, it is tempting to look back at this outbreak and speculate on the possibility that infected dust may have been brought to and disseminated in the college by a student rather than on the exterior or the contents of a packing-case, as tentatively suggested at the time.

The recent discovery that certain rodents and chickens can be infected and excrete the rickettsia points to another possibility which should be explored in future outbreaks where cattle, sheep, or goats are not obviously involved. Even if *R. burneti* is not regularly maintained in rats or chickens it may well be that these creatures can act as "short-term" or "secondary" hosts to the rickettsia and carry it into domestic or other environments well away from domestic ruminants, their products, or fomites directly contaminated by them. To mention this possibility is only to return to the theme of the variability of the ecology of *R. burneti* which has been stated in the introduction. Our information about the epidemiology of the disease in Great Britain as a whole is still quite limited. The indications from the most closely studied county, Kent, are of localized and complex endemic focus in which ticks and sheep are infected, with spread of infection from the latter to cattle and possibly to other creatures in contact, such as chickens. The distribution of sporadic cases and outbreaks of Q fever in man corresponds to the intensity of stocking with sheep in Kent, but it is clear that infection does not always spread from them to man by the most direct route. Studies elsewhere in Great Britain might well show different combinations of hosts and different routes of spread of infection.

Summary

Investigations of the epidemiology of Q fever in Great Britain since 1949 have shown that the disease is widespread in the country.

Rickettsia burneti has been isolated from the milk of cows and goats and from the placenta and wool of sheep. It has also been isolated from the sheep tick, *Haemaphysalis punctata*, but not from *Ixodes ricinus* or *Dermacentor reticulatus*.

There was some evidence of an increased frequency of infection in cattle in areas of Kent with large numbers of sheep and in some sheep ticks.

Limited attempts to find a reservoir of infection in small wild animals or wild birds were unsuccessful. Serological evidence of infection was found in chickens, but there are, at present, no grounds for assuming that these birds are an important reservoir of infection in Great Britain.

Infection in man has not been limited to those persons working with animals, but has been found in all sections of the community. Sporadic cases and outbreaks of Q fever occurred at any time of the year, but, in the areas studied, were commonest in the months from April to July.

Studies of the transmission of *R. burneti* to man have shown that sheep or cows were directly or indirectly the main sources of infection. Good evidence was obtained of the importance of unpasteurized cows' milk as a vehicle of infection.

"The control of dark smoke can be achieved if the representatives of local authorities accept the responsibilities that the full implementation of the Clean Air Act, 1956, involves. The common practice of waiting for smoke nuisance complaints from the public before action is taken is over. All areas should be subject to constant inspection and contraventions should not be allowed to persist. In many cases the co-operation of the owners or occupiers of the premises is readily available once their attention is drawn to such contraventions, and persuasion rather than compulsion is the answer; on the other hand there is sometimes a hard core of resistance to be overcome, and in such cases the local authority should ensure that the enforcement of legal proceedings can be carried out. If the representatives of local authorities who are in fact the policy makers do not accept the responsibilities placed upon them by the Clean Air Act, 1956, then I suggest that one of the ideas of this Society, 'To encourage the adoption of methods to reduce and prevent atmospheric pollution,' will be of no avail."—Mr. G. W. FARQUHARSON, chief smoke inspector for Birmingham, speaking on October 1 at the annual conference of the National Society for Clean Air.

OESOPHAGEAL STRICTURES AFTER GASTRIC SURGERY AND NASO-GASTRIC INTUBATION

BY

J. A. W. BINGHAM, M.Ch., F.R.C.S.

From the Royal Victoria Hospital, Belfast

The occasional development of an oesophageal stricture without apparent cause following the use of an indwelling naso-gastric tube and, usually, some type of gastric surgery has been recognized for many years. Less often, this condition has followed naso-gastric intubation and either some other abdominal operation or a severe illness not treated by operation. Douglas (1956), when reporting five of these cases, referred to 23 reported in the literature since 1915.

The mechanism of production of these oesophageal strictures and the part played by various factors have previously been discussed by several authors, without any generally agreed or very convincing conclusion having been reached.

A personal experience of four of these cases is recorded below. Study of them throws, I believe, some light on the aetiology of the condition.

Case 1

A man aged 41 was operated on in the Mid-Ulster Hospital for a perforated duodenal ulcer on May 24, 1950, and the perforation closed. Gastric aspiration by means of an indwelling Ryle tube was maintained for 48 hours. During this time the patient was lying flat. Troublesome heartburn started 10 days post-operatively. Otherwise his progress was quite satisfactory until three or four weeks after the operation, when, shortly after he had returned home, he began to experience a little dysphagia. The dysphagia rapidly increased, and he was readmitted on July 7 able to swallow even fluids only with difficulty. Barium-swallow examination showed a narrow stricture involving apparently the lowest few inches of the oesophagus and slight dilatation of the oesophagus above. He was transferred to the Royal Victoria Hospital, Belfast, on July 19, in an advanced stage of starvation, with a slow pulse, hypotension, and extreme prostration and general weakness. A life-saving measure before any investigation of his dysphagia was undertaken. His condition rapidly improved.

At oesophagoscopy on August 7 I found that the mucosa in the lower oesophagus was reddened, oedematous, easily traumatized, and showed superficial ulceration just above a narrow stricture. Gum-elastic bougies were readily passed. It was noted at the time that the appearance suggested peptic oesophagitis.

Following the dilatation, improvement in swallowing lasted for only a few days, and after two further oesophagoscopy dilatations regular self-bougienage by the patient was begun, starting with the smallest sizes and gradually increased. He was able to swallow reasonably well, though having to be careful that solids were cut up fine or minced. He was discharged on September 10 to continue with self-bougienage, and found that by passing his bougie, at first daily, later at weekly intervals, and eventually at intervals of several weeks, he was able to swallow satisfactorily.

He continued, though, to be troubled repeatedly with ulcer dyspepsia, including one episode of haematemesis and melaena, and on June 8, 1955, a gastro-enterostomy and vagotomy was carried out by Mr. E. Morrison. Recovery was uneventful, and the patient returned home to continue with self-bougienage.

For a period of some weeks after this operation he again required to pass his bougie as often as two or three times a week, but, apart from this, the operation has proved most satisfactory in every way. Not only has the patient been free from ulcer dyspepsia, but he no longer suffers from heartburn, which had been very troublesome ever since his perforation in 1950, and he has been able gradually to lengthen the intervals between dilatations until these have virtually been discontinued. When last seen he had not required to pass his bougie for eight months, and, provided solids are cut up fine, he has no trouble with swallowing.

When he was first seen it was thought the radiographs showed the oesophageal stricture to extend to the oesophageal hiatus, but after Case 4 of this series had been seen the radiographs were reviewed, and it was then realized that the appearances were consistent with the presence of a hiatus hernia. Further radiographs, taken recently with this in mind, confirmed that a hiatus hernia was indeed present, and that gastro-oesophageal reflux could be produced.

Case 2

A man aged 68, who had had ulcer-type dyspepsia for many years, was operated on in Coleraine Hospital on January 4, 1954, and a perforated duodenal ulcer sutured. Two days after operation a Ryle tube was passed because of vomiting, and aspiration was carried out for at least 48 hours, with the patient lying flat during this time. He was discharged on January 28, but was readmitted on March 5 because of projectile vomiting. A gastro-enterostomy was performed and he was discharged on April 8. On June 15 he was again readmitted because of gradually increasing vomiting immediately after every meal. Barium-swallow examination showed a stricture with hold-up of barium in the lower third of the oesophagus. The gastro-enterostomy was functioning satisfactorily.

At oesophagoscopy on July 4 I found a stricture at 37 cm. Oesophageal mucosa for a short distance proximal to this was reddened, inflamed, and ulcerated, the appearance being that of reflux oesophagitis. A biopsy specimen showed granulation tissue infiltrated by acute inflammatory cells.

The patient learnt to pass oesophageal bougies himself and was discharged on July 30 to continue bougienage at home. At first daily bougienage was carried out, but it proved possible gradually to decrease the frequency of dilatations, and three and a half years later he required to pass a bougie only at intervals of several weeks, was keeping well, had no dysphagia, except occasionally for meat, and had put on over a stone (6.4 kg.) in weight.

This patient has recently been reviewed and further radiographic examination carried out. The presence of quite a large hiatus hernia with reflux was demonstrated, and above this a slightly strictured lower segment of oesophagus.

Case 3

A man aged 61 had a gastro-enterostomy and vagotomy performed for pyloric stenosis in the Royal Victoria Hospital, Belfast, on June 13, 1957. Gastric aspiration was carried out for 48 hours. He was transferred to a convalescent hospital 12 days later. Shortly after arriving there he began to have dysphagia. Barium-swallow examination on July 5 showed what seemed to be an unusually long, narrow stricture apparently involving the lower half of the oesophagus (Fig. 1).

At oesophagoscopy (by Mr. H. M. Stevenson on July 15) the appearance was of an area of gross oesophagitis, at the lower end of which was a tight, simple stricture. This was dilated easily.

The dysphagia soon became as bad as before, and further oesophagoscopy dilatations were carried out on July 26 and August 15. Any benefit from these dilatations lasted for only very brief periods, and when I saw him on September 19 he was able to swallow scarcely anything but water, and sometimes milk, and was in a state of extreme weakness and debility.

At oesophagoscopy on September 20 I found the condition apparently unchanged, the mucosa at mid-oesophagus being red and oedematous and ending in a stricture. This was dilated.

Thereafter self-bougienage was carried out by the patient, at first three times daily, and when he could pass a size 17 English bougie he was discharged from hospital. Since then daily bougienage has been continued. His condition has improved steadily. He has to cut his food up fine, and there is occasionally a transient hold-up with solids.

The earlier radiographs were regarded at the time as showing the oesophageal stricture extending to the oesophageal hiatus, and a hiatus hernia was not specially looked for. A recent barium examination, carried out with the possibility of a hiatus hernia in mind, demonstrated that below the stricture there was indeed a large hiatus hernia with free reflux, and that the stricture was not nearly as long as had been thought (Fig. 2).

FIG. 1

FIG. 2

FIG. 1.—Case 3. Barium-swallow radiograph (July 5, 1957) showing what seemed an unusually long oesophageal stricture. A hiatus hernia was not specially looked for. FIG. 2.—Case 3. Barium study of oesophagus and cardia (February 27, 1958) revealed a large hiatus hernia.

Case 4

A man aged 39 had a rather harrowing story of peptic ulcer trouble. It can be summarized as follows: 1935, perforated duodenal ulcer sutured. 1942, gastro-enterostomy (Professor P. T. Crymble). 1955, gastro-enterostomy undone and Polya-type gastrectomy performed because of an anastomotic ulcer (Mr. M. Lavery). 1956, perforation of anastomotic ulcer sutured. May 14, 1957, Polya-type gastrectomy converted into Billroth I gastrectomy, a portion of jejunum involved in an anastomotic ulcer being excised (Mr. I. Fraser).

The patient was extremely ill for some days after this last operation, and gastric aspiration was carried out for five days, with the patient lying flat. A few days later he began to be troubled with hiccup and severe heartburn. As soon as he went home, a little over three weeks after operation, he experienced some dysphagia for the first time. This continued and became progressively worse. When I saw him on January 9, 1958, he was unable to swallow solids at all. Barium radiographs, shortly before this, had shown a hiatus hernia with readily produced reflux, and above this a stricture at the lower end of the oesophagus. (It was after seeing this case that the earlier cases were re-examined

and were also found to have hiatus hernias.) It is worth noting that barium-meal examination three months before his last gastric operation had not shown any sign of an oesophageal stricture. A hiatus hernia was not looked for at that time.

At oesophagoscopy (January 12) the appearance was that of a reflux oesophageal stricture, the mucosa just proximal to the stricture being reddened, oedematous, and slightly ulcerated, and bled easily on trauma. The stricture was dilated. A biopsy specimen showed smooth muscle with a marked chronic inflammatory infiltrate.

The patient began self-bougienage and was able to swallow a reasonable diet. However, he continued to have heartburn, and in view of his age and the chances of his reflux stricture becoming progressively worse, I decided that, instead of treating his condition purely by dilatation, I would carry out Collis's operation of gastropasty (Collis, 1957). I have recently been using this operation with most gratifying results in some cases of hiatus hernia with reflux oesophagitis, stricture formation, and shortening of the oesophagus. The operation was performed on January 28.

Up to the time of writing, two and a half months later, the patient has done well. Since the operation he has had no more heartburn, has required no further dilatations, and his swallowing has improved steadily, though he still has to be a little careful with solids. On recent radiographic examination reflux through the hiatus from the portion of stomach below the diaphragm could not be produced.

Discussion

Possible reasons for the development of oesophageal strictures in this type of case have been discussed by others. Straus (1950), for example, suggested that they may be the result of trauma from the tube, but this view has usually been discounted. Certainly the finding of acute inflammatory changes, with redness, oedema, and ulceration of the mucosa, weeks and even months after the removal of the indwelling tube, as in the present cases, clearly is against this view. Douglas (1956), in reporting five cases similar to those described in this paper, suggested that the most important factor in the production of these strictures was probably the patients' vomiting. This, however, is not very convincing, for some of these patients did not have a great deal of vomiting, and the effect of gastric aspiration with an indwelling tube is to prevent vomiting post-operatively.

Once it was recognized that the four cases described above all had hiatus hernias these difficulties disappeared. As already mentioned, the oesophagoscopic appearances in these cases were identical with those found in the reflux oesophagitis and reflux oesophageal stricture so often complicating hiatus hernia. The association in each case of a hiatus hernia and these oesophagoscopic findings makes it appear certain, therefore, that the oesophageal strictures in these cases were due to the hiatus hernias and the result of gastro-oesophageal reflux. This is not to say, though, that the operations and indwelling gastric tubes did not play a part. Reflux oesophagitis certainly often develops in association with hiatus hernia without any prolonged period of recumbency and without an indwelling tube. But reflux occurs more readily in the recumbent position, and almost certainly more readily still if an indwelling tube is present at the same time. Therefore this combination of recumbency and an indwelling tube in a patient with an unrecognized hiatus hernia could well start off reflux oesophagitis where none had been present before or markedly exacerbate a pre-existing mild oesophagitis. The temporary increase in dysphagia in Case 1 following gastro-enterostomy and vagotomy, when the patient was again confined to bed and an indwelling gastric tube was again employed, provides support for the view that such a regime may exacerbate reflux oesophagitis in a patient with a hiatus hernia.

It cannot, of course, be stated with certainty that similar cases described by others have had unrecognized hiatus hernias. But as in the first three cases described here the hernias were at first unrecognized, and as a hiatus hernia

can be present and yet be extremely difficult to demonstrate radiologically, the possibility must exist that in many such cases, and perhaps in all, the essential factor is the presence of a hiatus hernia.

If any lesson is to be drawn from these cases it is that when a patient requires gastric aspiration with an indwelling tube he should, if possible, even if there is no reason to suspect the presence of a hiatus hernia, be kept in an upright position and not lying flat.

Summary

Four cases of oesophageal stricture following gastric surgery and naso-gastric intubation are recorded.

The oesophagoscopic appearances in these cases were those of reflux oesophagitis, and in each case careful radiological examination demonstrated that a hiatus hernia was present.

Reasons are given for believing that, while the recumbent position and an indwelling gastric tube play a part in producing oesophageal strictures in such cases by initiating or exacerbating reflux oesophagitis, the essential factor is the presence of a hiatus hernia.

In all four cases treatment started with regular self-bougienage. This has become unnecessary or virtually unnecessary in two cases. In Case 1 this improvement gradually developed after gastro-enterostomy and vagotomy performed for persistent duodenal symptoms, and in Case 4 immediately following Collis's operation of gastropasty. In the other two cases self-bougienage is being continued.

It is suggested that when gastric aspiration with an indwelling tube is required in any patient the recumbent position should, if possible, be avoided.

I thank Mr. W. M. Brennan, Mr. H. W. C. Bailie, Mr. H. M. Stevenson, and Mr. I. Fraser for referring these cases to me. I am grateful to Dr. F. McDowell for the radiographic demonstration of hiatus hernias in the first three cases when they were reviewed. I am also indebted to Mr. R. D. Wood for help with the illustrations.

OESOPHAGEAL STENOSIS AFTER PARTIAL GASTRECTOMY

BY

K. C. McKEOWN, M.Ch., F.R.C.S., F.R.C.S.Ed.
Senior Consultant Surgeon, Darlington Memorial Hospital
and Friarage and Rutson Hospitals, Northallerton

Benign stricture of the oesophagus consequent on reflux oesophagitis is now a well-recognized condition. Allison (1948), in a review of 74 cases of oesophageal stenosis treated at the General Infirmary at Leeds, emphasized the role of peptic oesophagitis as a cause of stricture formation.

The frequency with which oesophageal stenosis occurs after oesophago-gastric operations has been pointed out by Barrett and Franklin (1949), and by Ripley, Olsen, and Kirklin (1952). In all the cases reviewed by them the operative procedures had interfered with the cardiac sphincter, the cardiac valve, or the "diaphragmatic pinchcock." Since the continence of the cardiac mechanism had thereby been interfered with, and acid and pepsin were able to regurgitate into the lower oesophagus, it is not surprising that reflux oesophagitis followed by stenosis had occurred.

The cases described here are of particular interest in that stenosis of the lower end of the oesophagus followed partial gastrectomy. This is doubly surprising, since the cardiac mechanism apparently had not been grossly disturbed, so there was no special reason for oesophageal reflux to take place. In addition, complete absence of free hydrochloric acid had been attained in both cases after operation; it was therefore unlikely that acid pepsin should cause ulceration of the oesophagus.

It is interesting to note that oesophageal stenosis after various types of operations for peptic ulcer has escaped mention in textbooks of surgery, for review of the literature indicates that this complication does in fact occur following various purely gastric procedures.

Oesophageal stenosis after uncomplicated gastro-enterostomy for duodenal ulcer has been recorded by Larson, Layne, and Howard (1942), and by Allison (1948). A further case of oesophageal stenosis after gastro-enterostomy has been reported by Bergqvist (1946), but this case was complicated by regurgitant vomiting, and duodenostomy had to be performed.

Review of the literature indicates that oesophageal stenosis is rare after partial gastrectomy. Craighead (1954) recorded two cases; in one of these emergency Polya-Hofmeister gastrectomy had been carried out for bleeding duodenal ulcer; the other patient had had a long-standing duodenal ulcer with evidence of early pyloric obstruction. Both patients, however, had had serious post-operative complications. The first of these still had a high level of free hydrochloric acid after operation and had developed stomal ulceration with stenosis, for which jejunostomy and further gastric resection had to be effected; the second patient suffered complete bursting of the wound on the third post-operative day. A somewhat similar case to the former is recorded by Benedict and Daland (1938) in which, after partial gastrectomy, the patient developed efferent-loop obstruction and subsequently oesophageal stenosis.

It is interesting at this stage to note how frequently, in patients who subsequently develop oesophageal stenosis, the previous gastro-enterostomy or partial gastrectomy has been followed by post-operative regurgitation or obstruction.

The only case of uncomplicated partial gastrectomy followed by oesophageal stenosis that we have been able to find is that recorded by Straus (1950). From personal communications with many surgeons, however, it would appear that this complication follows subtotal gastrectomy much more often than the literature indicates. For this reason it is felt desirable to record the following cases.

Case 1

A housewife aged 72 had suffered from vague dyspepsia and attacks of vomiting at intervals for 20 years. The condition was fully investigated in 1939, the symptoms being attributed to pylorospasm. Response to medical treatment was satisfactory, and no further serious symptoms occurred until she suffered a relapse in 1953, when the former symptoms of pyloric obstruction recurred. A barium-meal examination at this time showed a low distended stomach, but no ulcer crater. After a further period of peptic ulcer diet the symptoms again cleared up, but vomiting recurred in the spring of 1955, and persisted until the patient was seen on August 11 of that year. At this time her general condition was poor, and her weight had fallen from 8 st. 4 lb. to 6 st. (52.6 to 38.1 kg.). The clinical picture was that of

complete pyloric obstruction, and this was confirmed by barium-meal examination.

After careful restoration of fluid and electrolyte balance, operation was performed on September 2. The stomach was grossly hypertrophied and dilated, and there was an extreme degree of pyloric obstruction. The pyloric narrowing was attributed to the healing of a peptic ulcer. No other abnormality was detected in the abdomen. Partial gastrectomy was carried out, the lesser curve of the stomach being reconstructed so that the gastric remnant formed a smoothly tapering tube which was joined by anastomosis with the jejunum in front of the colon, and with the afferent loop to the lesser curvature. The patient's immediate post-operative progress was entirely uneventful and uncomplicated. After operation a Ryle tube was left in the stomach for 72 hours.

On the twentieth day after operation, when the patient was awaiting discharge, she developed a burning pain behind the sternum which radiated through to the back just below the shoulder-blades, and was associated with hiccup. Swallowing food brought on the pain, and there was some sensation of obstruction at the lower end of the sternum. The pain and oesophageal obstruction were intermittent

and were attributed to spasm. Barium-swallow examination at this time showed a fixed smooth narrowing of the lower end of the oesophagus, which was attributed to spasm. Oesophagoscopy showed inflammatory changes in the lower end of the oesophagus with some narrowing. Dilatation of the oesophagus was carried out and the patient discharged.

After discharge from hospital the patient's general condition improved, and within three months her weight had increased by 21 lb. (9.5 kg.). She still, however, complained at intervals of attacks of the same retrosternal pain, with dysphagia. Further dilatation of the oesophagus produced a very temporary benefit, and, though her general condition improved and there was further increase in weight, the attacks of pain became more persistent and the difficulty in swallowing more constant.

Barium-swallow examination on

June 11, 1956, showed narrowing of the distal 2 in. (5 cm.) of the oesophagus with dilatation above the narrowed segment (Fig. 1). There was increased peristalsis, and the narrow portion showed a beaded appearance when the bolus was actually passing. There was no filling defect to suggest new growth (Fig. 2), and on placing the patient in the Trendelenburg position no reflux of barium occurred. The gastric remnant showed no abnormality and the meal passed through the stoma quite normally.

Because symptoms persisted the patient was admitted on June 20 for reinvestigation. The x-ray appearances were unchanged, and oesophagoscopy showed inflammatory changes in the lower end of the oesophagus with narrowing of the lumen and small superficial longitudinal ulcers on the crests of the mucosal folds. After dilatation of the oesophagus, specimens of gastric juice were obtained. These showed no free acid; the total acid was 10 clinical units, and the pH 6.5.

It was decided to explore the lower end of the oesophagus, and this was done on June 26 through an oblique

thoraco-abdominal approach along the line of the eighth left rib. The gastric remnant was found to be lying neatly below the spleen, and there was no evidence of obstruction of the efferent or afferent loop. The gastro-jejunostomy stoma was entirely free and normal in every respect and there was no evidence of either stomal ulceration or of jejunitis. The oesophageal hiatus was rather loose and admitted two fingers into the sac of a small sliding hernia. The lower end of the oesophagus was swollen and oedematous, though perioesophageal adhesions were not extensive.

It was decided that the oesophagitis was possibly due to the reflux of alkaline jejunal secretion in view of the pH of the specimen of gastric juice previously obtained. To confirm this, a further gastric specimen was obtained and the pH was found to be 7. In view of these findings and for reasons discussed below, it was decided to convert the Polya-Hofmeister gas-

FIG. 3.—Case 1. Barium-swallow radiograph, after dilatation and conversion of Polya gastrectomy to one of Billroth I type, showing a greatly increased lumen at site of former narrowing in lower third of oesophagus.

FIG. 4.—Case 1. Barium-meal radiograph showing normally functioning Billroth I gastrectomy.

trectomy into one of the Billroth I type. The gastro-jejunostomy stoma was excised, retrograde dilatation of the oesophagus was carried out, and an anastomosis was performed between the re-formed stomach remnant and the duodenal stump. The gastro-jejunostomy stoma, excised *in toto*, was sent for section. This showed no evidence of stomal ulceration.

Post-operatively, a naso-gastric tube was kept in for five days, and the patient made a completely uninterrupted recovery. The retrosternal pain cleared up at once and she was able to swallow with ease. Barium-swallow examination on November 9, 1956, showed no evidence of obstruction at the lower end of the oesophagus (Fig. 3), and the gastrectomy was working normally (Fig. 4).

The patient has been reviewed at intervals for the past two years and has been entirely symptom-free; she is still gaining weight. Examination by barium swallow has been done on several occasions and no recurrence of the oesophagitis or of oesophageal narrowing has occurred.

Case 2

A schoolmaster aged 64 had had occasional attacks of heartburn for some years, but no serious trouble until two months before his admission to hospital. As a result of serious domestic and personal worries he had been smoking and drinking to excess. He developed epigastric pain, which came on after food and was not relieved by food, with occasional night pain. Vomiting started some days before his admission to hospital; it was persistent and severe, and on several occasions he vomited blood.

On admission on October 31, 1954, his condition was very poor; he was dehydrated, and the haemoglobin estimation was 79% (11.9 g. per 100 ml.). The stomach was distended and there was visible gastric peristalsis and a succussion splash. Blood was frequently present in the vomit, and occult blood tests of the stools were constantly positive. Fractional test meal showed hyperacidity. Barium meal examination on November 9 showed a distended stomach with increased peristalsis. No barium was passing through the pylorus, and there was tenderness and deformity in the region of the duodenal cap, with gastric residue at 24 hours.

After four weeks' medical treatment the patient's condition improved. At operation on December 1 gross pyloric obstruction was confirmed. The narrowing had occurred round an ulcer exactly on the pylorus, which penetrated deeply into the pancreas and was surrounded by oedema and fibrosis. A partial gastrectomy was carried out with removal of three-quarters of the stomach, and after re-fashioning part of the lesser curvature an anastomosis of the afferent loop to the lesser curve was carried out, using exactly the same technique as in Case 1. Post-operative progress was entirely uneventful and uncomplicated. After operation a test meal showed complete achlorhydria. Section of the ulcer confirmed that it was a pre-pyloric ulcer with no evidence of malignancy.

On the day of discharge from hospital, three weeks after operation, the patient found that he could not take normal meals because of difficulty in swallowing. Solid food appeared to stick at the lower end of the sternum and there was a sensation of heaviness in the upper part of the epigastrium. On occasion a mouthful or two of undigested food was regurgitated.

These symptoms persisted, and after five months his weight had fallen from over 12 st. to 8 st. 10 lb. (76 to 55.3 kg.). During this period the patient had failed to report to hospital or to his own doctor, but on June 4, 1955, he was readmitted in emergency in an emaciated condition. He was unable to swallow anything except fluids, and bed-sores were developing.

It was thought that the patient had developed a carcinoma of the oesophagus, and after intense medical treatment he became fit enough for barium-swallow examination to be carried out on July 20. This showed a stricture in the lower third of the oesophagus (Fig. 5). Oesophago-

scopy showed an inflammatory narrowing at the lower end of the oesophagus but no evidence of growth. After dilatation had been carried out, specimens of gastric juice were taken, and these showed complete absence of free hydrochloric acid. After dilatation there was no improvement in the dysphagia, and the oesophagus was re-explored on July 22. A thoraco-abdominal incision was made along the line of the seventh rib from the mid-axillary line on the left side, over the costal margin to the midline on the anterior abdominal wall, and the chest cavity and abdomen were widely opened. No growth was found, but there was thickening and oedema of the oesophagus, suggestive of oesophagitis. There was no evidence of diaphragmatic hernia. For reasons discussed further below, it was decided to convert the Polya-Hofmeister into a Billroth I gastrectomy. The gastric remnant was re-formed and joined by anastomosis with the duodenal stump, and the jejunal stoma carefully repaired. After this operation a Ryle tube was kept in the stomach for five days, and the only other point of special notice was that a further oesophageal dilatation was carried out.

After operation the patient's condition improved steadily. The total proteins on September 12 had risen to 6.2 g. per 100 ml. (albumin 3.5 g., and globulin 2.7 g.). X-ray examination on February 17, 1956, showed very slight narrowing of the lower end of the oesophagus with a normally functioning gastrectomy (Fig. 6). There was no evidence of any hold-up, and the patient said he had no difficulty with swallowing. He has been seen from time to time since this operation, and his good progress has been maintained.

Discussion

A review of the histories of these two cases reveals some quite remarkable similarities.

Both patients were in advancing years, one being 64 and the other 72 years of age. They were both in a very debilitated condition in which vomiting and loss of weight had been marked features.

FIG. 5.—Case 2. Barium-swallow radiograph seven months after partial gastrectomy, showing simple stricture of lower end of oesophagus, with considerable dilatation above the narrowed segment.

FIG. 6.—Case 2. Barium-swallow radiograph after the Polya gastrectomy had been converted to one of Billroth I type. The oesophagus had not been dilated post-operatively.

FIG. 1.—Case 1. Barium-swallow radiograph taken nine months after partial gastrectomy, showing an elongated narrowing of lower end of oesophagus, with dilatation above the narrowed segment.

FIG. 2.—Case 1. Oblique (anterior-posterior) view of oesophageal stricture, showing no evidence of new growth.

Pyloric stenosis was present in each instance. In Case 1 there had been intermittent pyloric obstruction for many years, attributable to pylorospasm, but in the year prior to operation the obstruction was constant and almost complete, and the patient's weight had fallen to 6 st. (38.1 kg.). In Case 2 the symptoms of pyloric obstruction did not begin until two months before admission to hospital, but the rapid deterioration in his condition was aggravated by serious domestic worries and over-indulgence in alcohol and tobacco.

The original operative technique of partial gastrectomy was the same in both instances. It may be of significance to emphasize that the left gastric artery was ligated near its origin, but in such a way as to leave undisturbed the left inferior phrenic (and oesophageal) branches. The lesser curve of the stomach was reconstructed quite extensively to allow anastomosis of the afferent loop to the lesser curve to lie easily in the left paracolic position below the spleen.

Both cases were managed after operation in exactly the same manner. An indwelling Ryle tube was present for 72 hours in each case, and in neither were there any post-operative complications until the oesophageal symptoms developed. Both patients developed symptoms on the 20th day after operation. In view of the time of onset of the symptoms and of the domestic background in each case, a psychological basis for the onset of the symptoms was at first suspected.

In each case after gastrectomy complete absence of free hydrochloric acid was found, in response both to test meal and to histamine injection. In view of the fact that the hydrogen-ion concentration of the gastric juice varied between 6.5 and 7, it was thought that recurrent peptic ulceration was not likely to have occurred.

There were two points of difference in the histories which should be mentioned by way of contrast. The patient in Case 1 was shown at the second operation to have a small sliding hernia at the diaphragmatic hiatus which would admit two fingers, though reflux had not been demonstrated by x-ray examination. The patient in Case 2 had complained of some heartburn at intervals, but vomiting was more prominent than discomfort.

It is worth noting that the two cases here described are members of a large series at present under review, in which the pre-operative preparation, operative technique, and post-operative management have been standardized. It would thus appear that the incidence of two in a series of 1,000 cases gives an accurate view of the frequency of this complication, the incidence of which is therefore 0.2%.

Aetiology

The aetiology of this condition is not understood, though various theories have been advanced to explain its occurrence. Straus (1950) has suggested the possibility of a thrombophlebitis extending from the coronary vein upwards along its oesophageal tributaries and causing inflammatory changes in the oesophageal wall. Another possibility is that the left gastric artery may have been ligated at too high a level and that as a result the oesophageal branches were obstructed and the blood supply to the lower end of the oesophagus thereby impaired, producing an area where stenosis might well occur. As previously mentioned, great care had been taken in all the cases in the series to avoid ligating the left gastric artery at too high a level, so that this, though a possibility, is unlikely.

Mosher (1945), in discussing oesophageal stenosis in cases of cardiospasm, regarded oesophageal and perioesophageal infection as the cause of the organic narrowing. In the cases here described there was no evidence of subphrenic infection, and, at the second operation, changes in the region of the cardiac hiatus were in no way prominent.

The trauma of the indwelling Ryle tube must be considered as a possibility. The frequency of urethral stenosis following the indwelling urethral catheter provides an interesting clinical parallel. Following a review of 82 cases of

oesophageal stenosis studied at necropsy, Bartels (1935) felt that the naso-gastric tube was not an aetiological factor, but stated that it might act as an aggravating factor. Olsen (1948), Benedict and Sweet (1948), and Mason and Ausband (1952) all emphasized the significance of naso-gastric tubes in contributing to oesophagitis and stenosis. In the cases here described, however, it will be remembered that while the naso-gastric tube was left *in situ* for 72 hours after the Polya operation, on the other hand the tube was left in for five days when the operation was converted to a Billroth I gastrectomy. As oesophageal stenosis followed the first operation but not the second, it must be deduced that the presence of the tube does not play a fundamental part in the production of stenosis.

The final aetiological factor to be considered is that of reflux. The occurrence of peptic ulcer of the lower end of the oesophagus associated with either gastric or duodenal ulcer has been recorded on so many occasions that the vulnerability of the oesophagus to acid-pepsin is accepted without question.

In the cases here described the possibility that minor degrees of reflux might have occurred is accepted, in that one case had a sliding hernia and the other had pre-operative symptoms suggestive of reflux. What cannot be accepted is that acid-pepsin played a part as the causative factor. After partial gastrectomy both cases had complete achlorhydria, and estimation of the

hydrogen-ion concentration showed that this varied between 6.5 and 7. It would appear, therefore, that if reflux did take place the reaction of the fluid being so near neutrality could not of itself harm the oesophageal mucosa. Since the activity of pepsin at the pH's under review would be negligible (Fig. 7), a different explanation is required. Since trypsin is a most powerful proteolytic enzyme and acts in an alkaline, neutral, or slightly acid medium, it seems quite possible that tryptic activity could severely damage the lower end of an oesophagus, causing oesophagitis and stenosis. In the cases under discussion the hydrogen-ion concentration of the fluid obtained from the stomach and lower end of the oesophagus provided a very suitable medium for tryptic activity. It may well be, therefore, that in these cases a combination of factors has been involved and that tryptic activity, rather than acid-pepsin activity, was the primary factor in causing reflux oesophagitis followed by stenosis.

Treatment

It is not possible to be in any way dogmatic in regard to the treatment of this unusual condition. It is apparent, however, that after simple dilatation of the oesophagus recurrence takes place with great rapidity. In Case 2 dilatation was carried out under direct vision, but the oesophagus was oedematous and congested, so that no benefit could have been expected or anticipated, and no benefit in fact occurred. In Case 1 repeated dilatations were carried out in the first instance, but recurrence of stenosis took place with such rapidity that they were abandoned.

The failure of dilatation was presumably due to the fact that the conditions giving rise to the oesophagitis were still operative, so that the inflammatory condition persisted and stenosis recurred.

FIG. 7.—Graph showing the peptic activity of gastric juice at various hydrogen-ion concentrations. Note that peptic activity declines from a maximum at pH 2.1 to negligible activity at pH 6.0.

It was felt that reflux was the most likely cause of oesophagitis in the cases here described. Since both cases showed a complete achlorhydria, it was thought that acid or peptic digestion was unlikely to be the operative factor. On the other hand, the conditions for tryptic activity were ideal. It was therefore felt necessary to prevent jejunal contents from reaching the lower end of the oesophagus. The obvious means of attaining this end was to convert the Polya gastrectomy into a Billroth type. If reflux did thereafter occur, the contents would be gastric, achlorhydric, and free of jejunal content.

In both cases this manoeuvre was successful. The oesophagitis and dysphagia cleared up rapidly, and though reflux has taken place at frequent intervals for the past two years, no evidence of recurrence of stricture has occurred. This seems to confirm that reflux of jejunal content, and probably tryptic activity, were the cause of the oesophagitis which led to stenosis.

Summary

Two cases of an unusual complication of subtotal gastrectomy are described.

The possible causes of this complication are discussed. It is suggested, on theoretical grounds and as a result of the line of treatment adopted in these cases, that the reflux of the jejunal contents, and possibly tryptic activity, may be the operative factors in causing the oesophagitis which led to stenosis.

I thank Dr. P. N. Coleman, consultant pathologist, for the section reports and also for his work in association with Mr. S. Taylor, F.I.M.L.T., our chief technician, in preparing the photographs. I also thank Professor Ian Aird for his kind interest and help, and Dr. W. Irvin and Dr. A. K. Lamballe, who have taken the radiographs of these cases.

ADRENALINE IN HYPERTHYROIDISM AND INSULIN HYPOGLYCAEMIA

BY

W. F. DILLER, M.D.*

AND

R. KILPATRICK, M.B., M.R.C.P.Ed.

From the Department of Pharmacology and Therapeutics,
University of Sheffield

There are many similarities between the features of acute insulin hypoglycaemia and of hyperthyroidism. Tachycardia, weakness, finger tremor, sweating, and flushing can occur to a similar extent in both conditions. Furthermore, the similarity between the features of hyperthyroidism and those of phaeochromocytoma is striking; indeed, these disorders are not infrequently confused. All three conditions are known or thought to be related to an increase of secretion of adrenaline from the adrenal medulla. Cannon *et al.* (1924) reported an increase of adrenaline secretion in cats in response to insulin hypoglycaemia and showed that this was a mechanism for raising the lowered blood sugar.

*Now at Stadt Krankenhaus, Rüsselsheim am Main, Germany.

It has been suggested that adrenaline is responsible for many of the symptoms of hypoglycaemic reactions (Bell *et al.*, 1956). Similarly, in man, von Euler and Luft (1952) and French and Kilpatrick (1955) demonstrated a considerable increase in urinary adrenaline excretion following hypoglycaemia.

An association between hyperthyroidism and changes in adrenaline metabolism has long been suspected. Hyperthyroid subjects have a striking increase in sensitivity to adrenaline and noradrenaline (Rosenblum *et al.*, 1933; Peltola, 1951; Schneekloth *et al.*, 1953; Brewster *et al.*, 1956). Many observers have noted changes in adrenaline content of adrenal glands in animals in which hyperthyroidism was produced by giving thyroxine (Goodall, 1951; Hökfelt, 1951; Pekkarinen *et al.*, 1951; Durlach *et al.*, 1955). Accordingly, urinary catechol excretion has been measured in a number of patients with hyperthyroidism and the results are compared with those found in insulin hypoglycaemia and in normal subjects.

Methods

The urinary catechol excretion was measured in 12 euthyroid subjects, in 17 patients with hyperthyroidism of varying degree, and in two patients with hypothyroidism. The estimation was repeated in two patients previously hyperthyroid who had become euthyroid following treatment with radioiodine.

In all but one of the patients with hyperthyroidism the estimation was performed while they were in-patients and thus at rest in bed. The normal subjects, who were mainly hospital and university staff, were performing their usual duties. Urine was collected for 24 hours into a dark bottle containing hydrochloric acid.

Two methods of extraction were used, either aluminium hydroxide (von Euler and Hellner, 1951) or aluminium oxide (von Euler and Orwen, 1955). The latter method required modification as our assay was done on the rat-uterus preparation (Diller, 1958). Recovery by both methods varied between 65 and 90%. No correction was made for this.

Adrenaline assays were performed, using the oestrous rat uterus stimulated by carbachol (Gaddum and Lembeck, 1949). Values are given as L-adrenaline. The assay was checked in two ways. Firstly it was shown that all adrenaline-like activity was destroyed by boiling an aliquot of the extract at alkaline pH. Secondly, addition of known amounts of adrenaline to the extract after measurement produced only additive effects and no potentiation or masking was found. If either of these requirements was not met another extract was prepared from a further urine collection.

Total catechols were measured in the same extract on the cat's blood pressure, and the noradrenaline content was found by using the adrenaline value from the uterus assay (Burn *et al.*, 1950). Values are given as DL-noradrenaline.

Attempts were also made to measure adrenaline and noradrenaline by a fluorimetric method (von Euler and Floding, 1955), so that the number of estimations could be increased. However, it was found that there was much non-specific fluorescence in all the urines that were studied. This produced more inaccuracy when the level of catechols was in the physiological range. Similar results with fluorimetric methods are described by Pitkänen (1956).

Radioiodine tracer studies were performed in all of the patients with thyroid disorders. They were given 25 μ c. of 131 I and the thyroid uptake was measured after 4 and 48 hours. Protein-bound 131 I was measured at 48 hours, using trichloroacetic acid as protein precipitant (Goodwin *et al.*, 1951).

Results

The clinical diagnosis of hyperthyroidism was confirmed by radioiodine studies; in all of them the four-hour uptake was more than 40% of the dose and the 48-hour protein-

bound ^{131}I more than 0.4% of the dose per litre of plasma (Wayne, 1954).

The values for adrenaline and noradrenaline in normal subjects and patients with thyroid disease are shown in the Table. In normal subjects the mean daily adrenaline excretion

Urinary Catechols in Hyperthyroidism and Hypothyroidism

	No.	No. of Estimations	Mean Daily Output of		
			Adrenaline ($\mu\text{g.} \pm \text{S.E.}$)	Nor-adrenaline ($\mu\text{g.} \pm \text{S.E.}$)	Adrenaline (Percentage of Total Catechols $\pm \text{S.E.}$)
Normal	12	16	2.8 $\pm$ 0.5	22.6 $\pm$ 3.1	12 $\pm$ 1
Hyperthyroid	17	20	25.0 $\pm$ 6.8	15.8 $\pm$ 2.3	55 $\pm$ 4
Hypothyroid	2	3	0.8	14.3	5

tion was 2.8 $\mu\text{g.}$ (range 1–7 $\mu\text{g.}$) and the mean daily noradrenaline excretion 22.6 $\mu\text{g.}$ (range 9.4–50 $\mu\text{g.}$). No significant difference was found between the two methods of extraction.

A striking difference is apparent when the mean daily adrenaline excretion in the patients with hyperthyroidism is considered. This is 25 $\mu\text{g.}$ (range 7.5–130 $\mu\text{g.}$) and is significantly greater than the mean in normal subjects ($P < 0.05$). The mean excretion of noradrenaline is lower, but this difference is not significant. The high adrenaline excretion in hyperthyroidism is emphasized when this is expressed as a percentage of the total catechol excretion. In hyperthyroidism this is more than four times that found in normal subjects.

The protein-bound ^{131}I values reflect the rate of turnover of iodine by the thyroid and probably give an indication of the severity of hyperthyroidism, provided that the thyroid gland has not been disturbed by previous treatment. In this series all the patients with hyperthyroidism were studied before any treatment had been given. The 48-hour protein-bound ^{131}I values have been plotted against the daily adrenaline excretion, expressed as a percentage of the total catechol excretion (see Chart). The excretion of adrenaline apparently rises with an increased concentration of labelled hormone.

Urine adrenaline excretion in patients with hyperthyroidism, and the protein-bound radioactivity of serum at 48 hours.

In two patients with hyperthyroidism, who had become euthyroid some months after treatment with radioiodine, the daily adrenaline excretion had fallen from 30 and 20 $\mu\text{g.}$ to 5 and 7 $\mu\text{g.}$ respectively. These latter results are within the range of normal.

Only two patients with hypothyroidism were studied; both had low values for adrenaline excretion (see Table).

These results of adrenaline excretion in hyperthyroidism may be compared with those found in insulin hypo-

glycaemia. French and Kilpatrick (1955) found that the mean adrenaline excretion in three patients during the three hours preceding the injection of insulin intravenously was 5.1 $\mu\text{g.}$, and 46.1 $\mu\text{g.}$ during the three hours following it. As hypoglycaemia occurs acutely, it is difficult to compare with the daily adrenaline output in hyperthyroidism. However, the rise in output during the three hours following the induction of hypoglycaemia and for 24 hours in hyperthyroidism is approximately tenfold compared with the control results.

Discussion

The results for adrenaline and noradrenaline excretion in normal subjects agree with those of von Euler and Floding (1955) and of Bischoff and Gray (1956), using biological assay.

It seems that adrenaline excretion in urine is much increased when hyperthyroidism is present, and the correlation of adrenaline excretion with the amount of labelled thyroid hormone is suggestive evidence that this excretion is related to the degree of thyroid hyperactivity. It has been shown (von Euler and Hellner, 1952) that activity increases adrenaline excretion, and thus the adrenaline values in hyperthyroidism are even more striking, as these patients were in bed, whereas the normal subjects had no restriction on activity. If it is assumed that renal clearance of catechols remains unaltered, this suggests that the blood adrenaline level is also raised in hyperthyroidism. This may be due either to increased production or to decreased destruction. There is no direct evidence for or against the first, though many observers have noted changes in histology and adrenaline content of adrenal glands in experimental hyperthyroidism in animals (Herring, 1917; Goodall, 1951; Hökfelt, 1951; Pekkarinen *et al.*, 1951; Durlach *et al.*, 1955).

There is some evidence that there may be decreased destruction of adrenaline in hyperthyroidism. Spinks and Burn (1952) and Trendelenburg (1953) found a fall in liver amine oxidase content in rabbits when thyroid extract was given and a rise in the content of the enzyme following thyroidectomy in rabbits and rats. Kawamoto *et al.* (1952) noted a fall in adrenaline dehydrogenating enzyme in hyperthyroidism. Burn and Marks (1925) revealed this decreased destruction by showing that following thyroid feeding there was an increase in the hyperglycaemia produced by adrenaline and a decrease following thyroidectomy. They also showed that there was an inverse relationship between hyperglycaemia produced by adrenaline and hypoglycaemia produced by insulin. Thyroidectomy increased the fall in blood sugar following insulin, and thyroid feeding decreased it.

The insulin-tolerance test may show prolonged hypoglycaemia after insulin in patients with hypothyroidism (Fraser and Smith, 1941). These results are in accordance with the evidence that adrenaline is released in response to insulin hypoglycaemia (von Euler and Luft, 1952), even though this release appears to cause very few of the symptoms of hypoglycaemia (French and Kilpatrick, 1955). Adrenaline and insulin can be regarded as physiological antagonists for many of their actions, and thus the secretion of adrenaline in response to hypoglycaemia may be regarded as compensatory. However, this is not so with thyroxine and adrenaline. It is surprising, therefore, that the blood level of adrenaline appears to increase when hyperthyroidism is present. Direct measurement of circulating adrenaline, and if possible in adrenal vein blood, is required for final confirmation.

Summary

The daily urinary excretion of adrenaline and noradrenaline has been measured in patients with hyperthyroidism and in normal subjects.

A large increase in adrenaline excretion was found in hyperthyroidism, but no change in noradrenaline excretion.

There was a correlation between adrenaline excretion and severity of hyperthyroidism, as measured by output of labelled hormone following a tracer dose of ^{131}I .

Possible mechanisms for these changes and relationship to insulin hypoglycaemia are discussed.

We gratefully acknowledge the advice and encouragement of Professor G. M. Wilson, and the co-operation of our patients and normal subjects. This work was done while W. F. D. held a German Council Scholarship, and R. K. a B.M.A. Research Scholarship.

AETIOLOGICAL FACTORS IN PRIMARY RAYNAUD'S DISEASE

BY

J. H. PEACOCK, Ch.M., F.R.C.S.

From the Department of Surgery, Royal Infirmary, Bristol

The term "idiopathic," or "primary," Raynaud's disease is currently applied to those patients who present with intermittent attacks of digital pallor or cyanosis in whom careful examination fails to reveal either a local contributory cause or an associated systemic disease in which the digital symptoms might be considered to represent a single feature of a more generalized disease process.

The use of the term primary is in many ways open to individual interpretation by the clinician. This is not only due to the gradually increasing number of diseases with which the digital syndrome is now associated, but is also dependent on the care and accuracy taken to exclude systemic disease and to establish aetiological factors on which such a diagnosis may be accepted or rejected.

Apart from the influence of heredity and the frequent appearance of symptoms during childhood or at puberty (Lewis and Pickering, 1934), little is known about endogenous influences which may affect either the appearance of symptoms or the severity of the disease, and the purpose of this paper is to draw attention to certain features in the histories of a group of patients with this

disease which suggest that they should be regarded as aetiological factors in the evolution of the vascular abnormality of primary Raynaud's disease.

Clinical Material

The 21 cases recorded form part of a group of 42 patients diagnosed as having primary Raynaud's disease. Their symptoms were intermittent attacks of digital pallor or cyanosis of the upper extremities of such severity as to constitute a serious disability in their normal way of life. All were females, aged 23 to 52 years, who had been referred either for upper-limb sympathectomies or because of recurrence of symptoms following previous operations. All fulfilled both the criteria laid down by Allen and Brown (1932a) of a diagnosis of primary Raynaud's disease and those suggested by Hunt (1936) for primary Raynaud's phenomenon. They were otherwise in good general health, and with the exception of one case (No. 10) were non-smokers.

Clinical examination failed to reveal either a local cause for their symptoms or any associated systemic disease. All peripheral pulses were normal and the blood pressure ranged from 110 to 140 mm. Hg systolic and 65 to 80 mm. Hg diastolic. A careful investigation of the E.S.R., serum proteins, and blood excluded the presence of the collagen disease group.

Clinical Histories

Analysis of the clinical histories of the patients obtained by careful questioning of the patients themselves and their close relatives indicated that symptoms either arose for the first time, or pre-existing mild symptoms became greatly exacerbated, following three main events in the patient's life: (1) childbirth; (2) the onset of the menopause; and (3) a period of severe mental stress.

Aetiological Factors in Primary Raynaud's Disease

Case No.	Hereditary History	Age of Onset of Digital Symptoms	Age of Onset of Disability	Aetiological Factor	Progression to Nutritional Lesions
1	+	32	32	Parturition	Yes
2	+	15	29	"	"
3	—	Child	36	"	No
4	+	26	26	"	"
5	+	Child	18	"	"

10	+	47	47	"	"
11	+	Teens	35	Hysterectomy and unilateral oophorectomy	"
12	+	33	34	Hysterectomy	"
13	—	33	33	"	"
14	—	42	42	"	"
15	+	40	40	Mental stress	"
16	+	28	28	"	"
17	+	42	42	"	"
18	—	30	30	"	"
19	+	35	35	"	Yes
20	—	Teens	37	"	No
21	—	25	25	"	"

Childbirth.—In eight patients symptoms severe enough to make them seek medical treatment arose within six months of the birth of a child, the time period between parturition and the onset of symptoms being related to the interval between parturition and the onset of cold weather. In three cases it was following the birth of the first child, in four the second, and in one the third. Two of these cases progressed within a period of five years to nutritional lesions of the digits and sclerodactyly. In three patients the symptoms arose *de novo* and there was no evidence to suggest that previous mild attacks had occurred. In five cases occasional digital pallor had been present for many years, and it was the severity of the attacks that had been modified. These had been converted from occasional and mild to severe and prolonged, with marked pain and disability.

Menopause.—In four of the six patients in this group the digital symptoms followed within a few months of subtotal hysterectomy for fibroids. In only one case (No. 11) was

an associated unilateral oophorectomy performed. In two others the symptoms arose at a time when irregular menstruation was already present which culminated within 18 months in a complete menopause. Although pain and prolonged cyanosis were dominant symptoms in all cases, only one progressed to digital ulceration within the next five years and in only two cases of these did the symptoms arise *de novo*. In four it was established that mild attacks of pallor or cyanosis had been previously present for many years, and the effect of the menopause in these was to exacerbate a pre-existing mild form of the disease rather than to initiate it.

Mental Stress.—In seven cases the digital symptoms followed a period of prolonged and severe mental stress. In four cases symptoms appeared immediately before or after the death of a mother or husband whom the patients had been nursing, whilst in the three remaining cases they arose during a period of unhappy married life leading to separation or divorce from their husbands. In six of these cases the symptoms arose for the first time within a period of one to four months of either the death of the relative or the date of separation, and in only one case (No. 20) was there any evidence that pre-existing mild attacks of pallor or cyanosis had been present, so that the stress was predominantly an initiating rather than an exacerbating factor in this group of patients.

Discussion

The influence of heredity in Raynaud's disease has previously been commented upon, and it could be seen that in 16 of the 20 cases in which a complete family history was available a history of similar attacks was present in one or both of the parents. It would be reasonable to assume, therefore, that there did exist an inherited predisposition to such attacks in the majority of these patients, although the nature of the inherited defect remains unknown. In the first two groups of 14 cases nine had had symptoms before the event which precipitated the disability, but these had been minimal and had given rise to no disability. In only one of the group associated with mental stress were pre-existing symptoms present. In 10 of the 21 cases, therefore, the effect was to exacerbate a pre-existing mild form of the disease, and in all of these cases (with the exception of Case 7, in which the family history was incomplete) a hereditary history of similar attacks was present. In the remaining 11 cases the symptoms were initiated for the first time by the event, and in seven of these a family history of similar attacks was obtained.

Childbirth and mental stress seem to have been largely disregarded as possible aetiological factors in Raynaud's disease, as, apart from the 137 patients recorded by Allen and Brown (1932b), no large series of cases of this disease have been analysed. It is noteworthy, however, that these authors commented that "in a considerable number of cases the disease appears to be initiated by an operation, childbirth, infection, or the death or illness of a loved one, and these factors could doubtless be elicited in a larger percentage of cases if the patients were questioned specifically regarding this."

In this respect Case 5 in Raynaud's (1862) original thesis was a patient in whom symptoms occurred within a month of the death of the mother, and this was recorded by Hunt (1936) as being the only true example of primary Raynaud's disease in Raynaud's series. Hunt's following case (Mrs. H. G.) was also a patient in whom anxiety of the type described above was present, as she was an individual who was separated from her husband.

The menopause has been stated by Jepson (1951) to have occurred often in the condition he described as "the middle-aged female syndrome." I believe, however, that the use of such a term is not entirely satisfactory, as it is non-specific in character and, according to Jepson's description, covers a number of cases in the age group 35-55 years, in which symptoms were initiated in some instances by the menopause and in others by factors which were not discovered. If all cases of primary Raynaud's disease in this

age group are so classified it is quite probable that a number of cases will be included in which other factors in the aetiology would be disregarded. It should be noted also that, although the menopause is often the cause of symptoms severe enough to give rise to a disability and act as an initiating factor, careful questioning may well reveal that mild attacks had in fact occurred before this but were regarded by the patient as being so mild as to be of no importance.

Whether this latter group should be classified as primary Raynaud's disease or included in secondary Raynaud's disease may be regarded as controversial. Such cases do not exhibit any other signs of disease, and clinical examination fails to reveal any evidence of systemic disease—they therefore fulfil the criteria for a diagnosis of primary Raynaud's disease. To regard these cases as secondary in origin owing to their association with the menopause is no more justifiable than to regard the hereditary group, or those which occur at puberty, as falling into this category. It is believed that these cases should therefore still be included in primary Raynaud's disease.

Summary

Twenty-one cases of primary Raynaud's disease are recorded in which the digital symptoms were initiated, or pre-existing mild attacks were converted into a more severe form, at a time so closely related to childbirth, the menopause, or a period of mental stress as to indicate that these three events should be regarded as aetiological factors in primary Raynaud's disease.

These cases represent 50% of a larger series of 42 cases, in the remainder of which no such aetiological factors could be detected.

A CONTRIBUTION TO THE MYCOLOGY OF THE MOUTH

BY

E. C. FOX, M.D., L.D.S.Ed.

Department of Periodontia, University of Birmingham

AND

G. C. AINSWORTH, Ph.D.

Department of Botany, University of Exeter*

The published records of fungi obtained from the human mouth demonstrate that fungi of many types can be isolated both from apparently normal mouths and from mouths showing various disorders; in some of these diseases fungi have often been regarded as the causal agents. During recent years particular attention has been paid to mycotic infections of the oral cavity as a complication of antibiotic therapy (Cross, 1949; Tomaszewski, 1951a, 1951b, and numerous others).

The literature on the mycology of the mouth, which is both extensive and confused, will be reviewed elsewhere. Here it is only necessary to note that many of the earlier records are unsatisfactory owing to deficiencies in the clinical and mycological evidence, and that only a few attempts have been made to study the mycology of the mouth in relation to a number of fairly common oral pathological conditions.

*Now at the Commonwealth Mycological Institute, Kew, Surrey.

In an effort to supply additional data in this field, isolations of fungi were made from a series of selected cases at Birmingham Dental Hospital during 1952-5 to ascertain whether there were any relationships between fungi and certain well-known pathological conditions. Some of the findings are summarized in this report.

Methods

All the cases studied were subject to very careful clinical examination and detailed case histories were compiled. The isolations were made in the clinic by inoculating slopes of malt extract agar with scrapings taken with a sterile scalpel. Incubation was at 20-25° C., and any fungi which developed were obtained in pure culture for identification. Bacteria and actinomycetes were ignored.

Usually several attempts at isolations were made from each case by taking scrapings from different sites in the oral cavity. For any one case, however, any fungus was recorded once only—for example, as one isolate—irrespective of the number of different sites at which it was found or the number of times it was obtained from one site. In the control series (groups of schoolchildren, university students, and professional and office workers) some isolations were made as above, in others saliva was sampled by a single swabbing of the tongue, gums, and teeth, and streaking plates or slopes of malt agar with the swab within a few minutes of sampling.

Results

Of the 175 cases examined, 26 that were of miscellaneous conditions are excluded from Tables I and II. These conditions, which showed no distinctive mycological findings, were lichen planus, lupus erythematosus disseminatus, leukoplakia, fungating antrum carcinoma, and dry socket. The remaining 149 cases have been grouped as six reasonably clearly marked clinical conditions—namely, angular cheilosis, gingivostomatitis (comprising aphthous, herpetic, acute ulcerative, mycotic, and various stages of inflammatory periodontal conditions), lingua nigra, lingua geographica, coated tongue, and denture sore mouth—for which the sex and age incidences are summarized in Table I.

TABLE I.—Material

	No. of Cases	Male Female Ratio	Age	
			Range	Mean
Angular cheilosis	24	1.0	16-66	36
Gingivostomatitis	36	0.9	4-74	27
Lingua nigra	40	2.1	23-68	35
Lingua geographica	22	0.27	16-65	37
Coated tongue	20	0.43	10-61	38
Denture sore mouth	7	0.4	30-78	52
Controls	188	1.1	7-60	18

Angular Cheilosis.—This condition is characterized by cracks, fissures, and inflammatory changes at the angles of the mouth, usually accompanied by induration of the edges of the lesion. **Mycology.**—The mycological pattern was of the lesion. Only three of the 24 cases were negative for fungi and 17 of the remaining 21 yielded *Candida albicans*, one of which was in pure culture. Two of the four negative for *C. albicans* gave *C. krusei* and one *C. parapsilosis*—that is, only one case positive for fungi failed to yield a species of *Candida*. Of the other 13 species isolated, *Torulopsis glabrata* was recorded twice and the others were recorded once each. The results show a marked correlation between *C. albicans* and angular cheilosis and support the generally accepted view that *C. albicans* is present as a pathogen.

Gingivostomatitis.—This term is used to describe all inflammatory changes of the gingivae and oral mucosa. As noted above, only aphthous, herpetic, acute ulcerative (Vincent), and mycotic forms and various stages of periodontal disease are included here. **Mycology.**—The general mycological pattern resembled that for angular cheilosis. Although the proportion of cases yielding *C. albicans* was

lower than for angular cheilosis (52.8% as against 70.8%), in 14 of the 19 cases yielding *C. albicans* it was the only isolate. Two other cases gave *C. tropicalis* only. The only other species recorded more than once was *Aspergillus niger* (four times).

Lingua Nigra.—In this tongue condition there is an accumulation of densely matted patches of highly pigmented hypertrophied filiform papillae in front of the circumvallate papillae which may extend into the anterior third. The early literature on this disorder, first described by Rayner in 1835, is summarized by Swinburne (1939), and among other publications on lingua nigra the paper by Kennedy and Howles (1940) and the account by Schaffer (1951-2) may be noted. **Mycology.**—The "random" distribution of isolates from lingua nigra suggested that the isolates were present by chance and bore no causal relation to the clinical condition. This incidence of *C. albicans* was lower than in the control series, but Table II shows the incidence of fungi to have been higher than in either the controls or for angular cheilosis and gingivostomatitis.

TABLE II.—Summary of Isolations From the Controls and From Various Clinical Conditions of the Mouth

Condition	No. of Cases	No. Positive for Fungi	Isolates		
			Total	No. of Species	<i>C. albicans</i>
Angular cheilosis	24	21 (87.5%)	36	16	17
Gingivostomatitis	36	29 (80.6%)	39	17	19
Lingua nigra	40	37 (92.5%)	56	24	9
Lingua geographica	22	18 (81.8%)	35	22	8
Coated tongue	20	15 (75%)	19	10	4
Denture sore mouth	7	6 (85.7%)	8	7	2
Total	149	126 (84.5%)	193	A*	59
Controls (normal mouth)	188	124 (66.0%)	162	B*	52

* No figures are shown in A and B as the same species was often recorded for more than one condition. The net total of different species isolated was 54 for A and 37 for B.

Lingua Geographica.—This condition (see Schaffer, 1951-2) is characterized by a circumscribed circinate desquamation of the epithelium of the dorsum and of the edges of the tongue which seems to spread at the periphery whilst it is healing at the centre. It is a chronic condition of unknown aetiology which continuously changes its appearance. **Mycology.**—Table II shows the mycological pattern of the isolates for lingua geographica to be similar to that of lingua nigra. The incidence of *C. albicans* was about "normal" and the incidence of the other species recorded suggested that they were present by chance.

Coated Tongue and Denture Sore Mouth.—Coated tongue is a term applied to a non-specific furred appearance of the tongue. It is a common feature in many diseases of very varied aetiology. Denture sore mouth is a chronic erythema of the denture-bearing area of the oral mucosa and gingivae which has been attributed to traumatic, allergic, and toxic factors, and to yeasts. **Mycology.**—Fewer fungi were isolated from these two conditions of uncertain aetiology than from the other four, and the more or less random incidence of the isolates suggests that both are non-mycotic.

Discussion and Conclusions

The mycological findings from the clinically abnormal mouth must be considered against a background of the control series summarized in Table II. This Table shows fungi to have been isolated approximately as often from normal mouths (66.0%) as from abnormal (84.5%); the larger number of isolates and species from the abnormal series probably only reflecting the larger number of attempts at isolation. Little evidence was obtained of a characteristic fungus flora of the mouth. Of the 76 different species of fungi recorded, only 15 were common to the two series. Of these, *C. albicans* headed the list with 52 isolates from normal mouths and 59 from the abnormal. Only seven other species were recorded five times or more from abnormal mouths. These were *C. tropicalis* 9 isolates (5 from

the controls), *A. niger* 8 (2), *C. krusei* 7 (1), *T. glabrata* 7 (1), *C. parapsilosis* 6 (5), and *C. zeylanoides* 5 (5). The only species recorded more frequently from the control than from the pathological series was *Aspergillus versicolor* 8 (2), of which six of the isolates occurred in one group of Birmingham schoolchildren. Among all the isolates there was only one of *Absidia ramosa*, an interesting and striking contrast to the frequency of this species among isolates from animal sources (Ainsworth and Austwick, 1955) and from the sputum of agricultural workers.

When the usual significance tests are applied to the material in Table II, it is clear that there is an excess of *C. albicans* isolates in both angular cheilosis and gingivostomatitis (when they are compared with either the other pathological conditions or the controls) which is very unlikely to be due to chance. This is in agreement with the currently accepted view (see Conant *et al.*, 1954), but, bearing in mind the common occurrence of *C. albicans* in the human mouth, predisposing factors must also operate. Many factors may play a part, such as for angular cheilosis lack of vertical dimension with saliva dribbling.

The similarity between the incidence of *C. albicans* in the other conditions (25.8%) and the controls (27.7%) (see Table III) suggests that the control group is reliable and

TABLE III.—Incidence of *C. albicans*

	No. of Cases	<i>C. albicans</i> Isolates	
		No.	%
Angular cheilosis	24	17	70.8 ± 9.3*
Gingivostomatitis	36	19	52.8 ± 8.3*
Other conditions	89	23	25.8 ± 4.6*
Controls	188	52	27.7 ± 3.4*

* Standard error $\sqrt{\frac{pq}{n}}$

that the presence of *C. albicans* seems to be associated with the two specific diseases and not just with any abnormal pathological condition of the mouth. That the isolation of *C. albicans* from the mouth may have no pathological significance hardly needs reiteration, but it should be emphasized that a clinical diagnosis of moniliasis must be confirmed by culture. This is well borne out by the case of a boy aged 19 months who, on examination, showed extensive curd-like whitish plaques on the inner aspects of the upper and lower lip, floor of the mouth, and anterior third of the tongue. The plaques could be peeled off and left raw bleeding surfaces. A clinical diagnosis of oral moniliasis was made, but the only organisms cultured were *Aspergillus fumigatus* and *A. niger*. *C. albicans* is easily cultured and would appear to have been absent in this case. Unfortunately no microscopic examination was made of the fresh clinical material.

The assessment of 37 cases of lingua nigra strongly suggests that this condition is not mycotic. The number of different fungi isolated was greater than for any of the other conditions. No one fungus was isolated with regularity, and the incidence of *C. albicans* was lower than that in the normal mouth. It would appear that the proliferations of the epithelial cells provide a favourable site for the development of common saprophytic fungi. Lingua nigra is thought to be a dyskeratosis. In support of this view further evidence with full case histories will be published elsewhere.

The similar mycological pattern to that of lingua nigra shown by lingua geographica, coated tongue, and denture sore mouth suggests that fungi are not involved in the aetiology of these three conditions. No evidence was obtained for the claim that monilial infections are very often a cause of denture sore mouth. As can be seen from Tables II and III, the incidence of *C. albicans* was rather lower both in denture sore mouth and in coated tongue than in normal mouths, possibly due to the effects of bacterial competition.

It is interesting to record that during this survey no case of mycotic infection of the mouth which could be wholly

attributed to antibiotic treatment was observed. This is in agreement with Heymer and Doepfner (1957), who obtained no evidence of a higher incidence of mycotic disease of the oral cavity at the present time than that found by Knighton (1939) before the introduction of antibiotic therapy.

Summary

From the mycological findings in 149 cases of angular cheilosis, gingivostomatitis, lingua nigra, lingua geographica, coated tongue, and denture sore mouth (see Tables II and III) it is concluded that *Candida albicans* seems to play a primary part in the aetiology of angular cheilosis and has some connexion with the aetiology of gingivostomatitis. The diverse fungi associated with the remaining four conditions are of uncertain aetiological significance.

Thanks are due to Dr. C. Rainbow, department of brewing and applied biochemistry, University of Birmingham, for the use of special equipment; to Dr. C. R. Lowe, department of social medicine, University of Birmingham, for advice on statistics; to Mr. D. G. Thomson, Principal School Dental Officer, City of Birmingham, for collecting samples of saliva from schoolchildren; and to the Medical Research Council for training grants which enabled Mrs. June Robson and Mrs. Sheila Wenham to assist with mycological aspects of this investigation.

HAEMOGLOBIN J TRAIT IN TWO INDIAN WOMEN

ASSOCIATED WITH THALASSAEMIA IN ONE

BY

L. D. SANGHVI, Ph.D.

P. K. SUKUMARAN

Human Variation Unit, Indian Cancer Research Centre, Bombay

AND

H. LEHMANN, M.D., Sc.D., M.R.C.P., F.R.I.C.

St. Bartholomew's Hospital, London

Haemoglobin J was first discovered in an American Negro by Thorup, Itano, Wheby, and Leavell (1956). It has since been described in various parts of the world and in people of different racial stock. Raper (1957) found an example in a Gujarati Indian living in Uganda. This paper records the finding of haemoglobin J in two unrelated women belonging to the Gujarati-speaking Lohana. Of particular interest was that one of the two was also carrying a thalassaemia gene, and that it was therefore possible to observe the interaction of thalassaemia and of haemoglobin J.

Techniques

The haematological investigations were carried out by the accepted methods. Osmotic fragility was determined by measuring haemolysis in concentrations varying from 0.1 to 0.7% of Simmel's Tyrode solution, of which 0.4% was

taken as a critical dilution for differentiation (Silvestroni and Bianco, 1945). In more than a hundred normal adults examined haemolysis was found to be 90–100%. Foetal haemoglobin was measured according to the method of Singer, Chernoff, and Singer (1951). Electrophoresis of the haemoglobin was performed with the same haemoglobin solutions that had been used for the determination of the foetal haemoglobin. Paper electrophoresis was carried out by the hanging-strip technique as described by Lehmann and Smith (1954), and starch electrophoresis according to the method of Kunkel (1954). Electrophoresis on agar was performed according to the method described by Robinson, Robson, Harrison, and Zuelzer (1957). The plasma iron was measured after Walker (1938).

The identification of haemoglobin J was based on a comparison with known haemoglobin J samples kindly provided by Colonel W. H. Crosby, Dr. Lie-Injo Luan Eng, Dr. A. B. Raper, and Dr. F. Vella. On paper electrophoresis and starch electrophoresis at pH 8.6 haemoglobin J moves faster than haemoglobin K and more slowly than haemoglobin H (and the recently defined haemoglobin N). At pH 6.5 on paper and on agar electrophoresis haemoglobin J does not separate from haemoglobin A.

Haemoglobin A₂ was determined either by the elution of the separated haemoglobin fractions from starch or after paper electrophoresis by dyeing the dried paper strip with light green and by eluting the stain from the separated bands of haemoglobin.

The P. Family

This family was investigated after an infant had been examined because of severe jaundice 24 hours after birth. There was no haemoglobinopathy, and when the child was seen again nine months later no foetal haemoglobin was found and nothing haematologically abnormal could be demonstrated. It was, however, then noted that the infant was mentally retarded. In the routine investigation of the

FIG. 1.—Comparison by paper electrophoresis at pH 8.6 of the haemoglobin of Mrs. P. (A+J) with a haemoglobin A+K control. At the end of the electrophoresis (hanging-strip technique) the paper was dried and the haemoglobin stained with light green.

painful conditions of the nipple, such as simple pain or cracked nipple, will be expected to lead to a decrease of breast-feeding, but not necessarily to failure to gain in the infant, as a complement would be offered to avoid this. Further, it must be remembered that changes in weight gain and the introduction of bottle-feeds may be either the result or the cause of breast and nipple complications.

Table IV shows that only a small number of infants were adversely affected by their mothers' breast complications as judged by the weight criterion. On the other hand, a painful

TABLE IV

	Total	Infants Over Birth Weight on 10th Day	Infants Breast-fed on 10th Day
Complications with pain	258	52%	61%
" without pain	171	58%	78%
No. complications	598	56%	73%

or cracked nipple led to a fall in the breast-feeding rate from 73% to 61%. Common sense would suggest that this should be attributed to the pain experienced by the mother, but it is equally possible that failure to breast-feed was responsible for some of the instances of pain recorded. In any event, it can be stated that out of 306 mothers not breast-feeding on the 10th day, 33% suffered breast pain, where of the 721 mothers who were breast-feeding on the 10th day, only 23% had either a painful breast or nipple.

Summary and Conclusions

Of 1,027 mothers observed during the 10 days following delivery, 42% were found to have one or more breast or nipple complications during that time. Engorgement was most frequently encountered, particularly in elderly primiparae. This complication was not related to the infant's birth weight or the infant's sex, nor to the mother's obstetrical history. The same findings held for the next most common complication, simple nipple pain. Cracked nipples were slightly more common in the younger than the older primipara. Its incidence was unrelated to the infant's birth weight or the mother's obstetric history, but the trouble was distinctly more common in mothers with male babies.

As regards treatment of the breast complications, stilboestrol cream applied to the nipple did not decrease the incidence of simple nipple pain, but did prove slightly more useful than other methods in avoiding fissured nipples. A "no treatment" routine was found to be the best all-round method of avoiding the various complications of breast-feeding. Most of these complications were of short duration, the great majority lasting less than four days. Because of this, and because of the relatively smaller incidence of painful as opposed to painless breast complications, there was little effect on the introduction of complementary bottle-feeds. The infants' weight gain was not interfered with, as bottle-feeds were offered when necessary.

I am grateful to Mr. M. P. Curwen, statistician, St. Bartholomew's Hospital, for his expert help. I am indebted to the maternity sisters and staff nurses of Lewisham Hospital for their enthusiasm and co-operation, and to Midland Silicones Ltd. for the supply of the silicone barrier cream.

APPENDICITIS IN THE AGED

BY

ERIK CHRISTENSEN, M.B., B.S.

From Surgical Department A of the Frederiksberg Hospital, Copenhagen

Appendicitis is still a serious disease even if its mortality has fallen considerably. During 1952 there were 127 deaths from appendicitis in Denmark. The British figure for 1948 given by the Registrar-General was 1,257—that is, more than 100 people die from appendicitis every month in England and Wales (Rees, 1952). With the generally rising life expectancy, a corresponding rise has taken place in the number of appendicitis cases among older persons admitted to hospital (Stalker, 1940; Simpson, 1946; Schullinger, 1950; Boyce, 1954; Brotherus, 1955).

In Surgical Department A of Frederiksberg Hospital this rise has also been registered. As it was felt that a higher percentage of complicated cases occurred among this group of patients, the cases of appendicitis occurring in the period 1948 to 1952 were investigated.

Present Investigation

Among 1,254 cases of acute appendicitis there were 9 (0.7%) deaths (all in the group of appendicitis with perforation). Ninety (7%) of the cases occurred in patients aged 60 years and above (7%), distributed as follows: 56 aged 60–69 years, 30 aged 70–79 years, and 4 aged 80 and above, the average age being 68 years. Five of the 90 patients died, a mortality of 5.6%, while the mortality among the 1,164 patients below 60 was 0.34%.

In Table I these results are compared with the figures from similar published series.

TABLE I.—Appendicitis in the Aged

	No.	Mortality
Fitch (1928)	13	54%
Lewin (1931)	28	28%
Wood (1934)	43	28%
Taylor (1935)	20	20%
Stalker (1940)	82	15.9%
Simpson (1946)	53	25%
Schiebel and Moise (1949)	53	13%
Wolff and Hindman (1952)	88	4.5%
Surgical Dept. A, Frederiksberg Hospital (1955)	90	5.6%

In Table II a comparison is made between the 142 patients aged 30–39 years and the 90 patients aged 60 or more. The incidence of complicated cases is four times greater in the older group. This is in complete agreement with the findings of Wolff and Hindman (1952).

The cause of this high incidence of perforation in the older age group is to be sought in diagnostic difficulties. Hoffman and Suzuki (1954) maintain that "the diagnosis of appendicitis is frequently difficult in the very young, the very old, the obese, and the pregnant patient." According to Lewin (1931) and others the peritoneum of the aged reacts only slightly, and muscular guarding is seldom to be elicited, perhaps owing to slackness of the abdominal wall. He points out that the sense of pain is blunted and the bowel reflexes are weakened; this leads to less nausea and vomiting. Since many of these elderly patients are suffering from habitual constipation, the symptoms are not taken into account and perhaps only an aperient is used. The disease is thus allowed to progress before medical advice is sought. As Rolleston (1932) puts it: "The organs suffer in silence without any local or general disturbance."

From the standpoint of pathology the more widespread arteriosclerosis found leads to vascular occlusion and a correspondingly earlier onset of ischaemic gangrene and perforation. Thus Brotherus (1955), in his series of appendi-

TABLE II.—Comparison Between 90 Patients Aged 60 or More and 142 Aged 30–39

	60+ Years	30–39 Years
Acute appendicitis	42 46.2%	124 87.9%
Acute appendicitis with perforation and acute appendicitis with perforation and abscess	40 44.9%	15 9.5%
Acute appendicitis and diffuse peritonitis	8 8.9%	3 2.6%

citis cases in the aged, found that if the arteries were sclerotic a more destructive type of appendicitis arose. According to Carp and Arminio (1952) the atrophy or complete lack of lymphoid tissue follicles found at histological examination of the vermiform appendix of the aged might explain the early setting in of gangrene. A case is recorded below in detail.

A 79-year-old woman was admitted with a history of a tender lump in the right groin for five days. On examination her temperature was 37.8° C., and no signs of peritoneal reaction were seen. An irreducible, slightly tender right-sided femoral hernia was found, and the abdomen showed slight meteorism. Operation was found, and the abdomen showed slight meteorism. Operation disclosed oedema of the hernial sac, which contained a gangrenous appendix with perforation at its base and an abscess. Appendectomy, excision of the hernial sac, and a repair making use of Cooper's ligament were followed by an uneventful post-operative course.

Post-operative complications of appendicectomy are listed in Table III; these also show higher figures in the older age group.

TABLE III.—Post-operative Complications

	Patients Aged 60+	Patients Aged 30–39
Wound infection and delayed healing	10	15
Intraperitoneal abscess	2	2
Thrombophlebitis	1	0
Pulmonary embolism	3	0
Bronchopneumonia	3	0
Paralytic ileus	5	0
Cardiac incompenation	7	0
Atelectasis	2	0
Post-operative hernia	3	1

Treatment

Treatment has been along the usual lines—that is, primary operation—except when a palpable lump was present. In such cases conservative treatment with opium and antibiotics was instituted, followed by a secondary operation in the cold stage four to five months later (as in most Scandinavian departments of surgery). Eight cases among very debilitated or very fat patients were treated conservatively; in these there was no histological diagnosis. In perforated cases penicillin and streptomycin were administered, and in a few cases chlortetracycline was used. During the first four years of the period under review sulphadiazine-penicillin powder was applied intraperitoneally or subfascially; in some cases drainage of either the peritoneal cavity or the subfascial space was done. Bowel decompression by means of a duodenal tube and continuous suction was carried out as an adjunct to surgery; during the last year of the period a Miller-Abbott tube was the routine in cases of bowel paralysis.

Parenteral fluids and electrolytes, infusions of plasma, and blood transfusions were widely used. The standard approach to the appendix was through a muscle-splitting incision in the right iliac fossa. A pararectal incision was made in some very obese patients and in cases in women where doubt existed about the pre-operative diagnosis. Post-operative hernia occurred only in the drained cases, but as no follow-up has been undertaken the figures are minimal values. They are in accordance with Wolff and Hindman's (1952) figures for the same groups—namely, 3 and 0.9%.

Discussion

Our results are comparable to those found in the literature, and support the view that active treatment should be insti-

tuted in appendicitis among the aged. Furthermore, as emphasized by several authors (Povlsen, 1943; Costello and Saxton, 1951; Semb, 1953; Thomas, 1953), acute appendicitis may be the first symptom of a caecal cancer.

Three cases of caecal cancer were admitted to our department in the period surveyed (1948–52). None of these patients was over 60, but two showed signs of appendicitis. One patient with cancer of the appendix came for treatment during the period. (A woman of 61 was treated conservatively for a periappendicular abscess. Secondary operation, four months later, revealed a carcinoma of the appendix.)

In Costello and Saxton's (1951) series of 122 cases of caecal cancer the pre-operative diagnosis was appendicitis in one-fourth. Symptoms of appendicitis arise because of tumour obstruction of the appendix or its blood and lymph vessels. The surgeon may in some cases overlook the tumour; this happened in 60% of the cases in Thomas's (1953) series. Symptoms continued to be present in these patients, in several of whom faecal fistulas developed, causing an average delay of six months before the secondary operation was performed. For this reason, in some cases it was undertaken too late. Thomas advises the use of an incision large enough for inspection of the right colon in all patients over 30 coming for operation for acute appendicitis. Semb (1953) takes a more moderate view: in operations for appendicitis in the older age group the surgeon should, if possible, explore the right colon.

Summary

Appendicitis is no rarity in patients over 60 years of age. Among 1,254 cases in a surgical department 7% occurred in patients of this group.

In the older age group appendicitis very often leads to early gangrene and perforation without causing alarming symptoms. The mortality rate and the rate of complications are therefore considerable.

Early operation is advised irrespective of age. If a tender lump is felt, conservative treatment is preferred, with later appendicectomy in the cold stage.

By this early operative treatment tumours of the caecum or appendix may be detected and treated at an early stage of their development. The right colon should, if at all possible, be examined when patients of the older age group are operated upon.

The Antioxidant in Food Regulations, 1958, made jointly by the Ministers of Agriculture and Health, permit the sale and importation of certain foods containing propyl octyl, or dodecyl gallate, butylated hydroxyanisole, or butylated hydroxytoluene, or mixtures of these five substances, within prescribed limits; the regulations also lay down the manner of labelling antioxidants when sold as such and of certain foods containing them.

SALT-LOSING OTORRHOEA

BY

S. C. J. SHORTMAN, M.B., Ch.B.

AND

A. D. M. SMITH, M.B., B.Ch., B.Sc.

Department of Medicine, Bristol Royal Infirmary

Basal fractures of the skull are uncommon in children (Harris, 1957), and the following report is presented because it illustrates the development of two complications in a case of this nature.

Case Report

A boy, aged 3 years and 11 months, was admitted to the Bristol Royal Infirmary following an accident in which he ran into the road and was knocked down by a car.

On admission he was crying, and was drowsy but rousable. There was clinical evidence of a closed fracture of the right femur, and blood and cerebrospinal fluid were coming from his left ear. No other abnormality was found on clinical examination of the central nervous system. An antero-posterior view of the skull showed a vertical fracture in the middle of the left petrous temporal bone in a position to implicate the ear. Radiological examination also confirmed the presence of a transverse fracture of the upper third of the right femur. Traction was applied to the right leg and he was given 500,000 units of crystalline penicillin intramuscularly twice daily.

Thirty-six hours after admission the child complained of a severe headache and vomited. His temperature was 101° F. (38.3° C.), and pulse rate 144. Severe opisthotonos with marked head retraction was present. Lumbar puncture was performed and yielded a turbid fluid at a pressure of 50 mm. C.S.F. There were 2,000 cells per c.mm., of which 70% were polymorphs and 30% lymphocytes. The protein content of the fluid was 180 mg./100 ml. Examination of a film made of the centrifuged deposit showed numerous pus cells and possibly two isolated groups of pneumococci.

In view of these findings, intramuscular penicillin was increased to 1 mega unit four-hourly and intrathecal treatment with 10,000 units of crystalline penicillin daily was begun. Oral sulphadimidine, 0.5 g. four-hourly, was added. Cultures later confirmed the presence of pneumococci. The parents now recalled that a week before the accident the child had been seen by the school doctor for earache. Although they could not recollect which ear was painful it seemed possible that the pneumococcal meningitis may have arisen from a pre-existing ear infection.

Clinically, the patient showed a satisfactory response to treatment so far as his meningitis was concerned. Forty-eight hours after the onset, although neck retraction had increased still further, there was no disorder of consciousness to indicate deterioration. The rectal temperature had fallen to between 99 and 100° F. (37.2 and 37.8° C.). The C.S.F. showed a falling cell count, and no pneumococci were now seen on microscopy or obtained on culture. Dehydration, however, was becoming quite marked, and examination showed a dry, inelastic skin and soft eyeball tension. Oral intake of fluids was still excellent, and these were therefore increased.

Lumbar punctures on each of the first three days of treatment of the meningitis showed that the pressure of C.S.F. was very low. The fluid escaped from the needle only when the child cried. On the fourth day lumbar puncture failed. The possibility of a spinal block was considered, and because of this and the continued loss of C.S.F. from the ear, a neurosurgeon (Mr. G. L. Alexander) was asked to see the child. Cisternal punctures were attempted under both local and general anaesthesia, and because these were un-

successful tonsillar herniation was considered. A further lumbar puncture was, however, successful, and hyalase was given intrathecally with the penicillin.

The fluid balance chart for the four days following the commencement of treatment for the meningitis showed a daily oral intake of fluid of 1,290 ml., 1,780 ml., 1,300 ml., and 1,250 ml. respectively. His renal output for the corresponding period was 250 ml., 120 ml. plus wet beds, 100 ml. plus wet beds, and on the fourth day wet beds only. There was no visible sweating. The child's pillows were, however, persistently saturated by the discharge of C.S.F. from the left ear.

Five days after admission, and in spite of increased and adequate intake of fluids, it was obvious that his dehydration was increasing. The child was now apathetic and anorexic, and had generalized muscular hypotonia. The blood pressure was 95/50. Inelasticity of the skin and soft eyeball tension were more exaggerated. Examination of the electrolytes showed: plasma N.P.N., 50 mg./100 ml.; plasma Na, 122 mEq/l.; plasma K, 4.1 mEq/l.; plasma Cl, 82 mEq/l.; plasma proteins, 20.5 mEq/l. Dehydration was therefore confirmed biochemically and a profound loss of Na and Cl demonstrated.

The loss of C.S.F. from the ear continued, and it was now apparent that surgical intervention would be necessary to seal the fistula. On the evening of the sixth day after admission the child was transferred to the neurosurgical unit at Frenchay Hospital. The next day left temporal craniotomy and exploration of the upper surface of the left petrous bone was performed (Mr. G. L. Alexander). No crack or leak was seen, and muscle was tacked in blindly beneath the dura below the petrous ridge. The wound was closed.

The first operation was unsuccessful, and Mr. Alexander carried out a second operation four days later. During the period between the two operations the child's fluid intake by mouth had continued to be excellent, and in addition 3 g. of extra salt was given daily.

At the second operation retromastoid exposure of the petrous bone was performed. A vertical crack was seen in the petrous bone, occupying most of its length and extending down to the jugular foramen. No fluid could be seen escaping, but a thin layer of extradural blood clot was organizing over the fracture. This might have obscured a small opening. A sheet of muscle was laid in an extradural position and the wound closed.

This procedure was a complete success. The C.S.F. otorrhoea ceased and all clinical signs of dehydration disappeared. Two days later antibiotic therapy was discontinued. Estimation of the blood electrolytes showed them to be entirely normal. Treatment of the fractured femur was continued, and eight weeks after admission the child was returned home, having made an excellent recovery. His C.S.F. then showed no abnormality.

Discussion

There is no doubt that the low sodium chloride in the blood of this patient was due to the copious loss of C.S.F. from the ear as a result of the fractured base of skull. Most fistulous fractures into the ear seal off spontaneously, and it is very rarely necessary for the surgeon to have to explore the posterior fossa in order to stop an aural leak (Alexander, 1958, personal communication).

Pneumococcal meningitis itself still carries a very high mortality in spite of modern antibiotic therapy (Pengelly, 1955). Electrolyte imbalance is a well-recognized complication of cerebral lesions, and if a condition of hyponatraemia and hypochloreaemia is met with during the course of a meningitis three possibilities usually present themselves.

Doxiadis *et al.* (1954) studied 19 children with tuberculous meningitis and came to the conclusion that a correlation was to be found between the abnormal electrolyte pattern and the occurrence of serious vomiting. In this case no vomiting

Medical Memoranda

Sensitivity to Penicillin in British Poliomyelitis Vaccine

This poliomyelitis vaccine contains a small amount of penicillin. In a recent reply to a question regarding the safety of giving it to a penicillin-sensitive person, it was stated, "To our knowledge no report has been made of any case of sensitization to the antibiotics" (*Brit. med. J.*, 1958, 1, 1555). In view of this reply, and the increasing use of the vaccine, the following report of a case may be of general interest.

CASE REPORT

An apparently healthy boy aged 12 was given an injection of 1 ml. of the British vaccine into the left upper arm. He had a history of sinus trouble, and was known to be sensitive to penicillin, having developed a generalized erythematous rash during treatment with the drug following a toe injury. There was no history of any other specific allergic disorder, and he had never had an attack of bronchospasm. In his family, two maternal aunts have skin disorders. One develops eczematous reactions when in contact with the metal of jewellery and suspenders. The other has urticarial reactions with no apparent specific cause.

The day after the injection I was called to see the boy. He complained of a severe frontal headache, and was lethargic, anorexic, and generally unwell. A few hours after the injection a sparse itchy rash had appeared on the trunk and limbs, with the rapid development of vesicles, especially on the right buttock and leg. He was apyrexial, the chest was clear, and there were no abnormal signs referable to the central nervous system. Treatment with an antihistamine was begun with good results.

Three days after the injection, however, he complained of breathlessness and of a tight feeling across the chest. Bronchospasm was present, but was quickly abolished with an antispasmodic. Treatment with this and the antihistamine was continued. Six days after the injection a dose of the antihistamine was missed. He felt worse generally, and the bronchospasm returned, but settled when treatment was resumed.

Though the acute chest and skin symptoms and signs settled, the headache persisted, being severe at times and difficult to relieve. The general malaise also remained. He was therefore examined by Dr. J. P. Bound, consultant paediatrician, Victoria Hospital, Blackpool, who agreed, however, that there were no abnormal signs referable to the central nervous system.

After 10 days the persistent symptoms began to improve, and on the thirteenth day treatment was stopped, with no recurrence of them. He had been apyrexial throughout. Eleven days after treatment ended (twenty-four days after the injection) the signs and symptoms of mumps appeared.

COMMENT

In view of the known sensitivity to penicillin in this case, and the absence of other precipitating factors, I think that the skin reaction must be considered as part of a sensitivity reaction to the small amount of penicillin in the vaccine. The bronchospasm may have been related. The precise origin of the severe headache must be conjectural.

A. FOWDEN, M.B., Ch.B.,
General Practitioner, Blackpool.

Treatment of Cardiac Arrest

Several articles on cardiac arrest have appeared in the medical press (*Brit. med. J.*, 1956; Briggs *et al.*, 1956; Milstein, 1956; O'Reilly and Ohlke, 1956; Wylie, 1956). These have stimulated us to consider afresh how our efficiency in dealing with this emergency can be improved. As Milstein (1956) has said, cardiac arrest is an emergency which may suddenly face any surgeon, anaesthetist, radiologist, or physician, and it is well that even the most junior member

was encountered after the three hours during which the acute meningitis became clinically apparent, and hence this possibility is excluded.

Welt *et al.* (1952) discuss the salt-wasting syndrome which has been described in a group of patients with a variety of cerebral lesions (Peters *et al.*, 1950). The very nature of the cerebral disease, which was diffuse in each instance, defied any attempt to analyse the site of the responsible lesion. It would seem that hypothalamic involvement leads to renal tubular loss of sodium and chloride. These patients, however, responded favourably to the administration of salt; this was not so in the present case.

Adrenal apoplexy due to the Waterhouse-Friderichsen syndrome presents a typical fulminating picture; this was not seen during the evolution of the present case, and can undoubtedly be dismissed on clinical grounds alone.

The normal daily production of cerebrospinal fluid in a patient of this age is only 100–150 ml., but it has been shown that if artificial drainage is provided several litres a day may be produced (Best and Taylor, 1955). It is impossible to estimate the amount of C.S.F. lost by this child, but it must have been considerable. On one day alone, the child received 3,050 ml. of fluid plus additional salt orally and 925 ml. of normal saline intravenously. In spite of this, although the clinical evidence of dehydration became less marked, the blood electrolytes failed to return to normal. The low pressure of the cerebrospinal fluid is probably another indication of the seriousness of the leak. It was only after the fistula was sealed off surgically that the patient rapidly improved and the blood electrolytes returned to normal values.

Summary

A case is presented in which a child sustained a fracture of the base of the skull complicated by pneumococcal meningitis and a copious C.S.F. otorrhoea.

The loss of C.S.F. induced serious dehydration due to a "salt-losing" syndrome, and surgical intervention was necessary to close the fistula.

Our thanks are due to Professor A. V. Neale for much helpful criticism and advice. We are also grateful to Dr. J. E. Cates, Mr. G. L. Alexander, and Mr. A. L. Eyre-Brook, under whose united care the patient came during his stay in hospital, for permission to publish this case.

"There appear to be two schools of thought as to the duty of hospitals towards the elderly. One is to try to provide little else than a permanent residence for as many as possible and the other is to consider each admission to be temporary unless or until continuous care is proved to be unavoidable. The former system will give permanent care only to the few who are admitted. These will be well looked after while a vast and increasing majority will continue in distress. The latter system, on the other hand, makes the hospital service available to a larger number of people because beds will become vacant by frequent discharges. It will be possible to give early treatment and care to those who need it when they need it and enable them to return to the community, which is surely a hospital's purpose."—Report to December 31, 1957, of Hospital Personal Aid Service for the Elderly (King Edward's Hospital Fund).

of the hospital staff should know what are the essential steps in initiating immediate and adequate cardiac massage. In a patient who is well oxygenated before cardiac arrest, the maximum time which can be allowed before the establishment of artificial circulation is three and a half minutes; if, as so often happens, hypoxia has been a contributing factor in causing the arrest, then the time limit before irreversible cerebral damage occurs is even shorter than this.

The steps necessary for establishing cardiac massage through a thoracotomy incision are unfamiliar to most general surgeons and other clinicians, and they very often

cardium must be incised. (5) Adequate cardiac massage produces a palpable peripheral pulse and a systolic pressure of 70-80 mm. Hg; therefore an assistant must check the blood pressure while massage is being continued. (6) The rate of massage depends chiefly on the speed with which the ventricles fill during diastole. (7) Electrical defibrillation should not be attempted by anyone who is not familiar with this procedure.

The chart has been divided into two sections in order to emphasize that the only treatment necessary *without delay* is the institution of *efficient cardiac massage*; once adequate

MANAGEMENT OF CARDIAC ARREST

DUTIES OF PERSONNEL

ANAESTHETIST	SURGEON	NURSE	ASSISTANT SURGEON	OTHERS
1. When carotid pulse cannot be felt or heart cannot be heard inform surgeon and ask assistant to record time. 2a. Stop all anaesthesia. 2b. Respire patient with 100% oxygen. 2c. Tilt patient head down 15 degrees. 2d. Pass endotracheal tube as soon as possible. 3a. When cardiac massage is established check radial or carotid pulse. 3b. Check B.P.	1. When possible confirm presence or absence of pulsation in aorta. 2a. Open left chest in 4th interspace with transverse incision from sternal margin to mid-axillary line. 2b. Massage the heart.* 3. When adequate massage has been continued for 3 minutes, pause to see if contractions have returned; if not, follow col. 2 below.	1. As soon as absent pulse is reported bring emergency thoracotomy set. 2. Bring emergency tray of syringes and drugs. 3. Start I.V. if no one else is available.	1. Insert rib spreader and cut 1 or 2 adjacent cartilages for adequate exposure. 2. Stand by to relieve surgeon massaging the heart. 3. Start I.V. if no one else is available.	1. One person call out time at one minute intervals until adequate massage is established. 2. One person start I.V. and assist anaesthetist.

Don't—Wait for electrocardiograph or cardioscope to diagnose and begin treatment. An absent B.P. and absent pulse in a major vessel (e.g., carotid) means cardiac arrest.

Don't—Give drug of any type until type and cause of arrest is determined.

Don't—Fiddle and hope the heart restarts. You have only 3 minutes to establish circulation before irreversible damage occurs. So cut and massage.

Possible situation existing after adequate Massage and Oxygenation.

- The heart resumes a normal beat
 - Continue massage in rhythm with beat until contractions are vigorous and B.P. is maintained at 80 systolic.
 - If contractions do not improve or if they become weaker give adrenaline 1:1,000 0.5-1 ml. into the cavity of the right ventricle.
 - If the heart is contracting well but the B.P. remains low a noradrenaline (4 mg. in 500 ml. 5% glucose) drip should be started.
 - Observe the heart for at least 30 minutes of adequate action before closing the chest.
 - Close the chest with adequate haemostasis.
- The heart remains in arrest
 - Open the pericardium.
 - Observe the action of the ventricles for diagnosis.
 - Observe the colour of the heart: if it is well oxygenated it will be a good pink colour.

A. The heart is in fibrillation

- Procaine 1% 2-10 ml. into cavity of right ventricle.
- Give CaCl 10% 5-10 ml. into cavity of right ventricle.
- Massage for 3 minutes awaiting action of procaine.
- If no result use electric defibrillator (one of the thoracic surgical unit or a senior anaesthetist will be responsible for this).
- If shock is ineffective (or defibrillator is not available) give adrenaline 1:1,000 0.5-1 ml. into cavity of right ventricle.
- If spontaneous beat returns follow col. 1.
- If heart is in asystole follow col. 2 B.

B. The heart is in asystole

- Continue adequate massage.
- Give CaCl 10% 5-10 ml. into cavity of right ventricle.
- If asystole persists and the heart is a good colour, give adrenaline 1:1,000 0.5-1 ml.
- If heart beat returns follow col. 1.
- If asystole persists continue massage up to two hours or until the heart fails to fill in diastole.

*CARDIAC MASSAGE

Adequate Cardiac Massage should produce a palpable peripheral pulse and should be carried out thus:

Grasp the heart with the whole hand, apply pressure with the palmar surfaces of the fingers and the thenar eminence. Do not use the finger-tips. If the heart is large use both hands. 80-90 contractions per minute is the most effective rate, but this may be difficult to maintain. The rate must be slow enough for the heart to fill during diastole, and the maximum rate possible may be only 60-80 per minute.

The cerebral and coronary circulations can be improved by occluding the aorta below the origin of the left subclavian artery. The clamp should be released every 20 minutes to allow circulation to the kidney.

hesitate too long before embarking upon what seems to them a very drastic procedure. Even when the chest has been opened and the heart exposed there is much uncertainty about the correct way to massage the heart, and valuable time may be wasted injecting drugs which can do more harm than good at this stage. It has therefore seemed good to us to follow the example of Nowill and Hobler (1956), who have reported their chart on "The Management of Cardiac Arrest."

After consultation with the surgeons and their assistants who may need the help of such instructions we have modified the chart to include only the information that is immediately necessary, first, to establish adequate cardiac massage, and, secondly, to re-establish spontaneous cardiac action.

We have stressed the importance of the following points:

- The thoracotomy incision must be large enough to allow good exposure of the heart. (2) Because of the danger of rupture of the ventricles the finger-tips must not be used to massage the heart; if the heart is compressed between the thenar eminence and the palmar surfaces of the fingers this danger is avoided. (3) Drugs must not be given until adequate massage has been continued for at least three minutes and until the type of arrest has been diagnosed. (4) This diagnosis cannot be made until the pericardium has been opened; therefore, if the heart does not start contracting within three minutes of the onset of massage the peri-

culation has been established there is time to consider the next steps that may be necessary to restore spontaneous action. A sterile emergency thoracotomy set is always ready in every operating suite of our hospital and is available also for the x-ray rooms in which the cardiac and neurological diagnostic procedures are carried out, since these adjoin the main operating theatres.

The chart is hung in every scrub-room in a position where it can be studied by surgeons, nurses, and anaesthetists whenever they wash their hands, and a copy is given to each new resident together with further information that will enlarge upon some of the points given in the chart.

No doubt many hospitals have a similar routine worked out already, but, since we have seen no reference to such a chart in the British medical literature, we think that publication of our chart may be of value.

Reviews

PNEUMOENCEPHALOGRAPHY

Pneumoencephalography. By E. Graeme Robertson, M.D. (Melb.), F.R.C.P., F.R.A.C.P. (Pp. 482+xxi; illustrated. £5 10s. 6d.). Oxford: Blackwell Scientific Publications. 1957.

Dr. Graeme Robertson has been keenly interested in the technique of encephalography for many years, his first paper on this subject appearing in 1941. The present volume gathers together previously published material and presents his very considerable experience in the use of this valuable method of investigation. It is always a matter to marvel at that bubbles of air introduced by lumbar puncture can be persuaded, by appropriate positioning of the patient, to pass by a devious route into the ventricles of the brain. The first part of this book deals with the anatomical and physical factors governing the successful passage of air and describes the ingenious apparatus by which the author studied the entry of air into the lateral ventricles depends largely upon a flow of cerebrospinal fluid from the convexity subarachnoid spaces, thus allowing a slight expansion of the lateral ventricles, which renders their pressure lower than that within the third ventricle. The physical factors show that the passage of air through the aqueduct and other narrow orifices depends upon the diameter of these "narrows" and the surface tension of the fluid. The technique of pneumoencephalography is given in detail, including advice on the important items of speed of injection, time intervals at which the ray films should be explored, and the position in which the head should be placed. Most failures of encephalography—excepting those due to the nature of the lesion—result from the head being flexed too much or too little during the introduction of the air. The rest of the book—about three-quarters—forms an atlas of the normal appearances and the most frequent abnormalities. An advantage of encephalography over ventriculography is the ability to demonstrate (and to recognize) the various cerebrospinal fluid cisterns. The value of this in the diagnosis particularly of posterior-fossa and of basal lesions has only been appreciated in recent years, and the author has given proper prominence to this aspect of his subject.

The book is beautifully produced, with superb illustrations, the radiographic reproductions being for the most part excellent. There are many line drawings which are most helpful in clarifying the shadows of air seen in accompanying radiographs; these have been executed by the author, and with their stippling and hatching in contrasting colours and set a high standard. Both author and publisher are to be congratulated; and neurosurgeons and those radiologists whose work includes encephalography cannot fail to gain enjoyment and instruction from studying this volume.

D. W. C. NORTHFIELD.

HOMOSEXUALITY

Homosexuality: A Subjective and Objective Investigation. British edition edited by Charles Berg, M.D.; American edition edited by A. M. Krich. (Pp. 415. 30s.) London: George Allen and Unwin, Ltd. 1958.

Female Homosexuality: A Psychodynamic Study of Lesbianism. By Frank S. Caprio, M.D. Foreword by Karl M. Bowman, M.D. (Pp. 334+xxviii. 30s.) London: Peter Owen Ltd. 1957.

Homosexuality: Its Nature, Causation, and Treatment. By Clifford Allen, M.D., M.R.C.P., D.P.M. (Pp. 143. 15s.) London: Staples Press Ltd. 1958.

Live and Let Live: The Moral of the Wolfenden Report. By Eustace Chesser. Foreword by Sir John Wolfenden. (Pp. 126. 8s. 6d.) London, Melbourne, Toronto: Heinemann. 1958.

The authors or editors of these four books agree that the prevalence of homosexuality (however defined) is commonly unsuspected; that the whole subject is surrounded by emotion and prejudice; and that ignorance concerning homosexuality is widespread and should if possible be overcome. The emphasis is on exposition and interpretation. The

reader will seek in vain for new proven facts that add to knowledge, although much that is known or considered probable as regards causation, incidence, manifestations, and possibilities in treatment is recapitulated or rehearsed, with, however, so many personal trimmings that "you can't see the fish for the parsley."

The book edited by Dr. Krich is a scissors-and-paste production or anthology of "the thoughtful studies of more than thirty authorities on the subject," to which Dr. Berg has added a discursive "Editorial Survey" for the English edition in which he expounds his own views. (The emphasis Dr. Berg himself lays upon the fetishistic element in homosexuality is interesting.) The field drawn upon is wide and includes many well-known names, ranging from Hirschfeld to Freud and beyond. The numerous papers and extracts reprinted here vary greatly in date, length, value, and interest. Why this particular selection of writings on homosexuality and allied topics should have been chosen is not clear; the effect of the book is kaleidoscopic and confusing.

Dr. Caprio points out that the subject of female homosexuality has been strangely neglected; but he has muffed his chance. It might be argued that much of his book does not rise above the level of traveller's anecdote—some of it interesting. Here too the orientation is interpretative. The rules are: don't be taken in by the obvious; things may (rarely) be what they seem, but are more probably the opposite. For example: "In short, many prostitutes are latent homosexuals in so far as they resort to sexual excesses with many men to convince themselves that they are heterosexual." Although "psycho-analysts have demonstrated" that this is so—only the naïve would suppose that girls become prostitutes because they like the life and the pay—Dr. Caprio considered that confirmatory field work was called for. Accordingly he embarked upon a world tour "from China to Peru," not omitting "London, England; Paris, France," "Whenever necessary" (for example, "Tokyo, Japan; Bombay, India") "I engaged the services of a taxi-driver who acted as interpreter during the interviews with prostitutes." The results obtained confirmed Dr. Caprio's expectations.

Dr. Allen, whilst recognizing that homosexuals, "like Leonardo da Vinci, are sometimes very creative," is a firm advocate of the view that "homosexuality is just as much a disease as cancer or hysteria." The psychogenic origin is proved by the excellent response, in skilled hands, to psychotherapy, as to the efficacy of which Dr. Allen draws special attention from his own experience in private practice. "It is well known that homosexuals dislike attending clinics and do not respond half so well as when treated privately." Concerning prevention, Dr. Allen claims: "It is unkind to force milk puddings on a child who is trying (by hating them) to overcome its longing for milk"—that is, presumably from the maternal breast, and hence a "mother fixation" danger, and hence possible homosexuality. Many of us may never have connected milk pudding with homosexuality in any way; the deeper significance of a "cissie" being a "milkop" had probably escaped us.

Dr. Eustace Chesser has produced another confident and fluently written little book on a sexual topic. It is commended by Sir John Wolfenden in a foreword in which he stresses the importance of being broad-minded.

Much in these books can justly be criticized for lax thinking, unverified speculation, and complacent dogmatism. All four—with the possible exception of the anthology, which does include some valuable pieces—can safely be omitted from our library lists. It is, however, important to stress that the works reviewed here are not representative of informed medical opinion on the subject. The major part of the medical evidence submitted to the Wolfenden Committee rightly impressed the lay as well as the medical members by its high standard, able presentation, critical approach, and modesty in claim. For those who want to read a short, informative monograph, *Homosexuality*, by Dr. D. J. West (Duckworth, London, 1955), can be commended.

DESMOND CURRAN.

PSYCHO-ANALYSIS OF THE CHILD

The Psychoanalytic Study of the Child. Volume XII. Managing Editors: Ruth S. Eisler, M.D., Anna Freud, LL.D., Heinz Hartmann, M.D., and Ernst Kris, Ph.D. (Pp. 417. 50s.) London: Imago Publishing Company, Ltd. 1958.

The first section of this new volume of the series contains six papers which are classified as "Contributions to Psychoanalytic Theory." Of these the first, "The Nature and Development of the Concept of Repression in Freud's Writings," by Charles Brenner, gives a historical survey of the kind that is invaluable in the teaching of psychoanalytical theory to students. When Freud's work is presented in this way it seems logical to expect developments in the theory, and the student is not left with a sense of a closed system. Phyllis Greenacre, in "The Childhood of the Artist," tries to get at some of the elements of genius apart from those that are a "gift from the gods," and she discusses the "love affair with the world which seems to be an obligatory condition." Loewenstein examines interpretation in the "Theory and Practice of Psychoanalysis," concluding with the comment that "every psychoanalysis can and perhaps ought to be conducted as though the theory were never completely taken for granted." In the second section, named "Aspects of Early Development," an analyst gives a description of his own child who at 10 months discovered his genital. The relationship of this discovery to his emotional development in general is of great interest. In another intimate study, by William Niederland, the earliest dreams of a child are recounted. This was possible because the mother was in analysis—a fact which enabled the author to have a full biographical background of the dreamer and of his immediate environment. The dreams were experienced in a non-therapeutic situation and communicated spontaneously and verbally. They represent "a sort of recorded longitudinal dream history during the first years of life." The first was a nightmare and non-verbal, occurring when the boy was 17 months old. In another chapter in this section various authors draw attention to the effect of inconsistencies in the mother on the character development of children. In the clinical section, consisting of seven short contributions, there is one by Margarete Ruben which describes a boy of 10 who was treated for delinquency. The delinquency was a defence against loss of objects and reality. In the "Applied Psychoanalysis" section there is a study of the childhood of Stanislavski by Philip Weissman.

I can only pick out what interests me most when reviewing these volumes, of which this number is a good sample. Volume XIII will be published in November, 1958, and will be dedicated to the memory of Ernst Kris, and the present volume starts with an appreciation of Kris by Heinz Hartmann.

D. W. WINNICOTT.

BRITISH SURGERY

Textbook of British Surgery. Edited by Sir Henry Souttar, C.B.E., D.M.(Oxon.), F.R.C.S., and J. C. Goligher, Ch.M.(Edin.), F.R.C.S.(Edin. and Eng.). Volume 3: Genito-Urinary Surgery—Peripheral Vascular Diseases—Plastic Surgery—Actinomycosis—Surgery in the Tropics—Venereal and Allied Diseases—Radiology and Radiotherapy—Surgery of the Adrenal and Parathyroid Glands—Blood Transfusion—Fluids and Electrolytes—Haemorrhage—Chemotherapy. (Pp. 619+vii; illustrated. £5 5s.) London: William Heinemann Medical Books Ltd. 1958.

The first two volumes of the *Textbook of British Surgery* have already been very favourably reviewed; it is therefore pleasing to record that the present third volume (of four) maintains the characteristics and high standard of the previous issues. The subjects covered include genito-urinary surgery—a textbook in itself of 150 pages; a considerable section on vascular surgery, which modern work on the subject clearly demands; plastic surgery, including a special chapter on the hand; and radiology both diagnostic and therapeutic, giving a sufficiency of information for the general surgeon. Other rather less extensive sections deal

with surgery in the tropics, venereal diseases, the adrenal and parathyroid glands, actinomycosis, blood transfusion, electrolytes, shock, and chemotherapy. The information provided in all parts of the book is up to date and well suited to the needs of candidates for the higher examinations. The numerous illustrations are maintained at an excellent level of reproduction.

As was commented in reviewing the second volume, the proof-reading could have been more carefully done, so that there are numerous spelling and other errors, such as "anastomosis" for "anastomosis," vaso-epididymal "reflex" for "reflex," "right" side of scrotum when "affected" side is meant, and so on. The use of the term "radial" instead of the commoner "radiation" is probably etymologically correct, but in this particular application is perhaps ambiguous in view of its usual anatomical use—for example, radial nerve. One error almost verges on the comic when we read that if, for incontinence, a ureterocolic anastomosis is impossible "an ideal hoop may help." But the fact that I have mentioned these small points shows that I have no major criticism to offer of the work as a whole, for it appears to be a well-balanced account of present-day British surgery.

NORMAN C. LAKE.

COLD COMFORT

Doctor Tonrondo. By Owen Guinness. (Pp. 352. 16s.) London: Chapman and Hall, Ltd. 1958.

This is a story about Wales, where (as all Englishmen know already) the farmers go to bed in their best boots after leaving milk and honey on the doorstep, to assure the fertility of their unions. The result of one of them is a brilliant young man who takes up medicine and marries an Englishwoman who (as all Welshmen know already) are dreadfully frigid. Mrs. Tonrondo's sexual disability appears, understandably, on a honeymoon in a Welsh hotel, with the landlord stoking up the husband with whisky downstairs while an engraving of the local preacher glares down on the marriage bed. Her difficult clinical problem is resolved suddenly on page 157, and she becomes in time the mother of two little psychopaths. But her constitutional coldness sends her husband on all manner of adventures, including a rather jolly romp with two barmaids up a mountain. It is all treated with disarming gusto, and might have been written by Mr. Eric Linklater while he was still a medical student. The editorial staff of the *B.M.J.* may be gratified to learn of the hero's first reaction to his agonizing marital crisis—"He paced wildly round the room, picking up old *British Medical Journals* and staring at them."

RICHARD GORDON.

The Evolution of Modern Medicine, the first Maurice Bloch Lecture, delivered at the University of Glasgow by Lord Cohen of Birkenhead in October, 1957, has now been published by Jackson, Son and Co., Ltd., 73, West George Street, Glasgow, C.2 (pp. 30; 5s.).

A symposium on hospital coccal infections arranged by the Association of Clinical Pathologists and the Committee on Cross-infection in Hospitals of the Medical Research Council took place in London on January 2, 1957. A report of the proceedings (*Hospital Coccal Infections*; Swan Press Ltd., 20, Bakers Row, E.C.1; 3s. 6d.), edited by R. E. O. Williams and R. A. Shooter, contains 14 papers and accounts of the discussions. The papers are in four groups: general aspects, infection in operating theatres and in wards, and methods of control. All who are faced with the problems of staphylococcal cross-infection—and in surgical and maternity hospital practice who, at some time, is not?—will find this booklet a useful compendium of information on the investigation of such outbreaks and on measures for dealing with them, including the control of ventilation, methods of sterilization, and the treatment of carriers.

Psychiatry in the Modern World, by Dr. E. B. Strauss (pp. 71; Michael Joseph, Ltd., 8s. 6d.), which appeared originally as a series of articles in the *Sunday Times*, is an outline of the nature and causation of mental and emotional disorders, written primarily for the non-medical reader.

SATURDAY OCTOBER 4 1958

PATHOGENESIS OF FEVER

It has long been thought possible that naturally occurring fever might be due to endogenous pyrogenic substances. In fact almost one hundred years ago Billroth,¹ Weber,² and Frese³ independently showed that pus can cause fever when injected into animals. However, it always seemed likely that this effect was due to the presence of bacteria, especially since the discovery that endotoxins from many organisms, notably Gram-negative bacilli, cause pyrexia on injection.⁴

These endotoxins are heat-stable polysaccharides or lipopolysaccharides, and it is they which under the name of pyrogens contaminate injection solutions and apparatus and give rise to febrile reactions. Polysaccharides with similar properties exist also in the body tissues and even in the skin of fruits. V. Menkin described a substance in inflammatory exudates called by him "pyrexin" which produced fever on injection.⁵ The properties of pyrexin make it almost certain that it belongs to the group of polysaccharide pyrogens. Its source may have been contaminating bacteria or tissue polysaccharide. The pyrexia which follows injection of all such polysaccharides has certain well-defined characteristics, recently described by W. B. Wood.⁶ There is a relatively long latent period between the injection and the onset of fever. After the injection there is a leucopenia, which is ultimately replaced by a leucocytosis. Another important sequel, observed only after repeated, frequent injections, is that the animal acquires tolerance. It becomes immune to the pyrogenic action not only of further injections of endotoxin but also of infections and trauma. The immunity is non-specific between different endotoxins, disappears

within about two weeks, and is not due to formation of antibodies.

The recent sweeping advances in the study of the pathogenesis of fever were ushered in by the discovery that saline extracts of polymorphonuclear leucocytes cause pyrexia on injection into animals.⁷ The importance of this observation lies in the differences between the properties of leucocytic pyrogen and those of the endotoxic pyrogen described above. The fever caused by leucocytic pyrogen has only a short latent period and is not associated with significant leucopenia. In addition, leucocytic pyrogen fails to cause tolerance, is fully active in animals rendered tolerant by endotoxin, and is partly species-specific in its action. The next major advance was the discovery that injection of bacterial pyrogen in the form of typhoid vaccine was followed by the rapid disappearance of this endotoxin from the circulation and the equally rapid appearance in the blood of a pyrogenic substance with all the properties of leucocytic pyrogen. The concentration of this leucocytic-pyrogen varied directly with the height of fever.⁸⁻⁹

These experiments showed that the fever which follows injection of endotoxin is due to release of endogenous pyrogen of the leucocytic type, probably because of damage to the polymorphs themselves. That it is this substance which acts on the thermoregulatory centre in the brain was shown by injecting both types of pyrogen into the carotid artery and a peripheral vein. Endotoxin caused a similar delayed response when injected by both routes. Leucocytic pyrogen, on the other hand, yielded a more rapid and intense pyrexia when given into the carotid artery than into the venous system.¹⁰

Study of the pathogenesis of fever in experimental infections has shown that injection of influenza virus is followed by the appearance in the animal's circulation of a pyrogenic substance indistinguishable from leucocytic pyrogen.¹¹ In pneumococcal peritonitis in rabbits leucocytic pyrogen has been detected¹²⁻¹³ at the height of the infection in the peritoneal exudate, in lymph from the thoracic duct, and in the circulation. The pyrogen disappeared after penicillin therapy had led to defervescence. In experimental cellulitis induced by group-A haemolytic streptococci, in which, unlike the pneumococcal experiments, there was no septicaemia, similar results have been obtained.⁵

It would seem desirable to repeat some of these experiments in species other than the rabbit. The suppression of naturally occurring fever by measures antagonistic to leucocytic pyrogen would also provide useful evidence. Nevertheless, it seems likely that, as Wood has stated,⁶ the cause of fever in acute

bacterial infections has been established. It is also apparent that hypotheses based on experimental infections can be extended to some types of naturally occurring fever, though leucocytic pyrogen, whose chemical nature is not yet known, has been detected so far only in polymorphonuclear leucocytes. These successful experiments lend great encouragement to those research workers who look for endogenous mechanisms in inflammation and other bodily reactions to injury, and the imagination is stirred by the thought that fever, one of the most ancient signs of illness, is at last yielding up its secrets.

DIAGNOSIS OF HYPERPARATHYROIDISM

Primary parathyroid overactivity is not a common disorder, but it can no longer be described as rare. Unfortunately the clinical picture, which may include anorexia, constipation, polyuria, and hypotonia, is not a specific one, and the patient usually presents with some complication such as renal calculus, renal failure, or pathological fracture. Once the disorder is suspected the diagnosis becomes a biochemical problem, and the investigation tends to be a protracted affair entailing considerable laboratory work and frequent abortive discussions between biochemist and clinician before the decision to operate is finally reached. Discussion usually turns on the reliability of the serum-calcium estimations and the significance of hypercalcaemia, and is inevitably influenced by the technical difficulty of parathyroidectomy and the consequent reluctance to advise exploration in the doubtful case.

There is general agreement at the present time on the paramount importance of accurate estimation of serum calcium in the diagnosis of primary hyperpara-

thyroidism, and this point was emphasized again in a letter from W. M. Keynes which appeared in our correspondence columns recently.¹ It is therefore unfortunate that the application of flame photometry to the estimation of calcium has presented a number of technical problems which are only now being overcome.² However, it is when the presence of hypercalcaemia has been convincingly established that the diagnostic problem really begins, for it is not always easy to exclude other causes of this abnormality.

Exclusion of the diagnosis of sarcoidosis may be helpful by giving cortisone,³ and the same presumably applies to adrenal insufficiency.⁴ Myelomatosis can usually be diagnosed by the examination of proteins in plasma and urine. In milk-alkali syndrome and hypervitaminosis D the serum calcium returns to a normal level soon after withdrawal of the offending agents. Malignant disease may be exceedingly difficult to exclude, since it can be associated with hypercalcaemia even in the absence of bone metastases.⁵

The finding of a consistently low concentration of inorganic phosphate in the serum is another diagnostic point in favour of hyperparathyroidism. This low serum phosphate is usually associated with a high renal clearance of phosphate.⁶ Some workers express this as a phosphate/creatinine clearance ratio,⁷ whereas others employ the converse value—tubular reabsorption of phosphate.^{8,9} Like most biochemical tests, these procedures may yield both false negative and false positive results,¹⁰ and it is particularly confusing that some patients with hypercalcaemia not due to parathyroid overactivity have recently been shown to excrete abnormally large amounts of phosphate.⁸

A number of other features of primary hyperparathyroidism are inconstant and their diagnostic value is as yet unknown. The incidence of peptic ulceration and gastro-intestinal symptoms is high,¹¹ which may well be attributable to the hypercalcaemia, and pancreatitis has also been seen.¹² The serum-alkali reserve is said to be low rather than high even in the absence of renal failure,⁸ and polyuria¹³ and potassium depletion¹⁴ are sometimes found. Examination of the neck for a palpable tumour should never be omitted,¹⁵ and barium swallow¹⁶ and angiography¹⁷ have helped to locate the tumour. Osteitis fibrosa is the classical skeletal disorder, but the commonest bone lesion is probably osteoporosis,¹⁵ and even rickets has recently been reported.¹⁸ Some workers claim that resorption of bone at the distal ends of the clavicles is the earliest radiological change.⁷

The knowledge that renal calculus is the commonest complication of primary hyperparathyroidism

continues to trouble the practising urologist, who urgently requires some simple screening procedure. Recently G. L. Mouzas¹⁹ reported the results obtained with a test entailing the simultaneous collection of samples of blood and urine for the estimation of calcium, phosphate, and creatinine. The object was to determine not only the serum concentrations of calcium and phosphate but also their urinary excretion. Since the cases in which Mouzas obtained results suggestive of parathyroid overactivity had not been surgically explored at the time of publication, the true value of this screening test remains uncertain.

The present situation is unsatisfactory, and perhaps progress will have to await the assay of the hormone itself in the body fluids. B. M. A. Davies²⁰ has reported some interesting results on the measurement of parathyroid activity in urine, but existing bioassay methods are relatively crude, and the purification of the hormone is still in its infancy.²¹ When it becomes possible to measure with ease the hormone in blood or urine, it may well be found that hyperparathyroidism is commoner than we at present suspect, and that hypercalcaemia is a relatively late manifestation.

THE PRESCRIBED DISEASES

Before 1897, when the first Workmen's Compensation Act was passed, a workman injured in his work had to resort to the Common Law for protection. In 1906 an Act introduced into the scheme of compensation six diseases which could be considered as occupational in origin. When this Act was before Parliament a departmental committee, with the present Lord Samuel as chairman, was appointed to report what diseases and accidents were "due to industrial occupations, distinguishable as such." This committee recommended three tests for including a disease or accident, the most important being whether "it was so specific to the employment that causation by the employment could be established in individual cases." The tests were endorsed in 1920 by the Holman Gregory Committee, which also rejected the suggestion for extending the scheme to cover every case of disease or injury that could be shown to the satisfaction of the court to be due to employment. The Rolleston Committee in 1933 further endorsed the Samuel Committee's findings and brought the number of scheduled diseases up to a total of forty-one, and this increased to forty-eight by 1948.

A workman could always obtain compensation for any disease or injury whether it was scheduled or not if he could show that it had occurred as a result of a

provable accident, including any consequences following from the accident; these conditions continued while the Workmen's Compensation Acts were in force. In 1946, on the passing of the National Insurance (Industrial Injuries) Act the present State-administered scheme of social insurance came into being. Instead of compensation there was a system of injury, disablement, and death benefit. The Minister was empowered to extend insurance to other diseases he might prescribe by regulation, and also to promote research into the causes and prevention of accidents.

A departmental committee under the chairmanship of Judge (now Sir) Edgar T. Dale reported in 1948¹ that the tests propounded by the Samuel Committee were no longer appropriate, and to clarify the exact conditions that had to be realized before a disease could be scheduled, it considered that the

"primary matter to be decided was whether a disease is specific to the occupations of the persons concerned, or, if it is not so specific, whether the occupations of those persons cause special exposure to risk of the disease, such risk being inherent in the conditions under which the occupations are carried on."

The committee considered, however, that the wording of the Act gave such wide powers of discretion that there was no need to amend it.

In a developing industrial community the problem of the Industrial Injuries Scheme must be under constant review, and another departmental committee reported on the problems in 1955,² especially on diseases and personal injuries not caused by accident. This year a committee has again presented a Review of the Prescribed Diseases Schedule.³ It was particularly asked to recommend any adjustments that should be made in the terms of the prescription of industrial diseases (apart from pneumoconiosis and byssinosis), in order to achieve a greater precision in the description of the disease or injury, or in an appreciation of the risk. The report states that some of the scheduled diseases are now of little consequence—e.g., no case of poisoning by *Gonioma kamassi* has been reported for many years. New compounds have been introduced, such as phosphorus insecticides. Likewise the descriptions of lead, manganese, and other metals have been expanded to include compounds of the element. Other suggested additions to the list are chlorderivatives of benzene and poisoning by nitrochlorobenzene; it is recommended that there should also be the addition of poisoning by "substituted dinitrophenols or by the salts of such substances" to the dinitrophenol group. It was considered that the group of conditions "beat hand, knee and elbow" should be more precisely

described to include bursitis due to severe or prolonged pressure friction. Another important recommendation is associated with the description "Epitheliomatous cancer or ulceration of the skin, due to tar, pitch, bitumen, mineral oils (including paraffin), soot, or any compound product or residue of any of these substances." These conditions would be more precisely designated as "squamous celled carcinoma"; this would exclude rodent ulcer, which does not appear to have any occupational association. The new description also recognizes the carcinogenic properties of some arsenic compounds used in preparing colours. The diseases associated in the present groups 24 and 25 received special consideration. These are chrome ulceration, and those inflammatory and ulcerative conditions of the skin and mucous membranes of the upper respiratory tract resulting from exposure to dust, liquid, or vapour, together with the effects of radioactivity. A more rational classification is now possible for these conditions. A separate category has been suggested for occupations involving exposure to electromagnetic radiations other than radiant heat or ionizing particles, and which give rise to inflammation, ulceration, or malignant disease of tissues. This is more in keeping with developments in industry.

Canicola infection is now recognized as an occupational hazard. Work in a post-mortem room associated with "examination of human remains" is accepted as a possible factor in causing tuberculosis, and the report recognizes that there may be demands for extending the cover against this disease to other occupational groups besides nurses, research and laboratory workers, and the post-mortem room workers already accepted.

The report also acknowledges that primary neoplasm may occur not only in the bladder but also in the renal pelvis and ureter following exposure to aniline and some diphenyl compounds and certain derivatives of them.

This last report is an interesting attempt to provide cover for the occupational accident or disease for which the growing evidence is sufficient to meet the stringent legal criteria. The recommendations will not satisfy everybody. Some observers believe, for instance, that common diseases such as rheumatism and cardiovascular disease, which are prevalent in a few occupations or are said to be aggravated by some types of working conditions, should receive further consideration. The risks in some of the smaller industries may also not be fully recognized. This report cannot in the nature of things be a final pronouncement on the subject, and the need for further research is clear.

ORDEAL BY EXAMINATION

Medical teachers from the U.S.A., Sweden, and different British centres cast some doubt last week on the value of the examination as a professional test. Opening a two-day conference held by the Association for the Study of Medical Education (reported on page 851), Sir Russell Brain suggested that, if it were true that examinations determined the teaching of medicine, so was the converse true, for the same people were responsible for both. From the observations of subsequent speakers it seems as if the sense of responsibility might, in some places and at some times, be higher than it is. Sir George Pickering, for example, projected on the screen examination papers recently set for the Oxford B.M. degree to illustrate his contention that medical faculties were not interested in training the student's mind, but principally in stuffing it with facts. The three characteristics of a university medical course, he said, were its length, its complexity, and the rigours of its examinations. The test of any innovation in education should be in the answer it gave to the question, "Will it improve the student's mind as an instrument of precision?" Professor G. M. Bull brought the slide-rule down on the examiners' heads, and said that he and his colleagues in Belfast were replacing half their papers by multiple-choice questionnaires, some of the questions requiring only single-line answers. Such a test eliminated the examiner's marking error. It was possible in this way to test not only knowledge of facts but also skills such as the ability to make deductions from facts. Dr. J. Z. Bowers observed that in the U.S.A. the examination was not the severe final test that it was in Britain. In America much more attention was paid to reports from college teachers, to the continued observation of the student in his day-to-day activities throughout the medical course. All this was looked upon as being more important than the final examination, which would never be the cause of failure of someone who was regarded by his teachers as a good student. The failure rate was between 5% and 10%, and failure was often due to such factors as psychological disability. Roughly the same failure rate is the experience of Sweden, where, as Professor B. Rexed, of Upsala University, told the conference, the examination is "an affair between the student and the professor." The student could demand an examination, and if he failed and was dissatisfied with the way the professor conducted it he could ask for an examination in public before witnesses. In his summary at the end of the meeting Professor Robert Platt criticized the external examination in Britain and suggested that we must devise methods of testing students which cut across this.

It is encouraging to see the final examination, in particular, coming in for such criticism by such experienced teachers here and abroad. The examinations deaden the mind and cripple the spirit of inquiry latent in even the most cautious student. With the careful selection of students now prevailing, the percentage failing at the final examination should be much lower than it is if the British system of medical education were what some delude themselves it is. The theme of last

week's conference at the Royal College of Physicians was "experiment in medical education," and Dr. Hale Ham, of Western Reserve, Cleveland, gave an entrancing account of the new methods introduced there; and Dr. Nicolas Malleson intrigued his audience with his description of operational research on the London student. A.S.M.E., under its energetic secretary, Dr. John Ellis, has made such a good start that it is to be hoped its future will be made secure. In the meanwhile the examination of examinations must be carried through to a successful conclusion.

REACTIONS TO PENICILLIN IN POLIOMYELITIS VACCINE

Tissue cultures on the scale required for the commercial production of poliomyelitis vaccine cannot be entirely protected from bacterial contamination by physical means. It is therefore necessary to add antibiotics to which most bacteria are sensitive, whereas the virus is of course resistant to them. The medium used contains 200 units each of penicillin and streptomycin per ml. These antibiotics are not altogether eliminated from the final product, and there is at least a theoretical risk that a dose of the vaccine may cause a reaction in a subject sensitized to one of them. This is more likely to be penicillin, since sensitivity to this is commoner than to streptomycin and often of higher degree. This risk was pointed out in these columns¹ when the Ministry of Health announced the availability of the vaccine in this country to the lay press without prior information to the profession or any information about the composition of the product available.

That this is an actual and not merely a theoretical risk is evident from the report of a case by Dr. A. Fowden at p. 835 of the *Journal* this week. His patient developed a vesicular rash a few hours after the injection, and bronchospasm several days later. In the U.S.A., C. Zimmerman² has recorded six cases from his own practice in a seven-month period, and describes such reactions as "relatively common." In these six patients they were all of an urticarial type, developing at intervals of one to several or many days after the injection of vaccine, and apparently very resistant to treatment with A.C.T.H. and anti-histamines. Proof of their nature was obtained in several ways. All subjects gave a history of previous reactions to penicillin. A further dose of a make of vaccine containing penicillin provoked a further reaction of the same type, but one manufacturer's product in which the penicillin content has been reduced to below 0.001 unit per ml. did not have this effect. Finally, persistent reactions were rapidly relieved by administering penicillinase.

Sensitization to penicillin is believed to be much commoner in the United States than in Great Britain, but other cases may have gone unreported here. It would be worth while to bear in mind that urticaria and other skin rashes developing after an injection of poliomyelitis vaccine are probably of this nature.

COLOURED IMMIGRANTS

Earlier this year an estimate of about 190,000 was given in Parliament as the total of coloured people in Great Britain.¹ This is about one coloured to 250 white, though the distribution of the coloured people is notably uneven owing to the greater prospects of employment in the industrial cities. Of these 190,000, about 100,000 had come from the West Indies (chiefly Jamaica) and 50,000 from India and Pakistan. Because members of the British Commonwealth are free to come here, no administrative machinery exists to keep a count of their exact numbers, hence only estimates are available. But there is no doubt that, in the words of a broadsheet issued this week by the Eugenics Society,² this is "a phenomenon of the last decade."

Unrestricted immigration from any country, whatever the colour of its inhabitants' skins, is likely to cause difficulties when the country they enter is already densely populated. The social evils of slum life are apt to spread and defy attempts at their eradication. Fraud and frustration, says the broadsheet, appear, and the immigrants, "uprooted from gay and friendly company . . . will seek ephemeral friendship and sexual solace where they can find it." An additional problem, apparently specific to the migrants from the West Indies, is that over there marriage as understood in Britain has now largely given way, through a transition stage of "faithful concubinage," to "what may be described as promiscuity." It is thus not surprising that many half-caste children—and some full West Indian babies—are to be found in residential nurseries here. Indeed, a quota of four coloured children in ten has already been filled in these nurseries in some parts of the country.

While the social prospects of these considerable movements of population are not notably favourable, the strictly biological prospects are unfortunately obscure. As the broadsheet says, there is "an inconvenient lack of precise knowledge about the long-term implications of human genetic mixtures taking place in our times," partly because of the relatively slow rate of breeding in the human race, and partly because experimental breeding is out of the question. Moreover, it is debatable what, if any, inferences about miscegenation in human populations can be drawn from animal experiments, and in particular whether heterosis, or hybrid vigour, can be detected.

All would agree with the society's advocacy of more research into the results of race-mixing, for ease of travel is likely to increase rather than impede it. Nor can anyone doubt the need for more education of people in a "proper appreciation of the qualities" distinctive of unlike or alien nations. But the thorny question remains, Should immigration to Great Britain from the Commonwealth countries be restricted? While this is an issue that has many features outside the immediate professional interests of medical men and women, it is one that members of our profession are well equipped to provide evidence upon and to judge dispassionately. The

Eugenics Society, 1958. Price 1s. 6d.

Eugenics Society goes no further than expressing the opinion that the time has come "for very careful consideration."

SEXUAL FUNCTION IN MALE DIABETICS

The increased incidence of abortions and stillbirths among women with diabetes mellitus is well recognized, but little attention has been paid to the sexual functions of the male diabetic. A recent report by A. Rubin¹ on the reproductive capacity of 198 diabetic men, over three-quarters of whom were married, is therefore welcome. The impression that impotence is common was confirmed by the finding that this symptom was present in 25% of patients aged 30-34, and the incidence rose steadily to almost 75% by the age of 60. The overall figures are between two and five times those reported by Kinsey and his colleagues² in the normal male population. While impotence is particularly common in the early stages of diabetes, potency may return when the disease is adequately controlled. Nevertheless, approximately two in every five diabetics will be found to be permanently impotent, the cause being unknown and treatment ineffective. It does not appear to be related to the severity of the diabetes or to the presence of complications, though a connexion with neuropathy has been suggested. Fertility among diabetic males is said to be normal, which seems surprising in view of the greater frequency of impotence. Apart from a slight increase in the number of abortions there is no evidence that diabetes in the male affects the incidence of prematurity, stillbirths, or congenital malformations.

ANTHRAX FROM BONE MEAL

The terminal stage of anthrax is a profuse septicaemia, and anything derived from the carcass of an animal dying of this disease is therefore heavily infected. Moreover, the spores of *B. anthracis* are highly resistant and capable of prolonged survival. From many of the countries in which anthrax is endemic, wool, hair, and hides are imported into Britain. Another product is bone, which is imported chiefly for conversion into fertilizer. That bone meal may carry the infection has been recognized for many years, though cases of human disease are not often traceable to it. It is therefore remarkable that D. M. Green and W. M. Jamieson,³ of Dundee, who three years ago described 6 cases of anthrax derived from bone-meal fertilizer, are now able to report 4 more, all in agricultural workers who had been handling this type of material. An accompanying paper by R. Lamb,⁴ of Greenock, reports 4 cases from a factory in which imported bone is put to two different uses—fragments of a certain size are reduced to charcoal for use in sugar refining, while the remaining

powder is sold as fertilizer. The conditions in this factory appear from the description to have been insanitary: "bone dust is to be found everywhere, even in the offices," and, despite protective clothing, penetrates this and reaches the underclothing. All these cases were cutaneous, and were it not for the wearing of face masks there might well have been pulmonary infections, with a high probability of fatality. Indeed, it is perhaps surprising that there were not, because Lamb also describes two cases of empyema in workers in the bone-crushing plant due to species of *Clostridium*, another resistant type of organism invariably present in large numbers in material of this kind.

A committee of the Ministry of Health appointed early last year is inquiring into the hazards of imported materials infected with anthrax and possible precautions against them. If an economically feasible method of disinfecting bone can be devised it should evidently be made obligatory. In the meanwhile the possibility of this infection should always be borne in mind when suspicious skin lesions occur in agricultural or horticultural workers. Fortunately anthrax responds well to penicillin. In pursuance of a policy adopted at the Gateside Hospital, Greenock, of which the results⁵ were reported in this *Journal* last year, three of Lamb's cases were treated simply with penicillin V given by mouth, with evidently satisfactory results.

"DRUG TREATMENT OF DISEASE"

Nothing in the doctor's daily round has changed so much in recent years as his prescribing. The inventive capacity of chemists and pharmacologists seems unbounded. New drugs come from the laboratories with bewildering speed, and any doctor may be pardoned for feeling puzzled about when to prescribe a new vasoconstrictor called, for instance, "luvomine," whose composition is given in a chemical name that is in large part Greek letters and Arabic numerals. His bewilderment increases when he finds that half a dozen similar preparations are on the market, each having a different "side-chain" attached somewhere and each varying to a greater or less extent in its effects. In order to try to give some guidance on the pharmacology and therapeutic uses of drugs, we have invited distinguished contributors to provide a series of signed articles which it is hoped will be helpful to the general physician and surgeon. The first is on the antihistamines, by Professor J. H. Burn, F.R.S., and appears at p. 845 of the *Journal* this week. These articles, by comparing drugs with one another and providing some pharmacological background for an understanding of their effects on the patient, will supplement the comments that appear under the heading "To-day's Drugs." In that column individual contributors who have had experience of the drugs they comment upon give advice on their use.

Drug Treatment of Disease

THE ANTIHISTAMINE COMPOUNDS

BY

J. H. BURN, M.D., F.R.S.

Professor of Pharmacology, University of Oxford

An illuminating approach to the action of antihistamine compounds can be made by looking at them from the point of view of the pharmaceutical manufacturer. When a compound with new properties is introduced which are likely to command for it a wide use in medicine, each pharmaceutical firm is anxious to introduce a different compound with the same properties for the manufacture of which it will have the sole rights. Many compounds are prepared and tested first by laboratory methods and then clinically, but it is often difficult to make a final appraisal of the value of any substance until after it has been launched on the market.

The first antihistamine was mepyramine maleate ("neo-antergan"), and it has been sold in Great Britain under the trade name "anthisan." The aim of other manufacturers was therefore either to introduce a compound of a quite different formula with the same properties or to introduce a similar compound with a modified formula. As examples of a similar compound with a modified formula we may take tripeleennamine ("pyribenzamine"), methapyrilene ("histadyl"), halopyramine ("synopen"), and also chlorpheniramine maleate ("piriton"), all of which are very close chemically to anthisan. Diphenhydramine, or "benadryl," differs considerably from anthisan, though both contain the grouping dimethylaminoethyl. Substances chemically close to benadryl are bromazepam ("ambodryl") and diphenylpyraline ("histyl"); while chlorcyclizine ("histanin"), "diparalene", meclozine ("ancolan"), and buclizine ("vibazine") form a third group.

The substances which have been steadily added to the original antihistamines mepyramine (anthisan) and diphenhydramine (benadryl) have not greatly extended the scope of therapy. They differ from the original drugs mainly in two ways—first, in their rates of absorption and excretion, and secondly in the relative strength of other properties besides antihistamine action which all compounds of this type possess. It is thus possible to choose a drug with a brief or prolonged action, a drug which is a sedative or one which is not, according to the needs of the patient. It is also often found empirically that a particular patient will respond better to one drug than to another, even though statistics show the first drug to be less potent or to produce a higher incidence of toxic side-effects than the second.

Antihistamine Action

The action of all these substances on allergic symptoms is very similar. They act by combining with the receptors with which histamine normally reacts to produce its characteristic effects, and so they prevent the symptoms which result from the release of histamine. They have no direct action with histamine itself; they do not prevent the release of histamine from cells in response to injury or foreign substances, and they have no direct physiological action of their own which can account for their antihistaminic properties.

There are two consequences of this mode of action which are of practical importance in the treatment of allergy. The

first is that the administration of antihistamine drugs is only one part of the treatment, and must often be accompanied by measures either to prevent the release of histamine or to counteract its effects after it has been released, or both. The cause of histamine release may sometimes be removed by discovering the antigen responsible and desensitizing the patient. The release of histamine may also be suppressed by giving cortisone (Medical Research Council, 1956; Halpern, 1957). Finally the vasodilatation and fall in blood pressure due to histamine may be overcome by administering adrenaline or ephedrine, which have powerful properties opposed to those of histamine.

The second consequence of the competitive blocking action of the antihistamine drugs is that their effectiveness is limited by their ability to reach the site of action of the released histamine. While they are effective in about 60-80% of patients with urticaria or hay-fever, they are very rarely effective in asthma, even though histamine release has clearly been shown to be at least partly responsible for the symptoms of asthma. Sir Henry Dale (1950) suggested that the antihistamine drugs would be expected to prevent the action of "exogenous" histamine, which is liberated in one site, such as the epidermis, and acts on a site some distance away, such as the blood vessels, but would not prevent the action of "endogenous" histamine, liberated close to the receptors on which it acts. Schild (1956) showed that in segments of bronchial chain taken from asthmatic subjects at operation, mepyramine in a minute dose would prevent the contraction due to added histamine, but that a dose 10,000 times greater was necessary to prevent the contraction which was caused in the sensitized tissue when the appropriate antigen (pollen) was added. Smaller doses caused a graded reduction of the anaphylactic contraction.

It is still not possible to say how far the symptoms of asthma are due to histamine acting on receptors which the antihistamine drugs are unable to reach, and how far they are due to factors other than histamine. Halpern (1957) points out that the dyspnoea in asthma may be variously caused by oedema, spasm, bronchial congestion, secretory disorders, and imbalance of the autonomic nervous system. He has found that the antihistamine drugs are sometimes effective in treating asthma due to large protein molecules—for example, from feathers or animal danders—where the predominant symptom is oedema. Recently it has been shown (Hawkins, 1955) that a number of antihistamine drugs have a direct bronchoconstrictor action. This may be another factor contributing to the ineffectiveness of these substances in the treatment of asthma.

Another action of histamine on which the antihistamine drugs have no effect at all is the stimulation of gastric secretion. It has been suggested that the receptors for histamine in the gastric glands are of a different kind from those in smooth muscle, but there is no direct evidence for this.

In most allergic diseases the antihistamine drugs are very valuable in reducing the severity of the symptoms. In acute anaphylactic shock they may be life-saving. In serum sickness, urticaria, and hay-fever they are effective in a high proportion of patients. Their effects are, however, not always predictable, and some patients may fail to respond, or respond to one drug but not another, for unexplained reasons. There is no evidence that one antihistamine drug is more specifically effective than another in any particular form of allergic disease or type of patient. These unpredictable effects are not surprising, since the factors controlling

the release of histamine are still very incompletely understood. Much of the recent research on the problem has made use of histamine-releasing substances. These when injected into a normal subject cause symptoms identical with those produced when histamine is injected. In allergic patients, however, these initial symptoms are followed by reactions which closely reproduce the spontaneous symptoms of the individual's disease.

Other Properties

Drugs which act by combining with a histamine receptor will also be likely to have some effect on other physiological receptors. All the antihistamine drugs possess some anti-acetylcholine properties. They act like hyoscine in causing sedation and inhibiting the vomiting reflex, and they cause side-effects such as dryness of the mouth and constipation. They are also local anaesthetics. The potency of these secondary actions is not proportional to the potency of the antihistaminic action.

The most strongly sedative drugs are diphenhydramine and promethazine ("phenergan"). Sometimes this sedative action is useful, but it is better not to give these drugs to patients who work during the day, and they may be dangerous when taken by drivers or people working with machinery. Moderate sedation is produced by mepyramine, tripelemamine, and bromazine, and the other drugs, though usually free from sedative effects, may induce drowsiness in some individuals. The patients should be warned of this possibility.

Diphenhydramine and promethazine are also highly effective in preventing travel sickness. They are usually given for this purpose in the form of their chlorotheophyllinate salts ("dramamine" and "avomine"). Meclozine is also effective in preventing sickness. Other antihistamine drugs have weaker anti-emetic properties: this action is not related to the antihistaminic activity.

The local anaesthetic action of the drugs is a useful additional property when they are applied to the skin to relieve the itching of urticaria or insect bites. Sensitization reactions, however, are rather frequent, and antihistamine creams are best not used indiscriminately for skin diseases (*British Medical Journal*, 1954).

The antihistamine drugs do not cause addiction. A few cases of agranulocytosis have occurred, but these have been rare considering how frequently the drugs are prescribed. They are dangerous poisons if swallowed by children, producing ataxia and convulsions which may be followed by fatal respiratory depression. The treatment (Craig, 1955) depends chiefly on gastric lavage and artificial respiration.

Administration

All these drugs can be given orally, and this is the usual method of administration for the treatment of allergic symptoms. Since a continuous action is required, the drugs are usually given several times during the day. Some of the drugs have a more prolonged action, and adequate treatment is possible with a single daily dose. The non-sedative drugs chlorcyclizine and diphenylpyraline may be given once daily. Chlorpheniramine is made in double tablets, in which half the dose is in the outer shell and half in a coated inner core for delayed action; they are effective for 8-10 hours. Promethazine also has a long-lasting action. Because of its sedative properties it should be given at night, and on the following day it continues to exert antihistaminic activity after the sedative effect has worn off. Meclozine is also given at night. When avomine and ancolan are taken to prevent travel sickness they should be taken on the night before the journey; dramamine should be taken every four hours.

The administration of the correct dose for each patient, giving relief from symptoms with minimum side-effects, is an important factor in treatment. The dose of any drug required by different individuals varies considerably, and the

amount needed by the same patient may also vary at different times, depending on such factors as the weather (for hay-fever subjects) and emotional stress.

When a rapid action is required an antihistaminic drug may be injected, and those which are suitable for injection are supplied in injectable form. Triprolidine ("actidil") is reported to act more quickly than the other drugs when given orally. Several of the drugs are supplied as creams and ointments, but they should not be applied too freely to the skin. Antazoline ("antistin"), which is the weakest and also the least toxic, is supplied as the phosphate for application to the eye and the nasal mucous membrane.

THE PHARMACEUTICAL INDUSTRY

BY

R. S. INCH, M.D., M.R.C.P.Ed.

Director, Bayer Products Ltd.

The astonishing expansion of the pharmaceutical industry during the last quarter of a century, and in particular its even more accelerated growth during the past ten years, has, not surprisingly, resulted in certain conflicts. That there should be an undercurrent of disagreement between the industry and dispensing pharmacists is quite understandable, for the latter can claim that the expansion of the industry has resulted in an inevitable loss of prestige (and demonstration of skill), which for so long has been vested in the dispensing chemist. What is not so clear, except when considered in retrospect, is that the pharmaceutical industry should have become involved in a series of clashes with the medical profession and the State. The various aspects of this problem are here reviewed so as to establish, if possible, a better basis for understanding between the various parties involved.

Background to the Problem

The application of a critical approach came to medicine much later than it did to the other sciences. In 1865 Claude Bernard defined the attitude of modern medicine, emphasizing the absolute necessity of an experimental approach. This concept, when associated with the discovery of new synthetic compounds such as chloroform, "salvarsan," and aspirin, gave rise to what we now call pharmacology, a discipline which is so essential to any real advance in treatment. As compounds were synthesized it became necessary to screen them, and these functions were carried on for many years in the academic atmosphere of the university or technical college. In time, however, the complexity as well as the speed with which new compounds were produced necessitated the employment of various industrial techniques, so that more money had to be invested in the equipment of plant to make the compounds.

This transfer of emphasis from the academic to the industrial sphere resulted in the rise of a new class of technologists and scientists working for industry with a definite commercial aim as well as for the advancement of learning. Thus it was from industry that the next great advance, the sulphonamides, originated.

While progress continued in organic chemistry, equally great strides were made in biology. Unfortunately, when the probable therapeutic scope of penicillin was appreciated in 1941 there came coincidentally the realization that we in

this country had not the manufacturing facilities for large-scale production of the life-saving substance. Consequently the initial development work and manufacture had to be carried out in the U.S.A. The lead gained by the United States in pharmaceutical research and development has subsequently been maintained, though during the past few years it has shortened and many other countries have made valuable contributions.

It is now fully recognized that to produce the wide range of modern therapeutic agents a very high standard of technical skill is necessary. The production of these compounds on a commercial scale often necessitates costly and complicated plant; furthermore, the compounds must be manufactured to a uniformly high standard of quality.

The foregoing applies to the manufacture and quality of accepted products, but no mention has yet been made of the place that research must occupy in this already complicated picture. When standard drugs are being manufactured any research that goes on in parallel need only attempt to improve methods of manufacture so that a better quality, at a lower cost if possible, may result. However, when a firm is producing either new permutations of known drugs or is producing totally new compounds, research spreads far wider, so that it covers virtually the whole of medicine and still enlarges its scope to take in many other scientific disciplines. In subsequent sections the various implications that this vast structure imposes are dealt with, and it is hoped that a clearer picture of the pharmaceutical industry may emerge.

Criticisms of the Industry

Criticism is levelled at the pharmaceutical industry from three different sources: (1) medicine, (2) pharmacy, and (3) the State.

Medicine

A legitimate criticism is applicable to a few products such as "tonic" preparations containing drugs which may lead to the masking of serious symptoms or to the indiscriminate use of antibiotics. Another example, not in the therapeutic field, is the tendency of a few manufacturers to exaggerate their claims for a product in an attempt to persuade the less perspicacious physicians that the product is of greater value than is actually the case. A further complaint concerns the weight of advertising that comes through the post, particularly the purely "sales mailings" which make little attempt at being informative. In addition to this some doctors say that they are assailed by an increasing number of representatives from the drug firms extolling their products, sometimes without giving the doctor any real help or information about their true worth or mode of action. Though some of these criticisms are unfortunately true, there is, however, an increasing sense of responsibility in the pharmaceutical industry, and the Association of the British Pharmaceutical Industry does everything possible to promote the standing of the industry as a whole and encourage a high ethical level.

The medical profession in general is largely ignorant about the work of the pharmaceutical industry, and it is unfortunate that medical students are given so little insight into the wider aspects of it. A very brief course of lectures and a visit to one of the factories might enlighten them considerably.

Pharmacy

Some pharmacists complain that the industry is infringing their professional status and cite the decreasing number of their contemporaneously prepared prescriptions in support of this. This trend is inevitable, and it is unrealistic of the pharmacist to expect that it should be reversed. The main reason is that the great majority of new compounds have to be made on a large scale under special conditions and cannot be compounded in the retail pharmacy. Furthermore, with an increasing realization of the importance of uniformity, sterility, and quality, doctors are beginning to prefer the safety and predictability associated with a branded product. It is knowledge rather than craftsmanship that is required

to-day to ensure that potent drugs are supplied to the patient as the doctor wishes. Thus the pharmacist who wants to devote his life to compounding should, early in his career, consider entering the pharmaceutical industry, where a wide scope for his qualifications and capabilities exists.

The State

The conflict between the legislature and the industry mainly concerns the question of the cost of pharmaceutical products to the State. In this country probably well over 90% of the pharmaceuticals prescribed are paid for by the National Health Service, and the actual amount spent on drugs has been regularly increasing since the inception of the Service in 1948. But, as may be seen (Fig. 1), the total sum received by the manufacturers of proprietary drugs is less than 4% of the total cost of the N.H.S., while the cost of the hospital services is 57%. In making this comparison the national expenditures on alcoholic drink and tobacco have been included, as they are of considerable comparative interest.

So far as the State is concerned it is unfortunate that the first 10 years of the National Health Service coincided with inflation as well as with a period of quite unprecedented advance in therapeutics. Some officials seem to attribute this increase to extravagance on the part of the doctor or the pharmaceutical industry, rather than to the inevitable reflection of therapeutic advance. Fig. 2 shows the proportion of proprietary drugs supplied in other countries compared with the United Kingdom, and it is significant that in the U.S.A. and Canada, where they are paid for by individuals, there has been no comparable outcry about the rising costs.

In order to try to curb the mounting drug bill some rather makeshift measures have been introduced, such as the insti-

FIG. 1.—Cost of proprietary drugs (black portion of N.H.S. column) compared with other items of expenditure in the United Kingdom. *Hospital services accounted for 57% of N.H.S. costs.

FIG. 2.—Proportion of proprietary drugs prescribed in various countries.

tution of the prescription charge and the organization of local prescribing tribunals where doctors may be called upon to justify what is considered to be extravagant prescribing. Although the prescribing charge may restrain some unnecessary demands on the Service, the prescribing tribunals raise a very different problem. As they are constituted at present they do not seriously limit the freedom of the doctor to prescribe whatever he thinks best, but their existence raises the possibility that at some future date a government may enforce more stringent limitations on what the doctor may prescribe. Should this happen the medical profession would have to consider very seriously some form

of concerted action to prevent the State from interfering with the essential liberty of professional freedom.

A surprising feature of this complex situation is that so little has been said about the quality and general standard of the preparations prescribed. Until recently it has been tacitly assumed that the standard equivalents of proprietary preparations were in fact truly equivalent and as good as the proprietary product in every way. Recently, however, Bagnall and Stock¹ and McClure Browne *et al.*² have shown in impartial surveys that this is not always the case. They have demonstrated that many standard drugs were below the official requirements laid down by the B.P. and B.P.C. and in some cases were much less effective than their proprietary equivalents. These interesting findings have received little comment from official sources, where the policy holds that, whenever possible, practitioners should prescribe the official standard drug rather than its proprietary equivalent. If this opinion was based on comparative prices and if the standard equivalent was always identical as well as cheaper this policy would be justifiable. It is, however, by no means universally valid, and, when this is considered in association with the knowledge that some "standard" preparations are actually substandard, there can be little justification for the sweeping directives of the health authorities to avoid proprietary preparations whenever possible.

Propaganda

The dissemination of information about new drugs presents a peculiarly difficult problem. With the increasing speed at which new remedies are discovered it is obviously essential that doctors in general, and general practitioners in particular, should be advised about them. It is no longer possible, as it was even 50 years ago, to learn materia medica as a student and expect to go through professional life drawing on this small treasury of knowledge. Various methods have therefore been evolved in order to keep doctors up to date with therapeutic advances. It is generally agreed that the most valuable channel is through the pages of the reputable medical journals, but many doctors do not avail themselves regularly of this source of knowledge. Consequently, over the years pharmaceutical firms have devised other means of spreading knowledge about their products. The necessity for this is accepted by the great majority of the profession, but criticism is not unnaturally levelled at some of the means employed by certain firms.³

Although advertising in medical journals is a valuable reminder to doctors, this cannot be relied upon as the sole means of approaching the profession. Mailings have therefore to be sent direct to the doctor, and, as is to be expected from a large industry, the methods of individual companies vary greatly. In this respect it should be remembered that an increasing number of other groups, such as insurance brokers and motor manufacturers, have been using this method in recent years.

Some doctors complain about the type and content of the actual advertisements, and it must be admitted that some of the less ethical manufacturers do overstate their claims. This is quite indefensible, but at the same time the righteous indignation of doctors should be tempered somewhat by the knowledge that all of them, even the least qualified, have had at least six years' scientific training, and they should be better able to assess in a critical way the claims made by the pharmaceutical manufacturers than, for example, the general public is able to assess the claims made by manufacturers of soap or toothpaste.

The widespread sending of samples constitutes another problem, and certain groups of drugs likely to be dangerous cannot be sent except on the request of the physician. Sampling, however, has the advantage of allowing the physician to try out a particular remedy, and in this way to assess its value with no cost to himself or the patient.

Finally, as a means of disseminating information, come the pharmaceutical representatives. These men, many of whom are trained pharmacists and all of whom have

received some fundamental training, are in a position to give precise information to the doctor about their firms' products. Although their visits may, if they become too frequent, take up too much of the doctor's time, it seems to be generally agreed that the pharmaceutical representatives of the majority of firms are able to render a valuable service to the doctor by keeping him abreast of recent developments and at times by arranging for him to try out newer preparations on an experimental scale. Of all the methods of propaganda the representative is the most effective, and it is in the interests of the individual representative and the firm that he represents to maintain as high a standard as possible, for it is by him very often that the firm and its products are judged.

It seems likely that unless the pharmaceutical industry becomes State-controlled, which has already occurred in some of the "Iron Curtain" countries with most unfortunate results on therapeutic progress, advertising by the pharmaceutical industry to the doctor must continue. There would appear to be no simple solution, and the medical profession should try to adopt a tolerant attitude to what, at worst, is a relatively minor nuisance.

The Patent Position

Broadly speaking, pharmaceutical manufacturers may be divided into two distinct groups—those who carry out fundamental research, synthesis, and screening of new compounds, and who may spend on this up to a million pounds annually, and those other firms who make standard preparations and whose profits depend on the size of their sales and the economy of their manufacturing processes. These latter firms operate to a varying extent some form of quality control, but they do not take part in any coherent research programme. Consequently, it is in their interest to manufacture as much and as wide a range as possible, and, as they have no research commitments, the selling price of their drugs can be considerably lower.

With this background it should now be fairly simple to consider an example which has occurred not infrequently. As a result of their own research, a firm discovers a new drug which proves to be of considerable value. When it is marketed a selling price is fixed which takes into account the cost of the basic research and development. It is interesting to remember here that the Cohen Committee in its classification made a special category (Category 1) for new compounds considered to be of value and not subject to any price restriction. Furthermore, in recent negotiations between the pharmaceutical industry and the Ministry of Health a three-year period has been granted to the manufacturers of totally new compounds, during which time their prices fixed for the compound would not be subject to any criticism by the Ministry. If, however, the new compound has no patent coverage, it will almost certainly be copied by other firms who, as they have no research costs to cover, will be able to undersell the discoverers of the drug, and the outcome of this might well result in a serious financial loss to the original discoverers. Also, an international respect for patent law means that a country can build up a valuable pharmaceutical export trade with resulting benefit to its economy, as has been happening in Britain during the last few years.

When patent law as applied to the pharmaceutical industry is considered in this way it should be appreciated immediately that it is in fact based on the accepted principles of fair play and is not an aspect of wicked commercial monopoly.

Social and Economic Aspects of Prescribing

The wider economic aspects of prescribing are seldom considered, though recently J. P. Martin⁴ has thrown considerable light on the problem. It is generally appreciated that during the past twenty years there has been a striking fall in both morbidity and mortality figures, and associated with this there is an increase in life expectancy. This has been produced by an all-round improvement in living

conditions as well as by purely medical means, but nobody would deny the important part that the recently discovered drugs have played. As a result there has been a considerable decrease in the number and duration of admissions to hospital. This saving is not fully appreciated, yet the cost per patient per week varies from £24 to £34 for a convalescent to £63 1s. 11d. for an inmate of an acute hospital,⁵ whereas the average cost for a prescription over the same period under consideration is 57.08d.

In spite of these advances further progress is likely to continue, as it is estimated that the loss of man-hours due to sickness at the present time is 75 times greater than that from industrial disputes, and at any one time there are about one million people absent from work on account of illness.⁶ There is every reason to believe that future advances in therapeutics will further this progress, but it must be appreciated that any improvement will almost inevitably result in an increased expenditure on drugs. Consequently it is most important that not only politicians but the general public should realize that the slowly increasing drug bill does not necessarily reflect an increase in the total expenditure on the Health Service. If suitable figures become available at a future date it might be shown that this increasing expenditure has resulted in a striking saving to the community not only in hospital in-patient and out-patient treatment but in decreased absenteeism due to sickness.

At present, patients are required to report to their doctor for sickness certificates. This not only results in an increase in the bureaucratic type of work demanded of a doctor, but, as a visit to the doctor is traditionally associated with "getting some medicine," in many cases it must result in the patient also getting a prescription thought to be suitable to his malady even when this may not be really necessary. There is thus an inevitable increase in prescribing, and in this respect it is interesting that Martin has shown that in areas where prescribing is heavy it is due to an increase in the number of prescriptions issued rather than the high individual cost per prescription.

Finally, as is well known, we are entering a decade in which there will be an ever-increasing proportion of aged wage-earners, and it is becoming more and more important to keep the elderly at gainful employment as long as possible, not only for social but for economic reasons. A great deal of research work is being carried out in the degenerative diseases, and already geriatrics is established as a specialty. The pharmaceutical industry is fully aware of this important and growing section of the population, and it is not unreasonable to hope that before long some new discoveries will be made towards the prevention and treatment of degenerative conditions.

Future of the Industry

It should be clear that the place occupied by the pharmaceutical industry in the future should be an important one. Up to the present its record has been outstanding and its investment in the future by way of research is consistent. In Great Britain it is estimated that some £4m. a year is spent on pharmaceutical research,⁷ though this figure is small when compared with the Swiss pharmaceutical industry, which it is believed spends about £7m., or the American pharmaceutical industry, which spends over £45m., annually.⁸

The benefits accruing to the community from the pharmaceutical industry have not only been confined to individual countries but have affected the export market, so that during the past year Great Britain exported some £39m. of pharmaceutical goods compared with a quite insignificant sum ten years ago.

Because of the splendid prospects of the industry it should attract well-qualified people. Apart from the need for research chemists, physicists, and pharmacists, there is increasing scope for well-qualified doctors, and in particular pharmacologists, to engage in fundamental as

well as clinical research. At a time when serious bottlenecks are occurring in many medical specialties it is strange that there should still be such a great shortage of well-trained pharmacologists and bacteriologists, to name only two special groups. Already the number of specialists employed in the industry has increased enormously, and this in turn has promoted, though somewhat slowly, good public relations among widely different intellectual and social groups. The organic growth of public relations in this way is a gradual process, and the time is already overdue when a wider appreciation of the place occupied by the pharmaceutical industry should be put before the community as a whole. For only when the obstacles caused by lack of information and understanding are removed will the proper atmosphere of co-operation develop that will further the growth in size and status of the pharmaceutical industry.

SEVENTH INTERNATIONAL CONGRESS OF HAEMATOLOGY

ROME, SEPTEMBER 7-13

[FROM A SPECIAL CORRESPONDENT]

The Seventh International Congress of Haematology was held at the Palace of Congresses, Rome, from September 7 to 13, under the auspices of the International Society of Haematology. It was opened by the Italian Minister of Health, and attended by 1,700 delegates from more than 50 countries. The president of the Congress was Professor GIOVANNI DI GUGLIELMO, emeritus professor of medicine at the University of Rome. The subjects discussed included immunohaematology, haemorrhagic diseases, leukaemia, the spleen and the reticulo-endothelial system, anaemia, isotopes in haematology, anticoagulants, haematological genetics, and paediatric haematology. More than 600 papers were given, and in the main lecture hall there was simultaneous translation into English, French, German, Italian, and Spanish.

The first part of this report records some of the more important contributions to the plenary sessions on the first three days. Then follow summaries of symposia on human desoxyribonucleic acid, haematological genetics, and paediatric haematology.

Immunohaematology

In the first plenary session, Dr. J. H. JANDL (Boston) outlined some modern views on the acquired or auto-immune haemolytic anaemias. These anaemias were characterized by the adsorption on to the red-cell envelope of protein substances which diminish the cell's suspension stability. Antigen-antibody complexes could adhere to the cell's surface and caused agglutination either directly or by making the cells susceptible to agglutination by antiglobulin serum. Sensitized red cells were easily filtered by the spleen, but agglutinated red cells were filtered by the liver. Red-cell destruction did not correspond, however, with the amount of protein on the surface. Colonel W. H. CROSBY (Washington, D.C.), discussing therapy, said the haemolytic anaemia did not always need to be treated, as the patient might learn to live with his anaemia; the decision depended on careful diagnosis and observation, as in acute and severe haemolytic crises prompt intervention might be life-saving.

Dr. J. DAUSSET (Paris) discussed antileucocytic auto-immunization, which might be allergic or spontaneous. The

allergic antibodies were mostly antinuclear, as in disseminated lupus erythematosus. They could be assessed by leuco-precipitation tests and by complement fixation. The others were mostly anticytoplasmic. Dr. W. J. HARRINGTON (St. Louis) reviewed immune reactions affecting the platelets. These had been only partially defined owing to the lack of useful serological tests. The platelet had a complex antigenic structure and was peculiarly susceptible to auto-immune reactions. Antibodies for platelet antigens might be natural or immune, complete or incomplete, of the auto- or iso-type, or agglutinins or lysins. Steroids inhibited antibody production; splenectomy removed the site of antibody production.

Other papers on immunohaematology concerned the antigenic constitution of red cells, particularly in acquired haemolytic anaemia, the antigenic constitution of white cells (Dr. M. SELIGMANN, Paris), and a study of leucocyte and platelet agglutinins assayed by a quantitative determination of the total cytotoxic activity of the serum (Dr. J. L. TULLIS, Jamaica Plain, Mass.). According to this study, the platelet agglutinin was a single specific protein migrating as a γ -globulin. The leucocyte activity comprised two separate proteins which usually had the mobility of α_1 - or β_2 -globulins.

Leukaemia

The Adolfo Ferrata Lecture was given by Dr. W. DAMESHEK (Boston, Mass.) on the subject of the myelo-proliferative syndromes, with particular reference to Di Guglielmo's disease. He suggested that there were three stages in this disease—"erythraemia" (e.g., erythroblastosis), erythro-leukaemia, and myeloblastic leukaemia. The anaemia was probably due to ineffective erythropoiesis and possibly also to a haemolytic component due to haem diversion. The high vitamin-B₁₂ level and the presence of cells resembling megaloblasts might be due to vitamin-B₁₂ deficiency, just as in pernicious anaemia. Dr. Dameshek paid tribute to the president of the Congress, who 40 years ago had put forward his theory of erythraemic myelosis, which was now widely accepted. Dr. E. NEUMARK (London) described the pathological changes in erythraemic myelosis in a series of seven cases, which showed that the infiltration in the spleen, liver, and other organs differed from that seen in myeloid leukaemia, and that most of the cells in the marrow and other tissues were in fact abnormal erythroblasts, but not megaloblasts. Dr. J. H. BURCHENAL (New York) described how by the use of purine antagonists, folic acid antagonists, and steroids the average survival of a group of 253 children with acute leukaemia had been increased to over 12 months.

Experimental Studies

Dr. E. B. HARRIS (Belmont, Surrey) reported on the effects of single doses of x rays on the erythropoiesis of the rat, using as her index absolute counts of red-cell precursors in the marrow. Dr. E. P. CRONKITE (Upton, N.Y.), who divided the acute radiation syndrome into cerebral, gastrointestinal, and haemopoietic forms, said that only the last was typical of mid-lethal exposure and therefore of clinical importance. Dr. G. B. JERZY GLASS (New York) had studied the surface radioactivity over the liver following the administration of vitamin B₁₂ containing radioactive cobalt. The maximal uptake by the liver occurred about 7-20 days after the start of treatment and then remained level for some time, radioactivity declining by only 1-10% per month. In about a third of a series of patients with liver disease the uptake of labelled vitamin B₁₂ was reduced and in three patients it was abolished, a finding which might partly explain the high vitamin-B₁₂ levels in some cases of liver disease. Dr. C. V. MOORE (St. Louis) had investigated the biosynthesis of haemoglobin in thalassaemia, using labelled glycine and protoporphyrin. This suggested that there was a defect of haem synthesis.

The problem of increased susceptibility to infection after splenectomy had been studied by Dr. C. A. DOAN (Colum-

bus, Ohio) using Foshay heat-killed tularaemia vaccine. Although hypogammaglobulinaemia and atypical globulin patterns were found in some patients, he concluded that the capacity to form specific antibodies depended on the underlying disease rather than the presence or absence of the spleen. Dr. A. J. QUICK (Milwaukee) thought it was still uncertain whether a precursor or an activator of the Christmas factor was what was lacking in Christmas disease.

Human Desoxyribonucleic Acid

A special symposium on human desoxyribonucleic acid (D.N.A.) with particular reference to the D.N.A. of the haemopoietic system was held under the chairmanship of Dr. J. A. V. BUTLER (London). Dr. E. CHARGAFF (New York) outlined the fractionation of high polymers of biological origin such as nucleic acids. Dr. E. DEICHER (New York) presented evidence, obtained mainly by electrophoretic methods, suggesting that the serum of patients with lupus erythematosus may contain antibodies directed specifically against D.N.A. Dr. K. V. SHOOTER (London) pointed out that the rate of sedimentation of D.N.A. is a measure of its molecular weight. The D.N.A. of leucocytes from cases of lymphatic leukaemia had a higher, and the D.N.A. of leucocytes from cases of myeloid leukaemia a lower, molecular weight than the D.N.A. of normal white cells. D.N.A. from the spleen of a patient with Brill-Symmers disease resembled that of D.N.A. from lymphatic leukaemia leucocytes. Using chromatographic methods Dr. A. BENDICH (New York) found that the D.N.A.s from leucocytes of myeloid and lymphatic leukaemia and from normal spleen differed characteristically.

Dr. BURCHENAL said that antimetabolites active against leukaemia interfered with the synthesis of nucleic acids by blocking the synthesis of purines and pyrimidines or their incorporation into polynucleotides.

Haematological Genetics

The symposium on haematological genetics was held at the Institute of Medical Genetics under the chairmanship of Dr. L. GEDDA, its director. Dr. GEDDA and Dr. R. G. TORRIOLI (Rome) emphasized that the limits of genetic investigations had not nearly been reached so far as the red cells are concerned. They found that in twins the Price-Jones curves showed similar changes. Dr. L. I. UNGER (New York) had found differences in the Rhesus blood-group systems between a group of almost 500 caucasoid Rh-positive people and 400 negroid Rh-positive people.

Dr. W. LEHMANN (Kiel) discussed genetical problems of blood coagulation. It had been found that deficiency of factors VIII or IX does not necessarily cause death in homozygous females in a family of bleeders. The diagnosis of haemophilia in a female, however, must depend on coagulation and genetic studies. Thalassaemia, sickle-cell anaemia, favism, and other haemoglobinopathies were discussed in another part of this symposium, and cytomorphological sex determination in the third part.

Paediatric Haematology

In the symposium on paediatric haematology Dr. M. GERBASI (Palermo) said that in infancy megaloblastic anaemia might occur as a constitutional endogenous form, in goat's milk anaemia, during breast-feeding, in coeliac disease, kwashiorkor, and occasionally in cases of leukaemia.

Dr. C. GASSER (Zurich) discussed auto-immune haemolytic anaemia and related conditions. Idiopathic hyperacute autohaemolytic anaemia of the Lederer-Brill type was due to incomplete warm antibodies. Cold antibodies were rare in infancy, but immuno-aplastic and pseudo-aplastic crises in haemolytic anaemia were occasionally seen. Auto-antibodies occasionally developed in renal insufficiency complicated by acquired haemolytic anaemia. Dr. P. LEVINE (Raritan, N.J.) discussed neonatal haemolytic anaemia due to ABO or Rh-factor incompatibility. Professor S. VAN CREVELD (Amsterdam) classified the disorders of coagulation in

children. Phase 1 of blood coagulation was disturbed in haemophilia and Christmas disease; phase 2 in hypoprothrombinaemia, in hypoproconvertinaemia, and in deficiency of accelerin or parahemophilia; phase 3 in hypofibrinogenemia. Dr. R. CEPPELLINI (Turin) reviewed haemoglobinopathies in childhood.

Other symposia were concerned with vitamin B₁₂, the aetiology of leukaemia, the chemotherapy of leukaemia, anticoagulants, haemophilia, and blood and blood-forming cell tissue culture.

EXPERIMENT IN MEDICAL EDUCATION CONFERENCE AT ROYAL COLLEGE OF PHYSICIANS

The Association for the Study of Medical Education, whose aims include the exchange of information about medical education and the promotion of research,* held its first conference on September 25 and 26 at the Royal College of Physicians of London. The subject of the conference was "Experiment in Medical Education."

A Conscious Response

With the president of the College, Professor ROBERT PLATT, in the chair, Sir RUSSELL BRAIN, the opening speaker, said the significance of the occasion was that it represented a conscious response to a challenge. There was nothing new in an interest in medical education, but now the whole problem had emerged fully into consciousness. If there had been a conscious purpose in medical education, it had started with the idea that a qualified doctor must know something about certain subjects, and it had been left to the teachers of those subjects to teach them as ends in themselves rather than as means. The aim had been to make safe doctors, but that was by no means the same thing as a good doctor. The question was whether the present requirements were likely to produce good doctors, and that in turn raised the question, What was a good doctor? They had to decide what should be the relationship between the basic training recognized by qualification and the more specialized skills involved in general practice and the long-established specialties. One kind of good doctor might be needed in the United Kingdom, another in the United States, and yet others in Australia or Nigeria.

There were those who sometimes spoke as though examinations were the dead hand of medical education, and there were those who thought, with a pathetic faith, that the only way to get a student to take an interest in his subjects was to have examination papers on them. What a comment on to have examination papers on them. The relationship between teaching and medical education! The relationship between teaching and examinations was more subtle than that. While there was a sense in which examinations determined the teaching, it was equally true that the teaching determined the examinations—after all, the same people were responsible for both. To pass an examination it might be necessary to have not only the requisite knowledge and skill but an additional skill in passing examinations. Some of these problems, which were unsolved in education generally, were especially pressing in medical education.

Medical Education in the United States

Dr. J. Z. BOWERS, dean of the Medical School of Wisconsin and editor of the *Journal of Medical Education*, describing the study of medical education in the United States, said they must remember the great diversity of medical education, medical schools, medical research, medical faculties, and medical students in the United States. This diversity was much greater than in Britain, possibly because over the last 30 years their standards had been nowhere

*See *British Medical Journal*, June 14, 1958, p. 1405.

near as rigid, so that some schools had been able to surge ahead. The system was not perfect, but that was obviously a good reason for studying medical education. The medical schools were the most dynamic area in education in the United States to-day.

The United States required quality in quantity, and one of the major concerns was the student. One of the primary aims in medical schools was to create an environment in which the student could enjoy the maximum opportunity to learn, though many people felt that this was a rather low-pressure type of medical education, and there had been much concern about getting the environment which would be most conducive to learning. Much thought had been given to the preparation of students for medical school. It had been felt that the students were being given only a sound preparation in basic science and that they were ill-prepared to become citizens of the world, to be physicians able to deal with the various social, economic, and cultural factors which affected the practice of medicine. As a result of a study some ten years ago the preparation of students for medical school had been broadened, the attitude being that science requirements should be held to a minimum—although this was recognized as being an important minimum—and that the students should be encouraged to diversify their educational process.

A second important study had concerned the selection of students for medical school. Although a major factor, academic performance was not the sole criterion; the evaluation of the college teacher was also taken into account. Another interesting development had been the use of a national testing procedure, the medical college admission test. This tested scientific ability, quantitative ability, creative ability, and knowledge of modern society. More than 95% of the applicants for admission to medical school underwent the test, which was found to be a useful indicator, often giving a good line on the student's academic ability. The interview had also received some study. Opinions about it were still sharply divided, teachers being more favourable to it than psychologists.

In most medical schools the student's day-to-day activities were the fundamental basis upon which his final standing in the class was determined. In most cases the final examination contributed no more than about 30% to the final grading. Certainly a good student would never fail for having failed the final examination, and vice versa. It might be argued that this method put pressure on the student every day instead of only at examination times, but the student in the United States was accustomed to this.

The British System

Sir GEORGE PICKERING, Regius professor of medicine at Oxford, considered the British system. He defined the objects of education as twofold: first, to train the student's mind to acquire method in collecting facts, verifying them, arranging them, drawing conclusions, and testing his conclusions; secondly, to make him familiar with the material with which he proposed to work and, in the case of a practical art, to give him an acquaintance with the elements of the current practical techniques. The first was common to all education, the second peculiar to each faculty. The results of education could be assessed immediately by examinations or similar tests, or over a long period by the achievements of its graduates. His experience of examinations at several universities had shown him that medical faculties were interested not in training the student's mind but rather in his familiarity with the subject and its practical handling. With few exceptions medical examination papers were not designed to test the student's ability to arrange or evaluate evidence or his appreciation of method.

In recent years there had been evidence that the attitude of teachers was changing, one of the pieces of evidence being the changing form of examinations. However, it was not changing fast enough. It was extraordinary how little attention teachers had paid to the objectives

and the form of examinations. Examinations were the chief outward manifestation of the teachers' purpose, determining not only the fate of the individual student but his attitude to what he felt he should learn. As a test of education they were of limited value. The second difficulty in experimenting with education was to know precisely what factors were changing. It had been shown that research work undertaken on a group of factory workers had had a profound effect on productivity. It therefore seemed not improbable that if a university or medical school conducted an experiment in medical education the enthusiasm aroused would be an important factor in determining the success or failure of the experiment.

Outlining the system of education followed in this country, Sir George said that the universities often complained that too early specialization was the fault of the school. He unhesitatingly placed the blame on the shoulders of the universities. His chief conclusion from his survey was that, while medical education achieved its object of making the student familiar with the subject-matter with which he would have to deal later in his career—although some revision was desirable in that respect—its failure was in training the mind. The fault was partly with the curriculum and partly with the teachers, but fundamentally it was the attitude of mind of the teachers. While it was nonsense to suppose that the subject-matter of an arts course was inherently more suitable for sharpening the wits than that of a science course, it was true that science faculties, including medicine, were smothering their students with technological detail.

In the discussion which followed, Dr. LESTER EVANS (Commonwealth Fund) said that when the student entered medical school he was still at an age when, like every other young animal, he wanted to explore and roam. Like all other living things, his mind would respond to his environment. If his environment was one of freedom and inquiry, he would become a learner, like his teacher. Professor J. W. CROFTON (Edinburgh) thought the most difficult problem in designing experiments in education was to find the right criteria of success. Dr. A. M. COOKE (Oxford) pointed out that anyone who wished to teach in an elementary school was encouraged to take a diploma in education, which among other things meant studying methods of teaching. Possession of the diploma entitled its holder to a slightly increased salary. He had never met a teacher in a medical school who had been taught how to teach.

Mr. D. W. C. NORTHFIELD (London) said that if they were to build for the future they had to know where they had failed in the past. He supposed that it was an English characteristic to criticize so devastatingly what had been done. He did not think that they need feel ashamed of what had been achieved in the past. Professor B. REXED (Uppsala, Sweden) said that it was obviously difficult to be a teacher in a medical faculty. This was because the university had two conflicting interests or responsibilities—to the student and to the patient. The student's mind should be stirred, but the patient had to be protected. This was becoming more important as patients began to look at the profession in a more critical fashion. Professor ROBERT PLATT, closing the session, said that they had come to grief in the past in trying to devise examinations for medical students. He hoped that they would not now come to grief in trying to devise numerical tests by which the results of their experiments could be judged.

Students and Examinations

The afternoon session, at which Sir JAMES PATERSON ROSS, P.R.C.S., took the chair, opened with a paper on the study of students, by Dr. N. MALLESON, physician in charge of student health at University College, London. Dr. Malleison said that it had been suggested that there was a sort of mechanism by which a standard number of students

were failed and sent down at the end of the first year—a kind of norm vaguely and unconsciously held in the mind of the department which allowed borderline students through if there were too many failures and which raised the standard if there were too many passes. Any such process nullified student selection research. Operational research, as opposed to student selection, meant looking into that process, and that meant looking at the staff and at departmental procedures. Its methodology was still primitive; operational research was an aid to "good deanery," not a substitute for it.

A number of figures had been produced, but their meaning was not always clear. Examples included the fact that students who married in their third year were more likely to get a first-class honours degree than students who did not take out a girl; students who habitually sat in the front of the class stood a better chance of getting a good degree than those who sat at the back. It was also the case that some students spent far longer than average on private work and yet failed or did badly in examinations, while others spending a shorter time on private study did well. This suggested that research into the techniques of private study might prove rewarding.

Professor G. M. BULL, professor of medicine at Queen's University, Belfast, then discussed examinations. When an examiner marked a single question answered by a class of students he created an array of marks with two sources of variance, said Professor Bull—that due to the students and that due to the examiner's error. If the examiner re-marked the question on another occasion, or if the same question was marked by another examiner, it was possible to divide the total variance into two components, that of the student and that of the examiner. One examiner might be more lenient than another; one examiner might spread his marks more widely than another. The first type of error was unimportant because the students were graded correctly. A third type of error was much more important. This was a random error, and any statistical assessment of marking required its isolation. It had been shown that the correlation coefficient between two markings of the same question isolated the two components of student's and examiner's random error. After showing slides illustrating marking variations, Professor Bull said that in the last five years he and his colleagues had replaced half of their papers by multiple-choice questionnaires, some of the questions requiring single-line answers. Such tests did not carry any examiner's marking error and it was possible to take a much wider sample of the student's knowledge. There could be questions testing both the honours candidate and the failed candidate satisfactorily. It was possible to test not only factual knowledge but other skills such as the ability to make deductions from facts. Finally, the papers made it possible to compare one group of students with another.

Interview examinations were very much more difficult to study, because there was an additional source of variance, in particular that introduced by the students examining different patients, and also because examiners did not necessarily ask the same questions of each student. He had made some estimates of the student's variance in interview examinations and had found it surprisingly high.

Professor G. M. WILSON (Sheffield) said that the precise order of examination results was not tremendously important. Examiners first determined what was very good and what was very bad. With that in mind he had examined papers going back over several years and had asked members of the Royal College of Physicians to mark some of the papers. The top 10% of examinees had been constant, but there was wide variation with the bottom 10%. Similar results had been obtained when six examiners had been present at interviews, with two examiners asking questions but all six marking. Dr. A. C. DORNHORST (London) said it was a remarkable response to the available evidence that the General Medical Council should have recently increased the time to be spent on long cases. Dr. R. L. RICHARDS

(Glasgow) said that Glasgow students in their fourth year took an examination which, while not affecting their final results, gave them prizes and so on; it lacked the strain of the final examination. Traditionally the examination was to answer three out of four questions, but in the last three years there had been added multiple-choice questions with the questions standardized so far as possible. What had been surprising was the general agreement between the results of the two types of examination. Professor G. A. SMART (Newcastle) said that about seven years ago, while at Bristol, he had asked students to volunteer for multiple-choice-question examinations. He also had been astounded at the degree of correlation. Professor G. P. MEREDITH (Leeds) pointed out that multiple-choice questions involved a great deal of work. They could not be made up overnight, and he hoped that it would be possible to build up a large pool of such questions.

Teaching of Social Medicine

The final paper of the day was by Dr. J. N. MORRIS, director of the Medical Research Council's social medicine research unit. He thought it interesting how the attitude of general practitioners to quantitative methods had changed over the years. Every doctor now knew that he had to deal with the problems of vaccination, polio, and smoking and lung cancer. It was important also for the doctor to know about the patient's background. For instance, a surgeon dealing with a crushed foot, the result of an industrial injury, had been surprised to find that in many factories there was a kind of collusion between management and labour to ignore safety measures. If students were to be taught in the best clinical tradition, by example and experience, the place to do it was in the family, in the home of the general practitioner and of all the other services to the community, not in the hospital. If it was desired to train students to keep people out of hospital, the place for that to be done was obviously not in the hospital.

Dr. J. K. RUSSELL (Newcastle upon Tyne) agreed that, if one was to make a complete study of the influence of environment on obstetrics, the place to do that was outside the hospital, but one needed a complete section of the community. Professor T. HALE HAM (Western Reserve) said that students in hospitals in the United States often dealt with one ethnic group, a limitation which introduced a number of problems. Dr. BOWERS added that in the United States the importance of "preventive medicine," as they preferred to call social medicine, had been increasingly recognized in the last 10 years.

Professor K. R. HILL (London) said that there might be an argument for a shorter course of perhaps four years with postgraduate work to follow. It had to be remembered that in many parts of the world the proportion of population to doctor was enormously higher than it was in Britain, and that what was done in England or in the United States had a marked effect on attitudes in places like India, where the shortage of doctors was acute.

The Western Reserve Experiment

On the second day of the conference the morning session was devoted to a paper and discussion on medical education at Western Reserve University. Dr. J. G. MCCRIE, dean of the medical faculty at Sheffield, was in the chair.

Professor T. HALE HAM, professor of medicine at Western Reserve, said that in planning the experiment in medical education at Western Reserve they had decided that policy should be the responsibility of the general faculty. This was composed of part-time and full-time members. Revision of the programme was undertaken through a standing committee of nominated representatives from each department, and the programme itself was the subject of research and report. Two-day summer meetings were held, when about 80 heads of departments and others discussed

problems and reports. There had been remarkable participation by the faculty members in the development of policy and deciding what should be done. The experiment had been begun shortly after the second world war, when most heads of departments were newcomers.

The faculty had worked on the principle that the medical student was to be treated as a mature individual and colleague, and given increasing responsibility for his own education, for knowledge of medicine, and for care of patients. That required a mature system of examination and grading. The student's initiative and resourcefulness were to be encouraged, and in each year students were to be given time for elective subjects or courses. The examination system, which had been very much a quiz system, was overhauled. During the first and second years there were interim examinations about every eight weeks. The students were not given grades on the examinations, which were intellectual exercises based on the work that had gone before. Only those students having difficulty were identified. Papers were handed back with helpful comments. At the end of the first year there was a comprehensive three-day examination and again those having difficulty were identified, but otherwise there was no grade or report other than a pass grade. About 5% of the students fell by the wayside during the four-year course. A few repeated their early years' work. National Board examinations came at the end of the third year, and clinical examinations at the end of the fourth year. Students expected to pass these examinations, and did so without making them a major problem. There was neither cramming nor loss of time. Students were characterized but not necessarily graded.

Every week students had a substantial amount of free time during which they could begin to learn on their own. Although about a third of the students had difficulty in usefully employing their free time in the first six months, by the end of the first year they were all using it and would not give it up. They spent it on academic subjects, studying for examinations, or working on the projects which formed part of the system. Free time had done a great deal to set the environment for the student.

It had also been decided that there should be longer contact between student and instructor to provide the education and personal guidance of a graduate school. This was obviously the tutorial method. They tried to correlate the teaching of biological and medical subjects, and this allowed multiple approaches to a subject and the avoidance of certain extremes of specialization. It also fostered inter-departmental communication and it had certain advantages for the faculty as well as for the student. Working independently, Harvard University had decided to use a similar system for teaching the biological sciences, and, with modifications, the programme was now to be extended to Harvard Medical School. Preliminary results at Western Reserve were such that there did not seem much likelihood that students or staff would want to change back to the old system.

The projects undertaken by the students very early in their course were not meant to be intensive studies of small areas of medical science. They afforded the student an opportunity of taking part in his education, and the students liked them. At least half the students worked on their projects for the second year. At the end of their second year students were required to write a thesis, which meant that they had to think carefully about what they undertook. Very early in his career each student worked with a newly born child, having met the mother during the latter part of her pregnancy. He made visits and discussed cases. Going into homes gave students an opportunity to observe the normal course of preventive medicine and gave them an insight into the lives of patients. The student examined patients, with his preceptor, or tutor, acting as consultant and ultimately responsible. That was different from being an apprentice, because the contact was between patient and student direct.

Some Criticisms

Opening the discussion, Professor G. A. G. MITCHELL (Manchester) said that they were apt to forget that dissatisfaction with medical education was not new. The medical journals of a century ago contained bitter denunciations of the teachers and methods of those days. The difference was that the subject was now receiving more attention and the Flexner Report had crystallized matters in the United States. The situation at Western Reserve after the war had been unusually favourable in that most heads of departments were changed in a relatively short period. One factor to consider was whether students on each side of the Atlantic were sufficiently similar for ours to be subjected to the same programme. On average, American students were three or four years older. Those years had been spent at college undergoing what was called a liberal arts training. Others were experienced in assisting in medical research projects. The result was that the American student was more mature than his British counterpart. He had found that many American students were married and that their wives worked full-time to help to defray the very heavy cost of a medical education in America. When there was a high failure rate, the blame was all too often attributed to the student. Only rarely, if ever, was it asked whether the teaching methods were sound. In the United States the failure rate was 5% to 8%. Here rates of between 25% and 40% were not uncommon among those training for the professions. Some examiners unfortunately regarded that as a matter for praise and not for blame, and referred to "keeping up the standards." They should examine themselves or their methods of teaching to see why there was such a shocking failure rate among students usually carefully selected.

Students being introduced to patients at a very early stage in their careers, as at Western Reserve, certainly stimulated enthusiasm. However, in his visit there he had gained the impression that some students were completely at sea, and he wondered whether a later introduction might not have been more profitable. He had questioned Western Reserve students and had found that none of them was treating "free time" as time off. They were using it for study and so on. Schools in Britain mostly left students a certain time to do as they chose.

Most American schools now devoted time to elective projects, but he had not been over-impressed by the results he had seen. The students seemed to be trying to run before they could walk. He thought that not more than 5% of students were capable of being taught and trained in that way. Too little time was devoted to basic subjects such as anatomy, physiology, and pathology, and to clinical work. The closer integration of preclinical and clinical subjects was admirable because it eliminated duplication and overlapping, made learning easier, instilled the idea of essential unity, and accomplished more in less time. However, he did not think four years was a sufficient training.

Professor W. M. ARNOTT (Birmingham) said that he did not take so gloomy a view as Professor Mitchell. He did not think that teachers knew how much talent students had. If students were encouraged more and given more opportunity for medical research, it would be found that they had a great deal more talent than was expected. Although Professor Mitchell had been disappointed with the papers published by Western Reserve students, it was a fact that papers by students had been published in medical journals in this country. The general physician had an important part to play in bringing together all the specialties in medicine, and in that way could be of great assistance to the student.

New Swedish Curriculum

Sir RUSSELL BRAIN presided at the final session, which was devoted to discussion of a paper on the new Swedish curriculum by Professor B. REXED, of Upsala University.

After explaining that all five Swedish universities were fully supported by the Government, Professor REXED said that until the introduction of the new system the regulations

operating in Sweden had dated from 1907. Since then new subjects had been born and science had made great progress. A committee headed by a senior administrator from the Department of Finance, and which included a Member of Parliament as well as representatives from different branches of medicine and a student, had therefore been appointed to go into the matter. This committee drew up a provisional curriculum which was offered to the different medical faculties three times, on each occasion incorporating fresh suggestions, until it was finally accepted and approved by the Government.

The old course had lasted eight years, followed by four in a junior hospital post. The present course lasted six and a half years, followed by hospital training. The first two years of the course were devoted to preclinical subjects, and then there was the four-and-a-half-years period leading to the examination required for medical registration. The Swedish system was not to have general examinations. Examinations came at the end of each subject and were a matter between student and teacher. At a time which the student decided, he could go to his professor and ask for an examination, which the professor was obliged to provide within two weeks. There was then an interview, after which the professor said whether the student had passed or failed. The student could take the examination again and again, though not more than twice in the same term; and, if the student was dissatisfied with the professor's way of asking questions, he had the right to ask for a public examination before witnesses. The failure rate was between 5% and 10%—about the same as in the United States—and the principal reason for a student failing an examination was not intellectual but psychiatric or some other cause. When a student passed an examination his professor signed the appropriate place in the student's examination book, and when the student had the necessary number of signatures he presented his book to the faculty and got a formal diploma. Although Swedish medical courses did not specifically provide for correlation, teachers were encouraged to correlate as much as possible and were doing so more and more.

Dr. J. R. ELLIS, secretary of the association, opened a short discussion on Professor Rexed's paper. Dr. Ellis said that from what he had seen on Swedish medical education it was clear to him that it succeeded in marrying clinical art and science. A big difference between the Swedish and British approaches was that in Sweden students and teachers recognized that most people would take more than the minimum period of time allowed in the curriculum, and arrangements were made accordingly. It seemed illogical and educationally unsound that all students should be expected to cover the same ground at the same speed.

Professor ROBERT PLATT then summarized the conference, and declared it concluded.

Officers of the Association

The following are the officers of the Association for the Study of Medical Education: Chairman, Professor Robert Platt; vice-chairman, Dr. J. G. McCrie; treasurer, Dr. M. I. A. Hunter; secretary, Dr. J. R. Ellis; executive council, Dr. E. R. Boland, Sir Russell Brain, Professor J. H. F. Brotherton, Sir David Campbell, Professor A. M. Claye, Professor M. W. Fullerton, Professor G. A. G. Mitchell, Professor G. W. Howie, Professor G. P. Meredith, Mr. M. F. Nicholls, Sir Harry Platt, Professor H. Scarborough, Dr. R. Scott, and Professor A. P. Thomson.

Higher Education in the United Kingdom, compiled jointly by the British Council and the Association of Universities of the British Commonwealth (Longmans, Green and Co., 5s.) is intended primarily for students from overseas, but should also be of value to anyone in Britain concerned with advising and placing such students. Medicine and related subjects are fully covered.

To-day's Drugs

In this column we publish from time to time authoritative notes on a selection of drugs in current use.

Arterochol (Ward, Casson Ltd.).—This emulsion contains 8.33 g. of corn oil, 0.6 mg. of pyridoxine hydrochloride, and 12 mg. of α -tocopherol acetate. It lowers the level of serum cholesterol. The active constituent is almost certainly corn oil, since there is at present no satisfactory evidence that either pyridoxine hydrochloride or α -tocopherol acetate produces any significant or lasting reduction of the level of serum cholesterol in man. To some patients an emulsion may be more palatable than an oil, but it is worth noting that corn oil is already available more cheaply as maize oil B.P.C.; it will produce comparable depression of the level of serum cholesterol when administered in a smaller quantity than as an emulsion. On present evidence the administration of any corn oil preparation is best restricted to hypercholesterolaemic patients with a bad family history of coronary disease or with xanthomatosis.

BRONCHIAL MUCUS SPECIMEN TRAP

Mr. K. S. MULLARD, F.R.C.S., writes: A quantitative investigation into some of the constituents of normal and abnormal bronchial mucus required the collection of specimens of bronchial mucus uncontaminated and undiluted. The U-tube specimen trap, which is usually attached by a short length of rubber tubing to the proximal end of the sucker, is unsuitable because the specimen of

mucus must traverse the full length of the metal bronchoscope suction tube. The small amount of mucus present normally makes it impossible to collect any measurable quantity by this technique.

To overcome this difficulty Messrs. Allen & Hanburys have made for me a mucus specimen collecting-tube and have made for me a mucus specimen collecting-tube and special bronchoscopic sucker, as illustrated. The collecting-tube is attached to the distal end of the metal sucker, and its calibre is such that it passes down an adult male Negus bronchoscope. The specimen tube, made of plastic, has a screw thread by which it is attached to the distal end of the metal sucker tube. The tip of the specimen tube is curved to one side so as to bring it in contact with the bronchial mucosa. The metal bronchoscopic suction tube, which is otherwise of the usual pattern, is fitted with a bevelled flange which has a screw thread, to which the specimen tube is fitted. The flange allows the instrument to be withdrawn easily up the bronchoscope. The orifice at the tip of the metal sucker is placed to one side to prevent the mucus specimens being withdrawn into the metal sucker tube. The specimen tubes are provided with rubber caps, which are fitted to each end when the specimen has been collected, and they are then sent direct to the laboratory. It is necessary to be able to control the pressure of the suction motor, as only a very small amount of suction is needed to draw the mucus into the specimen tube; excessive suction empties the specimen tube.

Correspondence

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

Tonsillectomy and Poliomyelitis

SIR,—A boy aged 6 years had his tonsils removed three weeks ago. While the boy was in hospital for tonsillectomy, his father became ill at home with headache, neck stiffness, and backache. This illness cleared up after a few days, but a fortnight after returning home the boy developed bulbar poliomyelitis. The father's illness must have been non-paralytic poliomyelitis, but tonsillectomy made sure the son's attack was bulbar.

The relationship between tonsillectomy and bulbar poliomyelitis is accepted. Poliomyelitis vaccine almost certainly gives some protection against the disease. Is there any justification for carrying out tonsillectomy in children, or adults, who have not been inoculated against poliomyelitis? It should very seldom be difficult to postpone the operation till two injections of vaccine have been given to the uninoculated, or a booster dose to those already inoculated.—I am, etc.,

Physiotherapy for Bell's Palsy

SIR,—The article by Mrs. J. Mosforth and Dr. D. Taverner (*Journal*, September 13, p. 675) is a valuable contribution to the literature on this subject, but the conclusions, unless amplified, may give an erroneous impression to many readers seeking information on this much debated subject.

During the past 10 years we have investigated about 2,000 cases of facial palsy at this clinic, and on the experience so gained we have based the following routine: (1) All cases, following clinical investigation, are referred to an aural surgeon so that aural pathology can be assessed or excluded. Facial palsies originating from trauma, cholesteatoma, neuroma, infections of the middle ear, and mastoid cells may thus be given the earliest possible opportunity of surgical treatment. (2) Transcutaneous electrical tests and an electromyographic examination are carried out about four weeks after onset. These tests are repeated at intervals until a final assessment has been reached. (3) No electrical stimulation is given to the affected facial muscles, but physiotherapy, in the form of mild heat, gentle effleurage, and re-educational movements, begins as early as possible, a support for the weak side of the mouth being fitted if necessary.

In regard to speed of recovery, a high percentage of Bell's palsies show considerable improvement a few weeks after onset and can soon be discharged from hospital clinics. All the uncomplicated Bell's palsy cases in our series improved without surgical treatment. Electromyography is of the most valuable help in determining the earliest evidence of recovery of innervation, but much patience and perseverance are required, as the earliest electromyographic evidence of reinnervation may be delayed for many months—one case in our series only showed its first electromyographic evidence of recovery 13 months after onset.

In their discussion portion of the article Mrs. Mosforth and Dr. Taverner appear to draw no distinction between electrotherapy and physiotherapy, and this may be misinterpreted by some readers as implying that such cases need not be referred to hospital clinics. Our own experience leaves no doubt that the most valuable part of physiotherapy in Bell's palsy is re-education in facial movements. This is not easy for most patients to carry out without much guidance and supervision. Frequently, where there has been a delay of several weeks or months before attendance at hospital, we have found that what appears clinically to be a severe facial palsy may, on electromyographic examination of the affected facial muscles, show excellent motor unit action-potentials on attempted voluntary movement. In other words, reinnervation has occurred but the patient is

unable to translate the cortical message into voluntary movement of the facial musculature—almost a replica of the Kenny conception of alienation in paralytic poliomyelitis. Such patients will improve on re-education in facial movements, although for weeks or months prior to such treatment the local condition would appear clinically to have been deteriorating.

There are many other interesting aspects of this fascinating problem, but for purposes of brevity I shall conclude by suggesting that, for exclusion diagnosis and for assessment of treatment, all cases of facial palsy should be referred as early as possible to hospital clinics.—I am, etc.,

Coventry and Warwickshire Hospital,
Coventry.

Attempted Suicide

SIR.—It is clear from Dr. A. A. Bartholomew's letter (*Journal*, September 20, p. 740) that our profession has developed a puzzling ataxia in its attitude towards individuals who have attempted suicide. While there is a consensus of medical opinion that genuine attempted suicide is a matter for the doctors and not for the police, some mental hospitals are disclaiming responsibility for a proportion of these patients. Many are intractable psychopaths and some are known to discharge themselves prematurely, but I have no doubt that hospital is a better place for them than prison. There is much to be said for the view that anyone who has made a recent serious suicidal attempt is *ipso facto* certifiably insane, being certainly in need of care, supervision, and control for his own safety.

However, if the recommendations of the Royal Commission on the Law Relating to Mental Illness and Mental Deficiency, 1954-7, become law, mental hospitals will not be obliged to accept certified patients and will be able to refuse them as they now refuse would-be voluntary patients. It is evident that, if the creation of a class of neglected outcasts is to be prevented, new legislation must embody provision for an overriding authority capable of securing a patient's admission to hospital, of ordering a given hospital to take him, in fact. This power should include voluntary patients as well as certified.—I am, etc.,

London, S.E.26.

Isoniazid Absorption

SIR.—Since 1952 isoniazid has been administered as a standard adult dose of 300 mg. daily in a number of centres. The tissue concentration of this freely diffusible drug will vary inversely as the body weight.¹ Hughes *et al.*² have shown the wide individual range in the rate at which isoniazid is handled biochemically. Therefore, before embarking on a prolonged course of antituberculous drugs of which isoniazid is to be one, these variables should be assessed to avoid ineffective treatment which may only become apparent when sputum conversion is delayed, often associated with the emergence of a strain resistant to the complementary drug, as occurred in the following case:

H.C., a 40-kg. woman aged 42 years, had excavating tuberculosis confined to the left upper lobe. The gastric contents contained virulent tubercle bacilli. Chemotherapy consisted of streptomycin 1 g., isoniazid 400 mg. by mouth, daily for 90 weeks. Although the x-ray appearance improved a little, the E.S.R. remained raised and the gastric contents grew tubercle bacilli insensitive to streptomycin at a concentration of 10 µg./ml. but sensitive to isoniazid in a concentration less than 0.3 µg./ml. Isoniazid-handling studies showed less than 0.02 µg./ml. in the serum when 40 mg./kg./day was given orally, and it was not until the dose was 80 mg./kg./day that a six-hour serum level of 1.6 µg./ml. was achieved. There were no side-effects save the inconvenience of swallowing so many pills. However, 100 mg. isoniazid given into muscle produced the same serum level of 1.6 µg./ml. in half an hour and this was sustained for one hour, when the level fell to 0.4 µg./ml. in 1 hour 40 minutes. It was concluded that her failure to respond to adequate chemotherapy over the preceding year and a half was accounted for by an inability to absorb oral isoniazid.

The decreasing number of new cases is now sufficiently small to permit routine isoniazid-absorption and handling

studies before instituting treatment. The method of assaying serum-isoniazid levels with cultures of H37RvS-RSM described by Kass *et al.*³ can be used routinely, although modification in detail was necessary in this case. Treated cases of pulmonary tuberculosis which relapse may repay investigation along these lines, but so far the number investigated by us is not large enough to provide evidence that abnormal isoniazid-handling is a significant factor.—We are, etc.,

Cutting Pains

SIR.—The cutting pains of short duration in which I am interested may be of no significance from a therapeutic point of view, and should usually cause no anxiety, but I believe that they are not "imaginary" and that they have an actual mechanical causation. Growing pains in children have sometimes been regarded as very mild forms of acute rheumatism, but the pains which I have in mind are, I think, not usually connected with joints but rather with the shafts of long bones, such as the tibia. I suggest that they are caused by the formation of the septa in the cancellous bone marrow, some of which may for a time have an irritating, cutting edge. I suggest that the occasional feeling in young persons as if their thorax were transfixed with a dagger may be due to calcification in some of the hilar lymph glands (bovine tuberculosis?) mechanically irritating nervous structures in their neighbourhood. Some kinds of sudden abdominal pains may have an analogous origin. When Sir Arthur Keith was demonstrating some spicules of calcification at the base of the brain, a well-known coroner's pathologist near me said: "That's where I come in; one of those spicules might cause death by perforating a blood vessel."

A sufferer from chronic hypertrophy of the prostate gland in addition to his ordinary pains and inconveniences may sometimes complain of a sharp, transitory, cutting pain, which, I suppose, is due to calcification connected with his disease.—I am, etc.,

Calf-pulse Sign

SIR.—In Scherf and Boyd's textbook¹ we read that aortic regurgitation, one of the commonest pure valvular lesions, is often discovered only late, as most patients have but few symptoms. It seems all the more important therefore to give very close attention to the physical signs of the condition.

The typical pulse is variously known as *pulsus altus* (or *magnus*) *et celer*, Corrigan's pulse, the collapsing-artery pulse, or the water-hammer pulse. According to Major² the term water-hammer pulse is more often used than understood. He reminds us that a water-hammer was a kind of toy or physical apparatus common during the nineteenth century. It consisted of a thick glass tube, about 1 ft. (30 cm.) long, half-filled with water. The air was expelled by boiling the water, and immediately afterwards the end of the tube was sealed. If such a tube is then inverted the water falls through the vacuum like a solid body, and the hand gripping the tube feels a hard blow or knock similar to the knocking of the pulse wave in aortic regurgitation. This hard short blow of the pulse wave is particularly well felt by gripping the volar surface of the patient's forearm with the whole hand.

I wish to draw attention to the fact that the water-hammer pulse can be felt even more distinctly, and moreover in several arteries, in the calf. The postero-medial aspect of the lower part of the calf is grasped firmly in the examiner's hand and relatively strong upward pressure applied on the lower calf muscles.

Why should the water-hammer pulse be felt so easily here? The reason is that the arterial pressure in the legs, especially in cases of aortic regurgitation, is higher than in

the arms, unless, of course, there is arterial occlusion; and this is also true of the pulse pressure, whose characteristic elevation accounts for the water-hammer pulse. For instance, in a patient of 25 with aortic regurgitation the blood pressure in the arms was 140/70 mm. Hg, while in the legs it was 240/115 mm. Hg—a pulse pressure of 125 mm. Hg. In normal subjects the differences in pressure in the arms and legs are usually much less (at least at this age). This peculiarity of aortic regurgitation has been called the Hill phenomenon.³

A water-hammer pulse is sometimes found in other pathological conditions besides aortic regurgitation—such as arteriovenous fistula, patent ductus arteriosus, aortic aneurysm, and occasionally where there are senile arteriosclerotic changes in the aorta and great vessels. However, closer examination will usually allow such conditions to be distinguished. In aortic regurgitation the calf-pulse sign is almost always present. Conversely, the forearm pulse can sometimes be felt in normal individuals, but except in the case of the elderly people with arteriosclerotic changes mentioned above I have not so far felt the calf pulse in a normal subject. I suggest, therefore, that the calf grip should be adopted routinely, in preference to the forearm grip, in the examination of cardiac patients.—I am, etc.,

Fritz O. P. Trautmann.

Ergometrine with Hyaluronidase

SIR.—I have read with interest the paper by Drs. M. P. Embrey and W. J. Garrett (*Journal*, July 19, p. 138) on the speed of action of ergometrine with hyaluronidase. Their results confirm and amplify the observations made at University College Hospital three years ago, using the same method.¹ Examination of the two sets of results suggests that the extent to which hyaluronidase accelerates the action is dependent on the dose of ergometrine used. In our experiments, two doses of ergometrine, 0.25 mg. and 1 mg., were used. With the 0.25 mg. dose, addition of hyaluronidase to the intramuscular injection resulted in a reduction of the average time between injection and response from 9.9 to 5.4 minutes. With 1 mg. doses, hyaluronidase did not affect the latency, which was about 4 minutes. The observation by Drs. Embrey and Garrett that the latency of an intermediate dose, 0.5 mg., is reduced from 7.0 to 4.6 minutes by addition of hyaluronidase completes the picture. The reduction in latency is, however, only one of several effects of hyaluronidase. I found that with 0.25 mg. and 1 mg. doses of ergometrine addition of hyaluronidase increased the strength of the resulting uterine contraction by 30% and 50% respectively.

The results of clinical trials using ergometrine, alone or with hyaluronidase, do not substantiate the view of Drs. Embrey and Garrett that the addition of the latter is of questionable value. Using intramuscular ergometrine alone, Daley² obtained a post-partum haemorrhage rate of 9.2%. Soiva³ an incidence of 8.7%, and Kimbell⁴ 3.5%. Combining ergometrine with hyaluronidase, Kimbell⁴ reduced the post-partum haemorrhage rate to 0.9%, and, using this combination, Dutton⁵ obtained a figure of 2.6%. If the ergometrine-hyaluronidase combination is made up ready for each delivery, then the disadvantage of the longer time taken to mix the injection need not be considered. The cost of an ampoule of hyaluronidase is 2s. 4d., which compares favourably with a course of "ferrivenin," a course of "imferon," or a bottle of blood, which may otherwise be required.—I am, etc.,

Iodine and Adrenocortical Function

SIR.—Clinical observations have suggested the possibility of adrenocortical function being decreased by inorganic iodine. To elucidate this question the corticoid (neutral phosphomolybdic-acid-reducing lipid-soluble substance) output of dogs was examined in conjunction with prolonged administration daily of 30 to 60 drops of Plummer's solution (iodine 0.5 g., potassium iodide 1 g., and distilled water to 10 ml.). In a great number of controls excretion of this steroid was found to be 10-20 µg. per hour. In dogs given Plummer's solution continuously, determination mostly showed values below 10 µg. per hour. After discontinuing the Plummer's solution corticoid excretion returned to normal; in some cases it even exceeded normal values, but decreased again upon administration of iodine.

The excretion of these corticoids as well as that of the 17-ketosteroids was then determined during the administration of Plummer's solution to four patients with adrenal hyperfunction. Almost always excretion of the reducing steroid definitely decreased, e.g., values of 990 and 920 µg. per 24 hours fell to 490, 410, 320, 650 µg. per 24 hours during the administration of the Plummer's solution. In another case, when Plummer's solution was given, initial values of 580 and 630 µg. per 24 hours declined to 260, 520, 290 µg. per 24 hours. In two patients with Cushing's disease body weight and blood pressure also diminished. In two instances ketosteroid excretion was likewise reduced—e.g., from values of 19.6, 17.7, 18.7 mg. per 24 hours to 11.5, 12.5 mg. per 24 hours.

Assuming that iodine may inhibit the secretion of corticotrophin, we carried out trials in rats of Wistar strain in order to clarify the mechanism of action. The ascorbic acid content of the opposite adrenal was examined one hour after unilateral adrenalectomy in animals iodinated in the usual manner and in controls. The experiment failed to confirm our assumption. After unilateral adrenalectomy the loss of ascorbic acid in the opposite adrenal was exactly the same in the animals receiving Plummer's solution as in the controls; and likewise no difference was observed in the degree of hypertrophy of the remaining adrenal. It was, however, striking that from the first the ascorbic acid content of iodinated animals was without exception consistently (about 30%) lower than that of the controls. According to our present knowledge, the lower ascorbic acid level cannot be ascribed to the use of iodine causing stress, since comparison between the adrenals of iodinated animals and control groups revealed no difference in weight.—We are, etc.,

Human Mammothrophin

SIR.—Professor Geoffrey Hadfield's letter (*Journal*, September 6, p. 633) concerning the mammothrophic activity of human urine will be welcomed by those who, on a humble scale, have been following his methods of investigation. It is reassuring to know that he and his colleagues have also found "the investigation of human pituitary function in the intact animal to be fallacious and confusing." As he has suggested, there are several reasons why this should be so, quite apart from the variation in control animals noted by Williams.¹ Even when the very pure sheep-prolactin kindly supplied by the Endocrinological Study Group of the National Institutes of Health, Bethesda, U.S.A., is used, relatively large quantities are necessary to induce breast growth in hypophysectomized or intact A2G weanling male mice in combination with other steroids. Until the properties of human prolactin have been determined it is difficult to equate the response of mice to human urine or to prolactin from other sources. Crude acetone extracts of 200 mg. wet weight of fresh human pituitary appear to be more effective in stimulating mouse breast growth than a total dose of 20 mg. of ovine prolactin. Another complication may arise from the presence of prolactin inhibitors or oestrogen competitors in human urine. For instance,

Starr and his colleagues² have recently described thyrotrophin (T.S.H.) inhibitors in the urine of certain patients. These and other factors may influence another aspect of this work, the correlation of urinary mammothrophic activity with the clinical response to hypophysectomy of patients with cancer of the breast.

Professor Hadfield has recorded that "significant regression of tumour growth was obtained only when the pre-operative specimen possessed easily recognizable mammothrophic potency, whilst little or no regression was the rule when no pre-operative potency could be demonstrated."³ This has not been our experience at the Royal Free Hospital.⁴ All investigations which may illuminate the shadows surrounding the problem of hormone sensitivity in breast and prostatic cancer are, as Dr. A. C. Crooke stated (*Journal*, July 26, p. 225), of potential value. But the facilities needed for the effective processing of large volumes of urine,⁵ the preparation of hypophysectomized mice of pure strain, and the sometimes neglected correlation of laboratory and clinical observations are not readily available at the present time. I hope that Professor Hadfield and his colleagues will continue to publish the results of their extensive and laborious clinico-pathological researches, for many of us are indebted to him for awakening interest in this field.—I am, etc.,

London, N.W.3.

Vitamin E in Habitual Abortion

SIR,—It is usually the concern of the general practitioner to advise a patient who has had one or more miscarriages and who wants to know what to do if she again becomes pregnant. I have been particularly interested in habitual abortion for nearly three years and can now report on the treatment of 32 patients. One case was of particular interest, and, in fact, it was the good result achieved in this patient which prompted me to treat more patients in the same way.

This patient already had a history of three miscarriages when I was called in to give her emergency treatment for a threatened abortion (she had recently moved into the district). She was admitted to hospital, where she again aborted. She came to see me afterwards, and the hospital notes stated that any treatment, hormonal or otherwise, would be unlikely to achieve a live birth. In view of previous successes with vitamin E, I encouraged this patient to become pregnant, and, as soon as she had missed her first period, she was instructed to take "ephynal," 50 mg. t.d.s., until the 28th week of pregnancy. At the end of the second month she had a chest infection and, as a result of coughing, she started to have a threatened abortion (i.e., bleeding). She was treated with sulphonamides and the bleeding stopped when her chest infection cleared. During the third month she again had a chest infection and untreated abortion, but bleeding again ceased as the infection resolved after treatment with an antibiotic. She had a home confinement, and I was present when she gave birth to a male child weighing 10 lb. 2 oz. (5.6 kg.).

Of the present series of 32 patients treated with vitamin E, all had had one or more miscarriages (usually two) occurring at the second or third month. One patient had had three miscarriages and another had had four. Following treatment, 19 have been successfully delivered and two are now due; three are six months and three are three months pregnant. Two patients have moved from the area and three have had another miscarriage.

It is often stated that progesterone is much more effective than vitamin E, but I have not found this to be the case. In addition, the administration of progesterone to pregnant women is not without danger, as there have been reports (see *Journal*, July 26, p. 218) of pseudohermaphroditism in babies whose mothers had been treated for habitual abortion with methyltestosterone or progesterone (which is partly converted to testosterone in the body). From my own results, I am fully convinced that vitamin E is effective in many cases of habitual abortion.—I am, etc.,

Congenital Deaf-mutism

SIR,—I agree with Dr. L. Fisch (*Journal*, September 13, p. 692) that the arguments produced by Dr. J. McKenzie (*Journal*, July 26, p. 201) in support of his thesis that the cases described had a gross middle-ear involvement are far from convincing. His assumption that congenital defects of the middle ear lead to a disuse atrophy of the cochlea is quite incorrect. It is well known that children with bilateral congenital atresia of the auditory meatus with malformation of the incus have an excellent inner-ear function and may be operated on successfully by tympanoplasty and made to hear even after many years of deafness.

Dr. McKenzie writes that "it is unlikely that a less degree of perceptive deafness could cause a major degree of conduction deafness." That is indeed true—in fact, no clinical condition is known in which perceptive deafness is the cause of a middle-ear deafness. Dr. McKenzie states that in his cases "no morphological evidence of a defect of the middle ear is available; x-ray examination with various projections has been of no assistance in identifying the presence or absence of the ossicles, far less their normality. . . ." It is unlikely that audiological and clinical arguments would convince an embryologist. The central problem, whether or not the middle ears of these deaf-mute children are grossly abnormal, can, however, be settled by direct inspection. Since the introduction of an operating microscope the middle ear is no longer a field for academic speculations and the state of the auditory ossicles need not be investigated by x rays.

As so many pathological conditions of the middle ear are now amenable to surgical treatment, it would be justified to explore the cases in which the bone conduction is considered to be good. (Dr. Fisch is sceptical about the reliability of the bone conduction audiograms in these cases, in my opinion rightly.) After reflecting a tympanomeatal flap from the postero-superior meatal wall forward over the handle of the malleus (Rosen's approach to the middle ear) with the aid of an operating microscope, the shape of the incus and the stapes can be seen and their mobility tested and the presence or absence of movement of the light reflex in the round-window niche observed. Thus direct inspection of the middle ear would prove or disprove Dr. McKenzie's assumption of a gross middle-ear lesion in his deaf-mutes.—I am, etc.,

Liverpool, 22.

FRANCIS BAUER.

Prevention of Lung Cancer

SIR,—I am a member of a unit into which annually 400 patients suffering from carcinoma of the bronchus are now admitted. As a man who enjoys tobacco smoking and as an ardent follower of the maxim that "a little of what you like does you good," I have tried to remain aloof from the enthusiastic evangelism of the anti-smoking crusaders. It becomes impossible, however, to maintain a neutral attitude. It is one thing for statisticians to demonstrate their theses with a slide rule and quite another when, having become aware of the possibilities, the truth shrieks at one from countless bedside ash-trays. I do not believe that any thinking man can see large numbers of patients suffering from this condition without becoming convinced beyond reasonable doubt that excessive cigarette smoking is a major aetiological factor.

Having accepted this, the duty of our profession is quite clear. We are no more entitled to issue a certificate of natural death for an excessive smoker who dies of carcinoma of the bronchus than we would be to certify natural death in a coal-miner dying of pneumoconiosis or a mule-spinner of cancer of the scrotum. It is in our hands to see that inquests are held in all such cases, and the cause of death—the poisonous effect of inhaled cigarette smoke—made plain. If only 50% of doctors will follow this course, the publicity that will follow in every local community might abort many of the tragedies now gestating. I propose in future to pursue this course of action.—I am, etc.,

Liverpool, 1.

LESLIE J. TEMPLE.

Imbecile Children

SIR,—Drs. Evelyn B. Lind and Brian H. Kirman (*Journal*, September 20, p. 743) show that the death rate in young imbecile children admitted to the Fountain Hospital is high—est in the immediate post-admission period, and give this as an additional reason for keeping them at home. The argument seems to be fallacious unless it can be shown that the death rate would have been lower had the children remained at home. As the patients admitted are likely to constitute a highly selected series by reason of difficulty in their upbringing, it would probably be quite impossible to check this by means of a control series. One would hardly expect, however, that skilled nursing and medical attention would hasten the death of these children.—I am, etc.,

C. GUY MILLMAN.

Morpeth, Northumberland.

Why Are Medical Journals So Dull?

SIR, I enjoyed reading Dr. Richard Asher's article "Why Are Medical Journals So Dull?" (*Journal*, August 23, p. 502). However, I cannot agree with all his suggestions. A medical journal contains articles of interest to physicians, most of whom are quite capable of disentangling the medical phraseology and separating the wheat from the chaff. On the other hand, the *Reader's Digest* and other popular magazines are written for sale to the general public, and technical terms and language are reduced to a minimum. Suppose, for example, that I had an article to write for a medical journal: a comparison between two analgesics. I might entitle the article "A Comparison of the Analgesic Properties of Morphine and Pethidine in the Geriatric Patient." In it I might show that in a series of 25 cases 15 patients seemed to have more relief from pain with pethidine than with an equivalent dose of morphine, 5 noticed no difference, and the remainder had more relief from morphine. This is no earth-shaking discovery; in fact, considering the small number of cases in the series it doesn't mean a thing. However, entitle the article "Pethidine More Effective than Morphine in 60% of Old People" and include a few dramatic pictures of elderly patients leaping out of bed, and the whole thing becomes much more dramatic. Even a layman could read and understand [sic] it. After a few such articles newspaper editors would start eagerly scouring each journal as it came out. Picture the headlines: "Does Your Doctor Still Use Morphine? Recent Scientific Tests Conclusively Prove that Pethidine is More Effective than Morphine, Although Many Physicians Still Use the Older Preparation," and so on. I agree with Dr. Asher that there is a need for more simplicity in the writing of articles for medical journals. There is, however, a danger in making medical journals too attractive, too easily (mis)understood. Let's keep them for doctors only.—I am, etc.,

PETER D. SEARS.

Flushing, N.Y.

Immunization Card

SIR,—Many difficulties arise as a result of the multiplicity of immunizing procedures (*Journal*, September 13, p. 691). One is that of ensuring that there is a complete and accurate record, and I feel that local health authorities should undertake the responsibility of ensuring that this is done. Every child and eventually every adult should have a record card which contains an adequate account of the immunizing procedures. Though there can be no guarantee that any such record will be complete and accurate it would be an improvement on the arrangements now prevailing. The record should of course be freely available at short notice to the hospital and the patient's doctor.—I am, etc.,

Sheffield, 1.

LYWELYN ROBERTS.

SIR,—For several years I have issued my patients with an immunization record card as sent to me free of charge by Messrs. Glaxo Laboratories Ltd. These cards are the same size as the National Health medical cards, and are very use-

ful to the parents when the children go to school, etc. Details of immunization are of course entered on the National Health Service record card at the same time.—I am, etc.,

Hartgate, Yorks.

RUTH BLACKWOOD.

Buzzers for Bed-wetters

SIR,—In your very fair and valuable annotation (*Journal*, August 23, p. 499) there is one disadvantage that you do not list. As the buzzer works when the child passes urine he becomes conditioned this way. I call it the "back to front reflex" and treat it by counter-suggestion—i.e., under hypnosis the child is told that the buzzer means getting up and not passing his water.—I am, etc.,

London, W.1.

GORDON AMBROSE.

SIR,—Discussing in your annotation on buzzers for bed-wetters (*Journal*, August 23, p. 499) the disadvantages of the enuretic apparatus, you mention firstly the cost. I feel I must add that a small-electrode machine lessens this considerably. Two perforated plates the size of a penny can be separated by a small piece of cloth or blotting-paper and wrapped up with a rubber band. This little parcel is arranged suitably to be alongside the external meatus so that it is the first thing to be wetted. A miniature relay is necessary in the "watching" circuit, which uses a hearing-aid 22.5-volt battery instead of the lower-voltage one. A larger bell is then used in the second circuit, since I have found that a really loud noise is often required after the patient gets used to it. After the first wetting the patient changes the small piece of cloth for a dry one and replaces the parcel.

This machine fires off in a fraction of a second and requires less than a drop of water to activate it. The increased sensitivity means much greater reliability. There are advantages apart from the cost of the electrode, which can be restored with waste rag indefinitely. Firstly, the reflex established is to urine which has only just left the urethra, and bears more comparison with the reflexes of the normal person initiated by urine in the posterior urethra. Trying to establish a reflex from a soaked bed must be less effective. Secondly, there is no wet bed and even the pyjamas usually stay dry. This means, particularly in the older more intractable case, that the patient can take the machine to hotels and holiday places without leaving his mark, even before he has attained a cure. The increase in confidence hastens the cure, and the relief from washing sheets changes the silently exasperated mother into a firm ally.—I am, etc.,

Sheffield, 6.

G. WYNNE-JONES.

"Nilergex"

SIR,—This new antihistamine has recently been introduced as having no, or minimum, soporific side-effects. It is reported that in an American trial only 5 out of 602 patients had drowsiness. During the early part of this year I carried out a pilot trial of this drug in 13 patients with chronic urticaria, all of whom had been on various antihistamines up to the time of the trial. Six patients had much more drowsiness than with the previous antihistamines, and in five of these the rash was also more severe whilst on nilergex. In only one patient was the side-effect, a feeling of tension, less than when on the previous antihistamines.

I have been used to comparing antihistamines in a separate out-patient clinic for cases of chronic urticaria held during the last nine years, and I appreciate the snags connected with such trials. One of the difficulties is to establish equipotent doses of the drugs, as the degree of urticaria often fluctuates. Because of the small number of patients, I did not feel that the trial was worth reporting. However, since this time I have seen a few patients treated with nilergex by their family doctors, and have been impressed by the number who have had drowsy side-effects, and now Dr. A. Fry in his letter (*Journal*, September 6, p. 636) records drowsi-

ness after taking this drug. Dr. Fry also raises the serious question of car-driving whilst on antihistamines. It is a difficult subject, and, perhaps wrongly, I do not seek to impose restrictions on my patients other than to advise that they take the tablets for a few days before driving, in order to assess any soporific effects. I cannot bring myself to talk of, or write about, antihistamines without adding that the patients should always be advised to keep them away from children.—I am, etc.,

Bristol.

Posture and Blood Pressure in Pregnancy

SIR.—Further to the letter from Dr. P. R. Boucher and Dr. Margaret J. Turpin (*Journal*, September 13, p. 693), I have found that the pressure in the sitting position is nearly always lower than in the recumbent. It seems desirable to use the latter in most cases, for the patient is more at ease and it is less difficult to standardize conditions. I think that, as the arm rises or falls above or below heart level, the phenomenon is explainable on ordinary hydrostatic principles.

What is not in the books, or at least what I have failed to find, is the effect of alcohol on arterial pressure. I remember a young man of 30 who was quite frank about a drinking party the night before. His pressure was 155/115 and he was passing sugar. I told him to come the next day, when the readings were 130/80 and no sugar was found. I have seen several similar cases. I hope to start some investigations in this matter if I can obtain the necessary facilities. Because alcohol is a vasodilator it has been too easily assumed that it will lower pressure. Some other mechanism is clearly involved.—I am, etc.,

Hitchin, Herts.

G. C. PETHER.

Complications of Pertussis Immunization

SIR.—I was interested to read Dr. D. Leigh's letter (*Journal*, September 6, p. 637). I have had a similar experience, but following the third diphtheria-pertussis immunization, the baby presumably being sensitized by the first two doses.

I gave a 5-months-old boy his third diphtheria-pertussis injection. Within four hours I was called back to find the baby collapsed and pulseless. I noticed baby food on the kitchen table, and, assuming that he had inhaled some, I immediately turned the baby upside down and put my finger down his throat. After a minute or two the child's colour improved and its pulse became palpable. On questioning the mother, who was a midwife, I discovered that the child had not yet been fed and that there had been no convulsion preceding the collapse. Some three hours later the baby once again became collapsed, but soon after my arrival it recovered without any treatment and there has been no further trouble.

The only history of allergy in the family is that the paternal grandmother was an asthmatic.—I am, etc.,

York.

PETER JONES

Radiological Societies

SIR.—It is with mixed feelings that one sees an announcement in the *Journal* of September 20 (p. 751) of the formation of yet another society of radiology. You were kind enough to publish a letter from me in 1950¹ drawing attention to the number of radiological societies of varying ages and activities already in existence in this country, and suggesting that the specialty could no longer adequately maintain all these societies. As a result of that letter a liaison committee was formed between two of the principal organizations, and this committee has prevented some overlapping of effort and has co-ordinated activities when a common front appeared to be appropriate.

Unfortunately, however, since that time various smaller private and public splinter groups have been set up to further social, political, or specialist radiological activities

both at national and regional levels. Now one is faced with yet another body. Surely it would have been preferable if those engaged in dental radiology, feeling that their needs were catered for inadequately, had approached some of the established bodies to discuss the best method of meeting those needs. This multiplicity of bodies in the organization of radiology can do nothing but harm, and may, indeed, through misdirection of effort, become actually dangerous.—I am, etc.,

Newton Abbot.

Trials of Contraceptive Methods

SIR.—The Council for the Investigation of Fertility Control is trying to organize clinical trials to test the efficacy of existing methods of contraception. We are also hoping to try modifications of these methods, and ultimately, we hope, entirely new methods will be tested in the same way.

To establish any new method of contraception needs volunteers who are willing to run a reasonable risk of becoming pregnant and who are also likely to be fertile. We have in fact two groups of trials running at present: Group 1, in which the volunteers use the method for from 3 to 12 months and then prove both its effectiveness and their fertility by becoming pregnant; Group 2, in which volunteers use a method for about a year, being prepared to run the risk of its failing but not being willing to undertake deliberate pregnancy after the trial. There is also a third trial in which patients are seen and medically examined at a special clinic session in London. Groups 1 and 2 patients are not seen unless the patient/volunteer specifically wants to be seen.

In view of our lack of accurate figures about the effectiveness of modern contraceptive methods and because of the importance of this problem both to individual families and to world population trends, we feel that the trials are of vital importance. If any of your readers can put us in touch with volunteers (who should write to the Medical Secretary at this address) we would be most grateful.—We are, etc.,

Council for the Investigation of
Fertility Control,
64, Sloane Street,
London, S.W.1.

G. I. M. SWYER,
Chairman, Technical Subcommittee.
H. B. WRIGHT,
Medical Secretary, Technical Subcommittee.

POINTS FROM LETTERS

Electrified

Dr. J. LAMB (Edinburgh) writes: With regard to the electric shocks received on examining patients, may I offer a similar experience and explanation? When I was a house-physician I found that I was unable to wear a certain pair of crêpe-soled sandals in the wards, because touching the patient or their beds gave rise to sparks at the place of contact. . . . The explanation was, I think, that the crêpe soles of the shoes acted as insulators, and so one's body became charged up with static electricity (e.g., by rubbing against blankets), and touching the patient or bed allowed this static charge to discharge to earth.

Tattooing

Dr. JNO. CRAWFORD (Sutton) writes: I wish to support heartily the suggestion of Dr. Derek Bunting (*Journal*, August 2, p. 326) that steps should be taken to protect juveniles from the mutilation of tattoos. As a ship surgeon for some years, I have seen many hundreds, some quite elaborate, and a very large proportion a matter of regret in later years; as a rule, the more improved the social status, the more acute the shame. In a simple case a young man with a ring tattoo on each finger and thumb, and tattoo bracelet on each wrist, would probably find his chances of advancement, social or otherwise, seriously handicapped. In ships there are a number of deck boys, saloon boys, laundry boys, joining usually at the age of 16, less often 17. Boys must be men, and quite commonly at the first port, possibly under the influence of unaccustomed alcohol, they are persuaded to have these operations. Restrictions at home would no doubt help, but I believe the bulk of seamen have these things done in foreign ports.

Obituary

A. C. PEARSON, M.D., M.R.C.O.G.

Dr. A. C. Pearson, consultant obstetrician and gynaecologist to the Chelmsford and Essex Hospital, was killed in a car accident at St. Inglevert, between Calais and Boulogne, on September 22. He was 40 years of age.

Anthony Cecil Pearson was born on July 28, 1918. He received his medical training at the Middlesex Hospital, graduating M.B., B.S. from London University in 1943 and proceeding to the M.D. six years later. He was elected a Member of the Royal College of Obstetricians and Gynaecologists in 1948. After graduation he held the appointments of registrar in the department of obstetrics and gynaecology at the Middlesex Hospital, resident medical officer at Queen Charlotte's Hospital, and senior registrar in the department of obstetrics and gynaecology at the London Hospital. From 1944 to 1946 he was in the R.A.M.C., and served with No. 2 Field Ambulance in the Middle East Force. In 1950 he was appointed consultant obstetrician and gynaecologist to the Chelmsford and Essex Hospital and to other Essex hospitals. He was elected chairman of the Mid-Essex Division of the British Medical Association in July, 1957.

K. O. G. writes: It was a pleasure to know Tony Pearson. As a colleague his opinion was of the best, and he showed a sympathy and understanding towards his patients which endeared him to them. He took every opportunity, in the local clinical societies, to discuss cases and problems with his colleagues. In this way he gave an example of what to-day is called intraprofessional relationship which made us feel very lucky to have such a man with us. He enjoyed teaching, and besides those in the hospital there are many who have been stimulated by the clarity with which he was able to elucidate the many clinical problems brought to him. He always appeared serene, unhurried, and, at times, one to whom time was of secondary consideration, but if late for an appointment his charm soon made us forget any irritation we may have felt. His friendship was very genuine, and in his kindness, sympathy, and unhesitating help to those in personal distress was no less real. He had a nice sense of the ridiculous; this, with his humour and enthusiasm, made many an encounter a gay affair. Much of his serenity came from his home, as it was there with his wife and children that he was completely happy. It is this knowledge that makes his death such a tragedy. He will be sadly missed by his friends and colleagues, who extend their deepest sympathy to his widow and three young children.

JAMES MILLER, M.D., D.Sc., F.R.C.P.Ed.

Dr. James Miller, who was professor of pathology in Queen's University, Kingston, Ontario, for a quarter of a century, died at his home at Painswick, Gloucestershire, on September 21. He was 82 years of age.

James Miller was born on October 1, 1875, the eldest son of Dr. A. G. Miller, and was educated at Edinburgh Academy and at Edinburgh University. He first graduated in science, in 1896, but went on to read medicine and obtained the degrees of M.B., Ch.B., with second-class honours, in 1899. Elected a Member of the Royal College of Physicians of Edinburgh in 1902, he was admitted a Fellow of the College nine years later. After graduating in medicine he held the appointment of resident physician at Edinburgh Royal Infirmary, and in 1900 served in South Africa as an assistant surgeon with the Edinburgh and East of Scotland Hospital. From 1902 to 1909 he was lecturer in pathology

and bacteriology in Birmingham University, and during the last three years was visiting pathologist to Birmingham General Hospital. He proceeded to the M.D. in 1903, gaining a gold medal for his thesis, and in the following year was granted the Birmingham D.Sc. For a few years, until the outbreak of the first world war in 1914, he examined in his subject for Aberdeen University. During the war he was pathologist to the 2nd Scottish General Hospital, with the rank of captain in the R.A.M.C., and at the same time he held the appointments of lecturer in the school of medicine of the Edinburgh Royal Colleges and in Edinburgh University and pathologist to the Royal Edinburgh Hospital for Incurables. He left Scotland in 1920 to become professor of pathology in Queen's University, Kingston, Ontario, and occupied the chair until 1946, when he returned to the United Kingdom, finally settling at Painswick in 1950. While in Canada he was also consulting pathologist to the Ontario Department of Health. A member of the British Medical Association for fifty-seven years, he served as a vice-president of the Section of Bacteriology, Pathology, Physiology, and Biochemistry when the Association held its Annual Meeting at Winnipeg in 1930. He was the author of *Practical Pathology, including Morbid Anatomy and Post-mortem Technique*, published in 1914. In 1907 he married Miss Margaret E. Clare, by whom he had one son and three daughters.

A. R. JORDAN, M.D., F.R.C.S.

Mr. A. R. Jordan, who was a general practitioner, with a particular interest in surgery, at Dover for many years, died at Ashford Hospital on September 11. He was 75 years of age.

Anson Robertson Jordan was born at Woolwich on July 4, 1883, the son of the Rev. Joseph Jordan, vicar of that parish. After the death of his father at an early age, his family moved to Bedford. He won an exhibition to Bedford School, and from there entered Clare College, Cambridge, where he obtained a first-class in the Natural Sciences Tripos in 1904. He graduated M.B., B.Chir. in 1907, proceeded to the M.D. in 1910, and was admitted a Fellow of the Royal College of Surgeons of England in 1911. After graduation he held the appointments of house-surgeon at the London Hospital, where he received his clinical training, and house-physician at Bristol Royal Infirmary. He first began general practice at Cambridge, where he was ophthalmic clinical assistant at Addenbrooke's Hospital, but before long he moved to Dover in 1913, to start his long association with that town. He joined the R.A.M.C. in 1914, on the outbreak of the first world war, and spent most of his Army career as a captain with No. 29 Casualty Clearing Station in France, working extensively on abdominal surgery. On his return to Dover he again took up general practice, and also surgery at the Royal Victoria Hospital, Dover. Between the two world wars he worked unceasingly at his surgical work and practice, endearing himself to his patients by his understanding and to his colleagues by his example and for his help to the younger members of his profession. He never married, and the loss of his sister (herself for some time on the staff of the London Hospital) in 1930 left him very much alone. In 1937 he went into temporary retirement at Cambridge, but found the inactivity did not suit him. He re-entered general practice a year later at Sandgate, Kent. After the outbreak of the second world war in 1939 his surgical skill was used to the full when he took up residence in Buckland Hospital, Dover, and worked for long hours dealing with casualties resulting from the British evacuation of the Dunkirk beaches; and later under most difficult circumstances during attacks by bombs, shells, and flying bombs. With the cessation of hostilities he returned to his practice in Sandgate. In 1948, as he never wished to go into complete retirement, he left Sandgate to take up a small administrative post in Buckland Hospital, which kept him in daily touch with his colleagues and friends of long standing. He

died as he wished, still part of the hospital staff. By way of relaxation he read extensively, especially theology and history, and was always eager to answer questions and hold long conversations on these subjects. He was a keen motorist and mechanic, and in the early days of motoring toured the country extensively, encountering all the hazards on his itinerary. A member of the British Medical Association for over forty years, he was honorary secretary of the Folkestone and Dover Division from 1922 to 1926 and acting honorary secretary from 1940 to 1945. He was also chairman of the Division from 1933 to 1935.

M. F. O'HEA, M.B., B.Ch.

Dr. M. F. O'Hea, radiologist to St. Vincent's Hospital, Dublin, died on September 8.

Michael Fergus O'Hea was born in County Cork, and received his early education at Castleknock College, Dublin, from which he entered the old medical school of Newman's foundation (now merged in University College, Dublin). After qualifying by taking the Irish Conjoint diploma in 1910, in which year he gained the Bellingham gold medal in medicine at St. Vincent's Hospital, he held house appointments at that hospital and the Children's Hospital, Dublin. In 1915 he obtained the degrees of M.B., B.Ch. of the National University of Ireland. He succeeded the late Mr. H. S. Meade as lecturer in radiology at St. Vincent's Hospital, and it was as a radiologist that he continued to serve the hospital until his death. He also examined in his subject at University College.

W. D. writes: After a long and busy professional life, punctuated uncomplainingly with periodical struggles against ill-health, Michael O'Hea has slipped away from our midst to the peace he so richly deserves. As one grows older the bare spaces on one's skyline increase in number, and to-day we mourn the passing of one of the bravest and most loyal colleagues any man could wish to have. He qualified in 1910 with P. T. O'Farrell, a Past-president of the British Medical Association, and the late Harry Meade, and all three served, with me, in their first house appointments at St. Vincent's Hospital, Dublin. From there O'Hea went on to a similar post at the Children's Hospital, Temple Street. A year or two later he was appointed to our x-ray department, in succession to Meade, on the latter's promotion as assistant surgeon. The department was then a small one, and the duties part-time only. With the rapid increase in calls on his time owing to the growing expansion of radiological services, O'Hea was beginning to feel the strain of the combination of private practice and long hours of service within the department, when fate struck. But recently married, he was compelled to lay aside work of either kind, and a tedious spell in a Welsh sanatorium ensued. On his return, he knew that henceforward radiology alone was to be his *métier*. Securing an active and energetic assistant, he devoted himself wholly to the development of his department, each year slipping away quietly to one or other of the bigger centres in England to return with a new technique or better equipment. On one such expedition he invited me to accompany him to Germany as an interpreter, that we might together report to the hospital authorities on the recent introduction by Wintz, of Erlangen, of deep x-ray therapy. We travelled by boat from Rotterdam up the Rhine to Mainz, breaking off there for our objective, Victor Schmieden's Klinik at Frankfurt-am-Main. It was an unforgettable fortnight, for reasons grave and gay. In our student days he had been a shy and silent companion, wholly concentrated on the work immediately ahead of him. Now was suddenly revealed the mature man of unsuspected delicate taste, who revelled in the beauties of nature and the colours on either bank as we steamed slowly up-river over a succession of days, and later in the old mediaeval city with its Römer and its many *Gassen*. But they were the days of devaluation, in which none paid more hardly for defeat than the children in the hospital upon whom had fallen

the penalties of undernourishment. Even O'Hea's epicurean choice of a new wine at dinner or his love of music refreshed on a visit to the opera could not wipe the memory of those emaciated infants from his mind. In all things he was a very gentle man, the "gentil parfit knight" of Chaucer's *Tales*. His courtesy was that of a bygone, less hurried age. Tall, erect, impeccably tailored, the manner was the man, whom past students and friends never failed to visit on their return to the hospital. He loved good-fellowship, and to him we entrusted the arrangement of our hospital dinners even when he was debarred in wintry weather from attending them. From the first ill stroke of fate he had learned to fit his life to its handicap. In every step of this he was nobly assisted by his wife and children. They had been his first thought when he had to reconstruct his manner of living, and, one is sure, his last as he slipped across to his reward on the other side.

R. H. SWINDELLS, M.B., Ch.B., F.R.C.S.Ed.

Dr. R. H. Swindells, formerly medical superintendent of New End Hospital, Hampstead, died suddenly at his home at Richmond, Surrey, on August 28. He was 77 years of age.

Raymond Herbert Swindells was born on November 26, 1880, and was educated at Owens College, Manchester, graduating M.B., Ch.B. from the Victoria University of Manchester in 1903. He was elected F.R.C.S.Ed. in 1908. After graduation he held the appointments of assistant house-surgeon at Taunton and Somerset Hospital and at Derbyshire Royal Infirmary, house-physician at Manchester Royal Infirmary, house-surgeon at York County Hospital, and assistant medical officer to the outpatient department of Manchester Children's Hospital. In 1911 he was appointed assistant medical superintendent to Fulham Infirmary. During the first world war he was a captain in the R.A.M.C. attached to the 3rd East Anglian Field Ambulance, and saw service in Gallipoli and Palestine. After demobilization he returned to Fulham to his former post, which he held until his appointment to New End Hospital in 1930 as medical superintendent. After his retirement in 1946 he lived at Richmond. He leaves a widow and two sons.

C. H. GUNSON, M.B., Ch.B.

Dr. C. H. Gunson, who was in general practice at Wisbech, Cambridgeshire, for over fifty years, died at his home there on September 8, after an illness of six weeks' duration.

Charles Herbert Gunson was born at Glasgow in 1876, the son of the Rev. John Gunson, and was educated at Dollar Academy, Glasgow High School, and at Glasgow University. He graduated M.B., Ch.B. in 1900, gaining a first-class certificate of merit, a high distinction in surgery, and distinctions in materia medica, therapeutics, pathology, and midwifery. Soon after graduation he became resident medical officer at the North Cambridgeshire Hospital, Wisbech, and two years later settled in general practice in the town. In 1904 he was appointed to the honorary medical staff of the hospital. He was medical officer to Wisbech Post Office from 1905 to 1948, when the appointment lapsed on the inception of the National Health Service, and from 1907 to 1939 he was part-time medical officer of health for the Wisbech rural district. During the first world war he served as a captain in the R.A.M.C. in Alexandria and Gaza. Keenly interested in the work of the British Legion, he was a founder-member of the Wisbech branch and its president for many years. He was honorary assistant county director of the Cambridgeshire branch of the British Red Cross Society during the second world war. A member of the British Medical Association for nearly 50 years, he was chairman of the Isle of Ely Division in 1915. For six years he was a member of the

Wisbech town council, having previously served on the Walsoken urban district council for some years before it was merged in the borough of Wisbech. He was also vicar's warden and bishop's reader at St. Augustine's Church, and a founder-member of the Wisbech Caledonian Society, of which he was president in 1951. At the funeral service of St. Peter's Church was filled to capacity, an indication of the esteem in which he was held by the townspeople. He was twice married. First, in 1901, to Miss Alice M. Greene, who died in 1951, three weeks after the golden anniversary of their wedding; and secondly, in 1953, to Miss Hilda M. Goodbody, formerly headmistress of a local school, who survives him, together with the son and daughter, Dr. Vivienne M. Hurst, of his first marriage.

G. W. POOL, M.R.C.S., L.R.C.P.

Dr. G. W. Pool, who was in general practice at Felixstowe for some forty years, died at his home there on September 14.

Garnet Wolseley Pool was born at Hayle, Cornwall, in 1884. He studied medicine at St. Thomas's Hospital, qualifying M.R.C.S., L.R.C.P. in 1915. Shortly afterwards he joined the Royal Navy for service during the first world war. He was transferred to the Royal Naval Air Service and posted to Felixstowe, and, later, as fleet surgeon, served in the Mediterranean in H.M.S. *St. George*. After the war he returned to Felixstowe, where he was in practice until three weeks before his death. He soon became an established and well-loved figure in the town, taking part in its activities and life. An excellent and conscientious physician, he was also a skilled obstetrician and an accomplished anaesthetist. He leaves a widow, the daughter of the late Mr. Samuel Rowbotham, of Felixstowe, one son, and one daughter.—A. S.

L. A. WILSON, M.R.C.S., L.R.C.P.

Dr. L. A. Wilson, who was in general practice at Barrow-in-Furness for some forty years, died at Littleover, Derby, on September 15. He was 79 years of age.

Lorton Alexander Wilson was born at Skipton-in-Craven, Yorkshire, on August 10, 1879. His father was Dr. J. Forsythe Wilson, and he was the elder brother of Charles McMoran Wilson (now Lord Moran). He was educated at Epsom College and Owens College, Manchester, qualifying M.R.C.S., L.R.C.P. in 1907. After qualification he joined his father in Barrow-in-Furness, succeeding to the practice a few years later. During the first world war he was a captain in the R.A.M.C. attached to the 4th battalion of the King's Own Royal Rifles and served in France. After the war he returned to his practice, and retired in 1946. A member of the British Medical Association for nearly forty years, he was honorary secretary of the Furness Division for the exceptionally long period of twenty-five years. He was also chairman of the Division in 1930-1 and president of the old North Lancashire and South Westmorland Branch in the latter year.

J. R. T. writes: The passing of Dr. Lorton Alexander Wilson from our midst brings back many memories of over twenty years' association with him in Barrow-in-Furness. Coming to Barrow a year or two before the first world war, he entered general practice and became a member of the local panel committee. During the war he was on active service for some years, but on returning to practice he became honorary secretary of the panel committee, and shortly afterwards began his great work as honorary secretary of the Furness Division of the B.M.A. In addition to these duties he took on the secretaryship of the Juvenile Medical Club in the town. His service as secretary of the Division of the B.M.A. continued until his retirement in 1946—of the twenty-five years. This is the period during which I had the opportunity of observing his capacity and talent for organization. In spite of the burden of a busy practice, he was always ready to meet any of his colleagues in any difficulty or trouble connected with the Association. Meet-

ings in some matters were held at his home, pleasantly enlivened by his hospitality. During the second world war additional responsibility was thrust upon him by the protection of practices scheme and by the local medical recruitment committee. He was also the medical officer in charge of the Home Guard in the town. Only by a gift for organization in a superlative degree could one man carry out, for years, all these manifold duties in addition to his work as a general practitioner. In conclusion I like to remember his kindness to me and to all he came in contact with, his welcome to newcomers to the Division, and his complete freedom from professional jealousy.

M. MARITSCHKE, M.D.

Dr. M. Maritschek died at his home in London on September 10. He was 83 years of age.

Moriz Maritschek was born in Vienna on May 15, 1875. He studied medicine at Vienna University and obtained his M.D. there in 1901. After clinical appointments in both Vienna and Dresden he started a practice as a physician in Vienna, well before the outbreak of the first world war. He made a name for himself as an excellent diagnostician. Devoting all his ability and experience to the well-being of his patients, he was able to build up a considerable practice. A victim of Nazi persecution, Dr. Maritschek had to leave Austria, and came to London only a few days before the outbreak of the second world war. Having lost everything, it was not easy for him to settle in the new country which he regarded with gratefulness as his second homeland. His profession meant so much to him that he gladly attended courses at London hospitals, and, when permitted to do so, worked as assistant to medical practitioners during the war. Although advanced in age, he was happy to join the National Health Service from its inception in 1948. Once again, settling in Hampstead, Dr. Maritschek started to build up a practice. Many of his former patients returned to him, and many others also sought his medical advice. His modesty, his friendliness, and his noble character were outstanding. He was the ideal family doctor of the "old school" who had always time for his patients. When he was taken ill in 1957, only temporarily recovering, he once said: "As I feel I cannot give any more of my best to my patients, I have to retire." This he did. After more than 50 years in general practice, Dr. Maritschek could unfortunately not enjoy his days of retirement. His health was failing and he passed away, 83 years old. He is survived by his devoted wife, so dear to him and an invaluable help in his practice. His many friends will always cherish his memory, and so will many of his colleagues, who held him in high esteem.—L. N.

FREDERICK ELLIOTT, M.B., B.S.

Dr. Frederick Elliott died on August 29 at his home at East Sheen, London, at the age of 47.

Frederick Elliott was born at Sunderland in 1911, and was educated at the Royal Grammar School, Newcastle upon Tyne, entering the medical school at Newcastle in 1931. After graduating M.B., B.S. (Durham) in 1936, he held the posts of house-surgeon at the Victoria Jubilee Infirmary and Fleming Memorial Hospital, Newcastle upon Tyne. It was his original intention to enter general practice, but before doing so he wished to see something of conditions overseas, and, with this object in view, he joined a steamship line as a ship surgeon, completing several voyages to the Middle and Far East. He married Miss Joan Bullen in 1939, but his intention to settle down in general practice was interrupted by the outbreak of war. Joining the Territorial Army in September, 1939, as a captain in the R.A.M.C., he saw active service in the Western Desert, Persia, Iraq, and Sicily. It was in Sicily, in January, 1944, that he was severely wounded in action, remaining in hospital for over a year before discharge in 1945 as medically unfit for further service, his right leg having been

amputated below the knee and his left knee-joint ankylosed. Some months after his discharge from the Army he joined the staff of the Ministry of Pensions, serving as a limb-fitting surgeon in the Ministry's establishment at Roehampton, where his specialized knowledge of artificial limbs was of the greatest value to his patients. Literary contributions of his during this period at Roehampton included a chapter in *Disabilities and How to Live With Them*, and "Loss of a Leg" (*Lancet*, 1948). In 1949 he joined the Home Office as an established medical officer and served in that capacity until his death.

P. L. C. C. writes: Frederick Elliott's death is a great loss to his friends and colleagues. His cheerful acceptance of his physical disability, the result of his war service, endeared him to all who knew him. Possessing a keen sense of responsibility, he brought to his work not only high professional capability but a quality of understanding and tact which impressed itself upon all with whom he came in contact. It will not surprise his many friends that, throughout his last illness and up to the end, he faced with great fortitude and patience what his own medical knowledge must have told him from the onset was a hopeless prognosis. To his wife and young daughter, the small family to which he was so devoted, and in which he had so much happiness, they will wish to extend their deepest sympathy.

H. A. SANDIFORD, M.C., M.B., D.P.H.

The obituary of Brigadier H. A. Sandiford was printed in the *Journal* of August 23 (p. 513).

Dr. GERALD I. PHILLIPS writes from Durban, South Africa: Among the many tributes to the late Brigadier Sandiford which have appeared, I would appreciate a small amount of space to add a sincere tribute from one of the "common men" from a far-off land. On a cold, cheerless January day in 1954—the coldest on record for 17 years—I arrived in London, unknown, unheralded, and, it appeared to me, unwanted. Armed with despondency and a fair share of fear for the future, I made my way to the Mecca of overseas students, the B.M.A.'s Commonwealth Medical Advisory Bureau, where I was introduced to Brigadier Sandiford. I spent only 15 minutes with him at that initial meeting, but it took no more to make me realize that, in spite of all the official posts which he had held in the past, he was to all of us a plain and simple "father." He turned a chilly, wet, miserable London day into one as sunny and warm as any I had ever experienced in my own South Africa. Where there was despondency he brought hope, where there was fear he brought confidence, and for my loneliness he exchanged friendship. However great the loss his departure will seem to those who knew him, so much greater will it be to those who were unfortunate not to have come within his sphere of influence. It is an accepted dictum in life that nobody is indispensable, but, just as there is an exception to every rule, so Brigadier Sandiford became the exception to this ancient dictum. In my country, when we bid farewell to friends we have known and loved, we say, "Totsiens." To Brigadier Sandiford—for the privilege of having known whom I thank God—I, too, bid a fond farewell and *totsiens*.

Medico-Legal

DRIVER'S UNSUSPECTED DIABETES

[FROM OUR LEGAL CORRESPONDENT]

Thomas George Wickins was convicted at Bournemouth Quarter Sessions after pleading guilty to driving his car while under the influence of drink or drugs to such an extent as to be incapable of having proper control. The Recorder found that his condition was due to the combined effect of

¹ *The Times*, July 15.

diabetes and his normal beer intake, and at the time of the offence he had not known that he was suffering from diabetes. He was disqualified from driving for 12 months, since the Recorder, though considering the case not to be serious from the moral point of view, did not think these circumstances could amount in law to a "special reason" within s. 15(2) of the Road Traffic Act, 1930, for not disqualifying him.

The Court of Criminal Appeal on July 14 allowed his appeal against the disqualification.¹ They held that in Mr. Wickins's case there was a mitigating circumstance which while not amounting to a defence was directly connected with the offence and might properly be considered in imposing punishment. Had it not been for the diabetes, of which he was ignorant, the offence would not have occurred. The requirements of a "special reason" for not disqualifying were thus fulfilled.

Vital Statistics

Health in R.A.F.

Athletic sports were the most common cause of injury in the R.A.F. in 1954, according to the report for that year, just published. They accounted for 27% of all injuries as compared with 28% in 1953 and 22% in 1952. Motor-cycle accidents caused 10% of all injuries and flying accidents 2.3%.

The chief cause of invaliding from the Service was mental disorder (22.5%). This was followed by tuberculosis (11.8%), locomotor diseases (10.2%), and diseases of the ear and mastoid (8.7%).

Industrial Accidents and Diseases

The number of workpeople (other than seamen) in the United Kingdom whose deaths from accidents in the course of their employment were reported in August was 56, compared with 104 in the previous month, and 98 in August, 1957.

The number of cases of industrial diseases in the United Kingdom reported during August, 1958, were as follows: lead poisoning 1, aniline poisoning 1, compressed-air illness 1, epitheliomatous ulceration 10, chrome ulceration 13: total 26. There were no deaths.—*Ministry of Labour Gazette*, September, 1958.

Week Ending September 20

The largest rises in the number of notifications of infectious diseases in England and Wales during the week ending September 20 were 138 for scarlet fever, from 296 to 434, 81 for dysentery, from 329 to 410, 67 for food-poisoning, from 302 to 369, and 30 for acute pneumonia, from 145 to 175; the largest falls were 133 for measles, from 1,603 to 1,470, and 28 for whooping-cough, from 746 to 718.

A notable increase in the notifications of measles was 60 in Lancashire, from 226 to 286. The increase in the incidence of scarlet fever was due to a small rise in most areas of the northern half of the country. Only small fluctuations were reported in the local returns of whooping-cough. 2 cases of diphtheria were notified, being 1 less than in the preceding week.

6 of the 11 cases of paratyphoid and typhoid fever were notified in London.

The notifications of acute poliomyelitis numbered 79, and these were 8 more for paralytic and 9 more for non-paralytic cases than in the preceding week. The largest returns were Yorkshire West Riding 19 (Leeds C.B. 5, Dewsbury C.B. 3, Shipley U.D. 3, Ripponden U.D. 2, Hemsworth R.D. 2), Lancashire 18 (Manchester C.B. 7, Burnley C.B. 3, Bolton C.B. 2), Somersetshire 6 (Burnham-on-Sea U.D. 4).

The chief centres for dysentery were London 63 (Islington 17, Bermondsey 10), Lancashire 60 (Liverpool C.B. 28), Yorkshire West Riding 46 (Leeds C.B. 12), Nottinghamshire

35 (Basford R.D. 17), and Warwickshire 20 (Birmingham C.B. 14).

The largest outbreaks of food-poisoning were 29 in Doncaster C.B. and 30 in West Lancashire R.D.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the years 1949-57 are shown thus -----, the figures for 1958 thus ———. Except for the curves showing notifications in 1958, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending September 13 (No. 37) and corresponding week 1957.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the whole of England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

Medical News

Royal College of Surgeons.—The College held its annual meeting in Cardiff on September 26 and 27, under its president, Sir JAMES PATERSON ROSS. This is the first time the annual meeting has been held in Wales, and only the second occasion it has been outside London. The surgeons of Bristol joined with those in Cardiff in acting as hosts to the College, and the Lord Mayor and Council of Cardiff signified the city's welcome by a reception at the Castle. Besides the annual business meeting of the College, there was a dinner for fellows and members on the first evening; a clinical morning at the Royal Infirmary, where operations, films, and scientific exhibits were demonstrated; followed by a luncheon given by the governors of the United Cardiff Hospitals, and a lecture by Sir RUSSELL BRAIN, who had earlier been made an honorary F.R.C.S. The College's visit was greatly appreciated; as one speaker at the dinner put it, why should not the College add Wales to its title? The dinner, under the chairmanship of the president, was attended by some 200 fellows and members and their guests. Sir PHILIP MORRIS, Vice-Chancellor of Bristol University, proposing the toast to the College, congratulated them on venturing outside London, leaving the barbarity of the metropolis for the ancient civilization of Wales. In the last resort, standards of treatment depended not on administrative arrangements and new techniques but on the friendly intercourse of those engaged in the practice of medicine. Sir JAMES PATERSON ROSS, replying, referred to the College's intense activity in teaching and research. At the moment about 1,000 postgraduate students a year, from all parts of the Commonwealth, were attending the College's courses. He appealed for a sense of belonging to the College on the part of its fellows and members, and for their support in maintaining the College's work. New fellows were now being asked for an annual subscription for this reason. The toast of "The Guests," who included the Lord-Lieutenant of Glamorgan, the Lord and Lady Mayoress, the presidents of two sister Colleges, and Sir CLEMENT PRICE THOMAS, the new president of the Welsh National School of Medicine, was proposed by Professor LAMBERT ROGERS. Guided by a letter in this *Journal* on after-dinner speeches (*Supplement*, August 30, p. 130), he toasted them collectively while assuring them that their invitations had indeed been truly individual. The Lord Mayor of Cardiff, Alderman A. J. WILLIAMS, and the chairman of the board of governors of the Bristol United Hospitals, Colonel H. BLAND STOKES, replied.

Teaching Hospital for Cardiff.—Speaking at Brecon on September 16, Mr. DEREK WALKER-SMITH announced a further step in the planning of a new teaching hospital at Cardiff and the Welsh National School of Medicine. "I have now been able to authorize the board of governors to proceed to the next stage," he said, "the appointment of the architects; and I understand that it is their intention to hold an architectural competition. The board will now be able to get on with the drawing of detailed plans, including provision for a dental school. This, however, will inevitably take a considerable time, and it is not possible at this point to name a starting date for building, which, of course, will have to be fitted into the total capital investment programme for hospitals."

Royal College of Obstetricians and Gynaecologists.—Professor G. SHEDDEN ADAM, of Brisbane, has been appointed Bernhard Baron travelling scholar for 1959. The following were admitted to membership of the College at a meeting of the council on September 26:

P. Aiman, P. H. Amarasinghe, D. T. C. Barber, C. T. H. Barrett, W. P. Bonnici, J. Breeze, J. M. Brudenell, D. P. Chan, H. J. H. Claassens, C. J. T. Craig, D. R. Das, R. M. Davie, R. F. Drake, G. R. Duncan, D. Edwards, G. H. Ellidge, W. H. Fernando, L. H. Fienberg, J. M. G. Harley, D. Heginbotham,

J. B. Hemsley, A. H. Hsu, T. R. Hunt, P. J. Huntingford, S. R. Ingold, K. I. Jack, R. D. Johnstone, E. W. P. Jones, A. J. Keane, A. C. Keast, D. M. D. King, S. V. Kinley, D. R. Lowe, J. McGlone, S. Malhotra, D. T. Mathews, C. C. Mitra, W. P. L. Morrison, A. D. Muirhead, S. Muscat, I. R. Napier, H. J. Pash, J. H. Peters, D. W. Pfanner, D. M. Reader, W. J. C. Rebello, J. St. George, P. C. Stichbury, J. O. Struthers, W. M. E. Tweed, R. N. Udipti, T. Visvanathan, A. W. G. Weir, D. J. Whitney, W. G. Wicks, and B. Yoganathan.

Haemoglobinopathies.—At the 6th International Congress on Tropical Medicine and Malaria, held at Lisbon on September 5-13, it was resolved that surveys of the distribution of thalassaemia and of the abnormal haemoglobins should be encouraged. Though much had been done, there were still wide gaps in knowledge, and without such information planning of public health measures would be handicapped. With the rapid rate of discoveries of new haemoglobins and new disorders a real risk arose that the terminology would become confused. The congress therefore expressed the hope that steps would soon be taken to arrive at international agreement. Cognizance was taken of the "Recommendations for Terminology of the Hereditary Haemoglobinopathies with Haemoglobin Variants" prepared by the Colonial Medical Research Committee's Working Party on Sickle-cell Traits and Sickle-cell Anaemia, London (*Journal*, May 25, 1957, p. 1235).

Resident Hospital Posts in Australia.—There are vacancies for junior residents, senior residents, and medical superintendents in country base hospitals in the State of Victoria. These posts are tenable for two or three years (return first-class fare is paid for doctor and family for a three-year period of service, and single fare for a two-year period). They offer an opportunity for medical graduates who have completed their pre-registration year of hospital residence and their National Service to widen their hospital experience in Australia. The salaries paid and other details were given in an advertisement (p. 57) in the *Journal* of September 6.

Medical Electronics.—The council of the Institution of Electrical Engineers, with the encouragement of members of the medical profession, has instituted a Medical Electronics Discussion Group. This will provide a forum where electrical engineers specializing in electronics can meet doctors to discuss problems of common interest. Further information may be obtained from the Institution of Electrical Engineers, Savoy Place, London, W.C.2.

Van Meter Prize.—The American Goiter Association again offers the Van Meter prize award of \$300 and two honourable mentions for the best essays submitted concerning original work on problems related to the thyroid gland. The award will be made at the association's annual meeting in Chicago on April 30 and May 1 and 2. Further information is obtainable from Dr. JOHN C. MCCLINTOCK, 149½ Washington Avenue, Albany, 10, New York. The closing date is January 15.

Mr. R. B. Duthie, a graduate of Edinburgh and research fellow of the Scottish Hospitals Endowment Research Trust, has been appointed professor of orthopaedic surgery and orthopaedic surgeon-in-chief in the University of Rochester School of Medicine and Dentistry, New York.

Family Doctor.—The October issue of *Family Doctor* includes articles on partial gastrectomy (by Sir Cecil Wakeley), the British Red Cross and Order of St. John, alcoholics (by Dr. F. R. C. Casson), and industrial psychology (by Dr. J. A. C. Brown).

COMING EVENTS

Harveian Oration.—SIR GEOFFREY KEYNES will deliver the Harveian Oration at the Royal College of Physicians of London on October 17 at 3 p.m. His subject will be "Harvey through John Aubrey's Eyes."

Edinburgh Postgraduate Board of Medicine.—Details of courses in endocrinology, gastroenterology, surgery, medical sciences, and internal medicine are given at p. 64 of the advertisements.

London Jewish Hospital Medical Society.—Mr. I. PREISKEL, F.R.C.S., will deliver the presidential address on October 9 at 8.15 p.m. at the Medical Society of London, 11, Chandos Street, W.1. His subject will be "Some Milestones in the Progress of Surgery."

American Heart Association.—Annual meeting and scientific sessions, October 24-28 in San Francisco. The association's address is 44, East 23rd Street, New York, 10.

Maudsley Lecture.—Dr. LEO KANNER, of Baltimore, will deliver the Royal Medico-Psychological Association's 33rd Maudsley lecture on November 13 at 2.15 p.m. at the Royal Society of Medicine. His subject will be "Trends in Child Psychiatry."

NEW ISSUES

SPECIALIST JOURNALS AND ABSTRACTS

The journals listed below are obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

British Journal of Ophthalmology.—Issued monthly (£6 annually). The new issue, Vol. 42, No. 9, includes:

SOPRACYCIN: ITS PENETRATION INTO THE EYE AND ITS EFFECT UPON EXPERIMENTALLY PRODUCED STAPH. AUREUS AND PS. PYOCYANEA CORNEAL INFECTIONS. D. Ainslie and W. G. Henderson.
DENervation OF THE LACRIMAL GLAND. J. Whitwell.
DIVERTICULUM OF THE LACRIMAL SAC. J. N. Ormrod.
STUDIES ON THE CORNEAL AND TRABECULAR ENDOTHELIUM. I. CEMENT SUBSTANCE OF THE CORNEAL ENDOTHELIUM. F. Vrabc.
RETINAL VASCULAR MICROMETRY BY THE USE OF A MEASURING OPHTHALMOSCOPIC EXAMINATION INCLUDING MEASUREMENT OF SELECTED RETINAL ARTERIOLES IN FIFTEEN CASES OF PRE-ECLAMPTIC TOXAEMIA. M. Snodgrass.
RETROLENTAL FIBROPLASIA ASSOCIATED WITH MENTAL DEFECT. C. E. Williams.
EXPERIMENTAL DEGENERATION OF THE RETINA. III. INHIBITORS OF GLYCOLYSIS AND OF RESPIRATION AS INDUCING AGENTS. A. Sorsby and A. Nakajima.
EXPERIMENTAL DEGENERATION OF THE RETINA. IV. DIAMINODIPHENOXYALKANES AS INDUCING AGENTS. A. Sorsby and A. Nakajima.
OCULAR RHINOSPORIDIOSIS. K. D. Sharma, J. B. Shrivastav, and S. Agarwal.

Ophthalmic Literature.—Vol. 11, No. 5, and Vol. 12, No. 1, are now available. This journal contains a comprehensive selection of abstracts of the literature on ophthalmology and related subjects. Issued quarterly with a volume index each year. £4 4s. annually or in combination with the *British Journal of Ophthalmology*, £9 annually.

Abstracts of World Medicine.—Issued in the first week of each month, this journal contains abstracts of important papers selected from the current medical literature of the world. Annual subscription £4 4s.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Sunday, October 5

MANCHESTER UNIVERSITY: FACULTY OF MEDICINE AND NORTH-WEST ENGLAND FACULTY, COLLEGE OF GENERAL PRACTITIONERS.—At Theatre 1, Clinical Sciences Building, York Place, 11 a.m., Professor W. Gaisford: Problems of Immunization.

Monday, October 6

INSTITUTE OF NEUROLOGY.—5.30 p.m., Dr. D. Richter: Protein Metabolism of the Brain.
LONDON UNIVERSITY.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., special university lecture in pathology by Dr. A. J. Quick (U.S.A.): The Hereditary Haemorrhagic Diseases—Their Classification and Diagnosis.
MARLBOROUGH DAY HOSPITAL.—8.15 p.m., reports by Dr. J. Bierer, Dr. E. Ledermann, Dr. A. J. Martin, and Mr. P. Sent on the International Conference for Psychotherapy, held recently in Barcelona.

Tuesday, October 7

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. P. J. Hare: Keratinization.
KING'S COLLEGE HOSPITAL MEDICAL SCHOOL.—4.45 p.m., 11th Thomas Percy Legg Memorial Lecture by Mr. H. J. Seddon: Recent Work on Polio-myelitis.
LONDON UNIVERSITY.—At Physiology Lecture Theatre, University College, W.C., 5.30 p.m., special university lecture in psychology by Professor Wolfgang Köhler (Princeton): Postulate of Invariance in Evolution.
MANCHESTER UNIVERSITY: DEPARTMENT OF OCCUPATIONAL HEALTH AND NORTH-WEST ENGLAND FACULTY, COLLEGE OF GENERAL PRACTITIONERS.—At Theatre 1, Clinical Sciences Building, York Place, 8.30 p.m., Professor R. E. Lane: Industrial Dusts and the Chest.
● ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Mr. W. J. Dempster: Kidney Transplantation.
● ROYAL COLLEGE OF SURGEONS OF ENGLAND.—6.30 p.m., Mr. A. Gorevitch: Intestinal Obstruction in the Newborn.
WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Mr. J. Minton: Ocular Manifestations in Clinical Neurology (Part I).

Wednesday, October 8

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. A. Tickner: Fats and the Skin.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. F. P. Lee Lander: Lung Manifestations of General Diseases.
INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Mr. H. G. Hanley: Tuberculosis of the Renal Tract.
LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.—At Royal Free Hospital School of Medicine, 8.30 p.m., Dr. Jean Mackintosh: Future of Medical Women in the Public Health Service.
MANCHESTER MEDICAL SOCIETY: SECTION OF PATHOLOGY.—At Large Anatomy Theatre, Medical School, Manchester University, 4.30 for 5 p.m., Dr. H. Lehmann: Abnormal Haemoglobins.
● ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Mr. A. W. Wilkinson: Water and Mineral Requirements After Operation; 6.30 p.m., Mr. A. H. M. Siddons: Bronchiectasis.
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Institute Lecture Theatre, 5 p.m., Dr. E. A. Brown (Boston): Single Annual Emulsion Injection for Pollinosis.

Thursday, October 9

LONDON JEWISH HOSPITAL MEDICAL SOCIETY.—At Medical Society of London, 8.15 p.m., Presidential Address by Mr. I. Preiskel: Some Milestones in the Progress of Surgery.
LONDON UNIVERSITY.—At Physiology Lecture Theatre, University College, W.C., 5.30 p.m., special university lecture in psychology by Professor Wolfgang Köhler (Princeton): Cortical Correlate of Perceptual Organization.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor W. E. Tucker: Traumatic Syndrome Phases and Stages: Certain Injuries, Their Prevention and Treatment.
● ROYAL COLLEGE OF SURGEONS OF ENGLAND.—6.15 p.m., Mr. Dickson Wright: Exophthalmos.
ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Dr. Desmond Curran: postgraduate demonstration in psychiatry.
UNIVERSITY COLLEGE LONDON.—At Anatomy Theatre, Gower Street, W.C., 1.15 p.m., Professor L. S. Penrose, F.R.S.: Mutation in Man.
WEST LONDON MEDICO-CHIRURGICAL SOCIETY.—At Clarendon Restaurant, Hammersmith, W., 7.30 for 8 p.m., dinner meeting. Presidential address by Mr. A. Walker: Midwifery Before We Were Born.

Friday, October 10

● CHARTEHOUSE RHEUMATISM CLINIC.—At 54-60, Weymouth Street, W., 5.30 p.m., Gilbert Scott Memorial Lecture by Professor Agrégé S. de Séze (Paris): Le Syndrome Dououreux Tropho-statique de la Post-menopause. (Lecture in English.)
● INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. F. R. Bentley: clinical demonstration.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. E. H. Hudson: clinical demonstration.
● ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Mr. O. G. Vaughan-Jackson: Hand Infections; 6.30 p.m., Dr. A. Crampton-Smith: Treatment of Tetanus.
ROYAL SOCIETY OF HEALTH.—At Corn Exchange, Dorchester, 10 a.m., Mr. L. Abbott: Winfrith Atomic Research Establishment—Anticipated Impact on Dorset; Dr. A. C. Sinclair: Mental Health—Outlook for the Future.

Saturday, October 11

NORTH-EAST METROPOLITAN THORACIC SOCIETY.—At St. Helen's Hospital, Ipswich, 10.30 a.m. joint meeting with East Anglian Thoracic Society. Papers by Mr. J. R. Belcher, Mr. E. C. Wynne Edwards, Dr. G. R. McNab, Dr. R. S. Francis and Mr. M. P. Curwen, and Dr. L. C. Lum.

Sunday, October 12

COLLEGE OF GENERAL PRACTITIONERS: YORKSHIRE FACULTY.—At General Infirmary at Leeds, 11.30 a.m., Dr. Richard Asher: Things are Not What They Seem.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Brooks.—On July 25, 1958, at 73, Elm Walk, Raynes Park, London, S.W., to Barbara (formerly Sutton), wife of Dr. Jack W. Brooks, a sister for Jennifer, Michael, and Peter—Anne Elizabeth Sutton.
Durham.—On September 25, 1958, at Ryde Nursing Home, 76, Pellhurst Road, Ryde, Isle of Wight, to Mabel (formerly Lewis), wife of Surgeon Lieutenant Commander P. D. A. Durham, R.N., a brother for Anthony—Jonathan Mark.
Gielw.—On September 21, 1958, at St. Bartholomew's Hospital, London, E.C., to Shirley (formerly Gazeman), wife of Dr. Harvey J. Gielw, M.B., M.R.C.S., D.Obst.R.C.O.G., of "Park Lodge," East End Road, East Finchley, London, N., a sister for Daryl Marsha—Lynne Janice.
Suchett-Kaye.—On September 18, 1958, in London, to Dr. Beryl White, wife of A. I. Suchett-Kaye, M.D., M.R.C.P., of 82, Christchurch Avenue, London, N.W., a brother for Charles, Robert, and Richard—George Henry Philip.

DEATHS

Attenborough.—On September 7, 1958, Cuthbert Hastings Attenborough, M.B., B.S., of Lismore, Camberley, Surrey.
Coope.—On September 8, 1958, at Zarauz, Spain, Hubert Macgowan Coope, M.B., Ch.B., of 10, Cambridge Road, Andsell, Lytham St. Annes, Lancs.
Corrigan.—On September 8, 1958, at Bretby House, Sherwood, Nottingham, David Richardson Goodlatte Corrigan, M.B., Ch.B.
Frier.—On September 24, 1958, at Ellesmere, Barrowby Road, Grantham, Lincs, Charles Matthew Frier, M.B., Ch.B., J.P., aged 87.
Johnston.—On September 10, 1958, in hospital, John Johnston, M.B., Ch.B., of 16, Worsley Road, Farnworth, Lancs, aged 86.
Jordan.—On September 11, 1958, at Ashford Hospital, Ashford, Kent, Anson Robertson Jordan, M.D., F.R.C.S., of Dover, Kent, aged 75.
Kirk.—On September 10, 1958, at Ryecroft, High Birthing, Harrogate, Yorks, George William Lister Kirk, M.B., Ch.B.
Thompson.—On August 27, 1958, at British Military Hospital, Iserlohn, Germany, Brian George Thompson, M.D., D.M.R., Major, R.A.M.C.
Winton.—On September 5, 1958, at his home, 2, Fairhaven, 71/73, Putney Hill, London, S.W., William Balcombe Winton, M.D., M.R.C.P., aged 85.
Young.—On September 5, 1958, at Apex Lodge, Highgate Village, London, N., Robin Edward Victor Bryce Young, M.B., B.Chir., aged 36.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Pregnancy After Hydatidiform Mole

Q.—What are the prospects of a successful pregnancy in a woman of 27 whose first pregnancy terminated as a hydatidiform mole and her second as an abortion? Is there any danger of a chorion epithelioma developing if she becomes pregnant again?

A.—The prospects are reasonably good, being 70–80%. The recurrence of hydatidiform mole has been reported in a subsequent pregnancy in the same woman, but this is extremely rare. The chances of chorion epithelioma developing from a hydatidiform mole after the intervention of one or more pregnancies are likewise extremely small. It is true that a few cases have been published of chorion epithelioma developing some years after a hydatidiform mole with the intervention of one¹ or more² pregnancies, but as it is believed that about 25% of chorion epitheliomas develop subsequent to a normal pregnancy these occurrences may not have been related to the earlier moles. Further reassurance can be offered on the basis of a report³ that out of 87 women treated conservatively for hydatidiform mole 65 later had normal viable pregnancies, with no recurrences or malignant sequels.

Antibiotic-treated Foods

Q.—What is known about the ill effects of consuming meat and poultry which has been treated with antibiotics to promote growth or to preserve the flesh?

A.—Antibiotics used as feed supplements to accelerate growth are believed to be entirely innocuous to the eventual consumer, because the amounts administered are quite small, and only the minutest traces could conceivably be present in the meat, even if such feeding had been continued until the time of slaughter.

The preservation of meat, fish, and poultry by dipping them in a solution of a tetracycline is a rather different matter: it was discussed in an annotation in this *Journal* (October 13, 1956, p. 870) and there is little to add to what was said then. In spite of widespread employment of this process in the U.S.A., Canada, and elsewhere, no ill effects have been seen. Some countries, including the U.S.A., have so far permitted its application only to poultry, because cooking has been shown to destroy remaining traces of the antibiotic in this class of food. Some kinds of cooking used for fish do not entirely destroy it. The theoretical dangers of consuming food containing detectable amounts of one of the tetracyclines are two: that a sensitized person may react to the antibiotic or that repeated consumption may itself sensitize, and, secondly, that resistance to the antibiotic may be induced in potentially pathogenic bacteria in the alimentary tract. There is no proof that amounts which are likely to be consumed can have either of these effects.

Intestinal Hurry

Q.—What is the treatment for intestinal hurry?

A.—The first consideration must be to stop the patient taking any drugs which might cause increased intestinal motility, to remove from the diet any foods which may appear to be irritating the intestines, and to look for and treat any condition of the gastro-intestinal tract which might be causing intestinal hurry. In some patients with ulcerative colitis or diverticulitis a low-residue diet may be helpful.

Opium is a drug commonly used to reduce intestinal motility. It is often prescribed in the form of the tincture with kaolin. Codeine is another useful drug. In severe dysentery morphine by injection may greatly help the patient, but it can only be used once or twice. Anticholinergic drugs, such as propantheline, in doses of 15 mg. thrice daily, will slow intestinal movements considerably. The constipating effects of ganglion-blocking hypotensive drugs are well known. In doses which hardly affect the blood pressure these substances can be useful in cases of intestinal hurry when other measures have failed. All these drugs must be used with circumspection in ulcerative colitis because of the danger of colonic dilatation.

NOTES AND COMMENTS

Midwifery Bag.—Dr. A. GOODMAN (Liverpool, 6) writes: I would like to make one or two modifications to the suggested contents of a general-practitioner obstetric bag ("Any Questions?" September 13, p. 700). I would include ampoules of nalorphine, 5 mg./ml., for intravenous administration to the mother near delivery and a 5-ml. vial of the neonatal nalorphine (1 mg./ml.). These are useful to prevent and overcome respiratory depression of the baby due to narcotics, especially in precipitate labour. 20% magnesium sulphate in 10-ml. ampoules (with ampoules of calcium gluconate as an antidote) is far safer than the use of sodium thiopentone. Morphine sulphate gr. $\frac{1}{4}$ (32 mg.) can also be given with this in cases of eclampsia. General anaesthetics are dangerous in labour, especially at home. It is extremely difficult to transfer an anaesthetized patient to hospital, should the occasion arise, and only those procedures which can be performed under a local anaesthetic should be undertaken at home. The one exception is a manual removal of placenta, and if ergometrine has not been given this can often be done using only gas-and-air or trichlorethylene. For local anaesthesia 1% lignocaine—and I recommend a minimum of 50 ml. should be carried—is safer and more comfortable to the patient. For a pudendal nerve block a lumbar puncture needle is invaluable. Presuming that the intravenous cannulae and the volsellum forceps are to be used, then a good light is automatically a "must." I feel that a Drew Smythe catheter may not only cause the separation of a low-lying placenta (type II or III) on the posterior wall of the uterus but it will introduce infection. If the membranes have to be ruptured, then Kocher's forceps are as good as any.

OUR EXPERT replies: The detailed contents of the midwifery bag suggested were intended to show the scope of equipment required rather than to dogmatize about treatment. Every general practitioner will have his own preferences and techniques, which he may change from year to year. So I would not object to Dr. Goodman's modifications except to say that I carry nalorphine in my "emergency" bag and a large battery torch in my car. The choice of anaesthetic will also depend on individual preferences. I believe that all anaesthetics, including local anaesthetics, are dangerous. It therefore behoves the general practitioner to use the anaesthetic he finds most efficient and least dangerous.

Collected Articles from the "British Medical Journal"

ANTIMALARIAL DRUGS IN NIGERIA: RESULTS OF A NEW SURVEY

BY

L. J. BRUCE-CHWATT, O.B.E., M.D., M.P.H., D.T.M.&H.
*Senior Specialist, Malariologist**

AND

D. W. HORN, M.B., Ch.B., D.P.H., D.T.M.&H.
Specialist, Medical Statistician
Federal Medical Department, Nigeria

The first survey of the use of antimalarial drugs in Nigeria (Bruce-Chwatt and Bruce-Chwatt, 1950) provided data on some special aspects of prophylaxis and treatment of malaria in this the largest British dependency in West Africa. A similar investigation by Nicol (1953) reported on the experience of the expatriate population in Lagos and discussed the value of various protective antimalarials in Nigeria.

Chemotherapy of malaria has progressed a great deal during the past decade, and a resurvey of the situation in Nigeria was called for. It was especially timely, because the difficulties of malaria eradication in holo-endemic areas of tropical Africa by residual insecticides alone have aroused more interest in the possibilities offered by chemotherapy (W.H.O., 1957). Moreover, it was thought that an assessment of the situation might be of value, as some new trends in the use of antimalarial drugs in Nigeria reflect the profound socio-economic changes seen in West Africa to-day.

This paper deals mainly with the small and transient but well-defined group of the non-immune expatriate population; problems of malaria in the indigenous population of Nigeria will be presented at a future date. Nevertheless, a considerable amount of information pertaining to chemotherapy of malaria in Africans was collected and is reported here.

The total population of Nigeria at the 1952–3 census was 31½ millions, and it was estimated that it increases at the rate of nearly 2% per annum.

The non-African population in Nigeria is distributed unevenly and its composition is constantly changing because of an estimated turnover (due to home leave) of about 30% during the year. This population numbered 16,700 in 1953 and nearly 18,000 in 1956. Of the total of 17,953 expatriates (in mid-1956), 30% were residents in the Federal Territory of Lagos, 31% were in the Northern Region, 20% in the Western Region, and 20% in the Eastern Region and the Southern Cameroons. The overall national composition of the non-African population of Nigeria at the census was approximately as follows: 60% were British; 3% Common-wealth citizens, including Indians; 6% Americans; 9%

Syrians and Lebanese; 3% French; 3% Dutch; 3% Irish; and the remaining 13% belonging to various other nationalities (Nigeria, 1954).

There are few reliable figures referring to the incidence of malaria in the expatriate population of the Federation of Nigeria. The reasons for it were discussed before (Bruce-Chwatt and Bruce-Chwatt, 1950), and the situation has not changed.

Reliable diagnosis of malaria in non-immunes in West Africa is not easy for reasons opposite to those discussed with regard to malaria of the indigenous population. The attitude of the individual medical officer towards this problem varies considerably between two extremes: (a) labelling as malaria any disease with vague clinical symptoms which might or might not be due to the plasmodial infection, and (b) recognizing malaria only on the basis of a confirmatory report of a blood examination. Errors are bound to be committed in either case, and some striking differences between two successive annual rates of malaria in the same locality are often due to a change of medical officers.

An additional difficulty arises from the universal use of antimalarial drugs by the expatriate population; this greatly decreases the chance of finding parasites in the blood, and the diagnosis is then made by presumption when the symptoms respond to a tentative specific treatment. Thus the records of malaria incidence among expatriates in Nigeria are not more than estimates subject to many errors.

INFORMATION ON MALARIA AND ANTI-MALARIAL DRUGS FROM TWO QUESTIONNAIRES

Two years ago it was decided that some more reliable information on the incidence of malaria in Nigeria and on the value of modern antimalarial drugs could perhaps be obtained through suitably designed questionnaires, similarly to what had been done in 1950. It was intended to have two polls of opinion: one addressed to the medical profession in Nigeria, the other to a large though selected group of the residential population of Lagos which relies on routine drug prophylaxis for individual protection against malaria.

The medical questionnaire asked the following ques-

*Now at Division of Malaria Eradication, W.H.O., Geneva.

tions: number, sex, and age of expatriates in the relevant station; number of cases of malaria during the year; type of prophylactic drug taken by the patients and regularity of administration; type of treatment favoured by the medical practitioner; evidence of toxic effects during prophylactic or therapeutic regimen; views on malaria prophylaxis and treatment in Africans and expatriates.

The non-medical questionnaire asked for information on the following: nationality, age, and sex; duration of stay in Nigeria and in Lagos; type of antimalarial drug taken and dosage; on whose advice and how regularly; reasons for change of drug if any; incidence of malaria and by whom diagnosed.

In July, 1956, the Federal Malaria Service dispatched two questionnaires. One, numbering 380 copies, was addressed to medical officers in Government stations and medical missions, and to private practitioners; the other was sent to 3,200 householders whose names appeared in 1956 in the official "residential list" of Lagos township.

The response to the questionnaire forwarded to 380 medical officers in Nigeria produced 146 complete replies, an overall percentage of 38.5. Of these replies, 128 came from the three Regions of Nigeria and 18 from Lagos. The expatriate population, under the medical care of 128 medical officers stationed outside the Federal Territory of Lagos, who answered the questionnaire, amounted to 6,859, which represents approximately 54% of the total expatriate population of Nigeria residing outside the Federal Territory in 1956.

Of the 3,200 questionnaires sent out to the "residential" population of Lagos, 1,026 were returned. Of these, 1,016 gave information in respect of 2,222 persons, distributed as shown in Table I.

TABLE I.—"Residential" Population of Lagos. Replies to the Questionnaire by Race and Age Group

	Adults (15 Years and Over)	Children 2-14 Years	Infants Under 2 Years	Total
Europeans (=Caucasians) ..	1,557	395	75	2,027
Africans ..	103	56	12	171

The collected data were coded, put on marginal punch-cards, and numerically assessed; they constitute the main subject of this paper and represent two polls of opinion—one medical, covering the whole country, and the other non-medical, limited to Lagos.

Incidence of Malaria

The two questionnaires provided some interesting data on the incidence of malaria in the expatriate population on a sample which amounts to 49% of the total 1956 population of expatriates in Nigeria (Table II).

Table II quotes for the three regions of Nigeria the number of cases of malaria duly diagnosed and reported by medical practitioners. The incidence of malaria in the

Federal Territory of Lagos is quoted from the replies forwarded by the "residential" population and refers only to malaria diagnosed by a medical officer. Reports of "suspected malaria" (a total of 97) not seen or not confirmed by a doctor were not included, as it was felt that many of the symptoms could have been easily confused with undetermined or minor ailments.

As pointed out previously, the diagnosis of malaria in expatriates in tropical Africa is, paradoxically enough, not easy (even when made by medical practitioners), and the figures quoted must be interpreted with caution, although they are the best data that can be obtained in the circumstances.

Table II indicates that, as one would expect, the incidence of malaria in non-immunes is much less in the mainly urban population of the Federal Territory of Lagos than in the regions, which, with the exception of a few main centres, are predominantly rural areas. Moreover, the overall figures indicate that the incidence of malaria in the expatriate population of Nigeria fell from 225 per 1,000 in 1949 to 142 per 1,000 in 1956. The low mortality from malaria in the expatriate population is striking. There was one fatal case of blackwater fever in a Syrian merchant, following an intramuscular injection of quinine. One death due to cerebral malaria was recorded in a European child, but no details of this case are available.

With regard to the "residential" population of Lagos the data collected during the present survey indicate that the malaria incidence of expatriates decreased during the past eight years from 149 per 1,000 in 1948 to about 60 per 1,000 in 1956.

Thanks to the ready co-operation of the Army medical authorities, it was possible to obtain valuable data on the incidence of malaria in the British military personnel serving in Nigeria and in their families. This group numbers about 1,000, of whom 60% are male adults. The incidence of malaria in the British Army personnel, including the families, was 25 per 1,000 in 1956 (data incomplete) and 35 per 1,000 in 1957. Both figures are well below the rates estimated for the civilian expatriate population and confirm the impression that a number of cases of malaria in expatriates are due to a lapse in the regular routine of drug taking.

Comparative Therapeutic Value of Antimalarial Drugs

From the 146 replies to the questionnaire sent by the members of the medical profession there seems to be nothing approaching a standard treatment of malaria in Nigeria. Although the replies revealed many variations of treatment and a large number of combinations of antimalarial drugs a general pattern was discernible.

For the emergency treatment of severe malaria mepacrine and chloroquine are used with equal frequency, mainly by intramuscular injection; quinine is also used, though somewhat less often, by the intramuscular and occasionally by the intravenous route. The most common single adult dose of quinine injections is 10 gr. (650 mg.); the relevant doses of chloroquine and mepacrine are 200 mg. of base and 300 mg. of base respectively. Because of the frequency of toxic reactions in infants and small children, quinine and chloroquine (in suitably graded dosage) are preferred to mepacrine in paediatric practice.

For peroral treatment of moderately severe malaria chloroquine is the most-favoured single drug, selected by 60% of all medical practitioners, with mepacrine second (24%), amodiaquine third (14%), and quinine fourth (2%).

A few correspondents placed much faith in the therapeutic value of proguanil, and two among them regarded pyrimethamine (at 100 mg. in 36 hours) as a good drug for the treatment of malaria.

Many medical practitioners treat ordinary attacks of malaria by a single intramuscular injection of quinine or mepacrine followed by oral administration of chloroquine or mepacrine or amodiaquine. A few use such combinations as amodiaquine-pyrimethamine, mepacrine-proguanil, etc.

The mean dosage of oral chloroquine is 1.8-2.1 g. of base in three to five days, of mepacrine 1.6-3.0 g. in three to five days, and of amodiaquine 1.2-1.4 g. in four days.

Many medical men adopt the logical principle that the drug used for treatment must be different from that used for prophylaxis. All of them agree that malaria in Africans past early childhood responds well to a less-sustained treatment than the disease seen in non-immunes.

Comparative Value of Prophylactic Antimalarial Drugs

(1) Medical Questionary

Out of 146 replies to the medical questionnaire, 97 (67%) favoured proguanil; of these, 52 advocated the standard dosage at 100 mg. daily, while 45, mainly from the Northern Region, preferred the daily dosage of 200 mg. Twenty-two replies (15%) gave pyrimethamine at 25 mg. or 50 mg. once a week as the best protective antimalarial. Twenty (14%) advocated chloroquine at two doses once a week totalling 300 mg., though a few preferred a weekly dosage of 600 mg. Three medical men considered that mepacrine and amodiaquine were the most reliable protective antimalarials, while two correspondents were staunch defenders of the "good old quinine."

In attempting to assess the protective value of antimalarials it was found from the medical questionnaire that the number of so-called "break-throughs" reported in the people who were taking various drugs was roughly the same as the different ratios of their uses. Thus, of the break-throughs, 75% were reported in takers of proguanil (mainly in those whose daily dose was 100 mg.), 8% in takers of pyrimethamine, 10% in takers of chloroquine, 4% in takers of quinine, and 1% in takers of mepacrine or amodiaquine. In other words, it was alleged that none of the drugs was 100% effective in preventing attacks of malaria.

As the regularity and adequacy of prophylactic drug administration was not always certain, the reports on break-throughs should not be taken too literally. The fact that these break-throughs occurred roughly in proportionately the same number of people taking various antimalarials suggests that many of them were due to an inadequate prophylactic regimen, while others were due to various febrile conditions.

There is evidence of two widely differing attitudes of the medical profession in Nigeria with regard to the use of prophylactic antimalarials in Africans. While 20 doctors maintained that mass prophylaxis for the indigenous population is neither necessary nor beneficial because of the possible loss of acquired tolerance to malaria, 25 doctors were strongly in favour of drug prophylaxis, especially in some selected indigenous groups such as expectant mothers, schools, labour camps, etc.

An interesting observation came from a large leprosy centre directed by a mission: 500 patients were kept for one year on a weekly pyrimethamine prophylaxis, and this not only reduced the incidence of malaria but apparently also only reduced the incidence of leprosy after sulphones. For prophylactic administration in African communities mepacrine, proguanil, or pyrimethamine once a week was favoured.

A few industrial organizations have adopted the policy of regular drug prophylaxis of their indigenous staff, and of reported satisfactory results either because of apparent decrease of sickness or on account of better public relations. The Army has recently introduced a regular prophylactic

regimen for all Nigerian members of the Forces, including their families. The drug selected was pyrimethamine at 25 mg. once a week.

(2) Non-medical Questionary

The results of the non-medical "residential" questionnaire are shown in Table III and refer to 2,027 European (=Caucasian) residents. The replies of 171 African and

24 Indian residents represent a very small group, and for the sake of convenience were grouped together. The replies showed that proguanil was used by 68% of the residential population of Lagos. It was the most popular drug in all races, except for infants and to a less extent for children, in whom it was replaced by pyrimethamine, used by 20% of the public. Chloroquine was the third (6%) most popular prophylactic, while amodiaquine was used by 0.5% of people; mepacrine, which in a previous survey was still being taken by 10.6% of the population, has almost completely dropped out of favour, being taken by only 22 persons (1%). Quinine, which in 1950 was taken by 18.7% of expatriates, has dropped to 4%—mostly "old coasters," though it is still favoured by some, particularly for children and infants. No drug, except perhaps mepacrine, showed any significant difference by sex: this antimalarial is rarely taken by women.

Thus proguanil is shown to be the drug of choice; but where ease of administration is of particular importance, as in children and infants, pyrimethamine replaces it as a favourite. It will be noted from Table III that five Europeans and 15 Africans stated that they take no antimalarials at all. Of the Europeans, one man said that "mosquitoes did not seem to bite him," another said it "was not required in Lagos," one woman put her faith in homoeopathic remedies, and two women stated that all antimalarials upset their digestion.

The "residential" questionnaire attempted to investigate the incidence of malaria in the non-immune population of Lagos on the basis of the information received from 2,027 expatriates.

The reported cases of illness attributed to malaria were divided into three groups: (1) malaria diagnosed as such by a doctor; (2) suspected malaria—not seen by a doctor; and (3) "fever." The results are set out in Table IV, which shows that the so-called "break-throughs" of malaria occur with all drugs in about 6% of persons.

The first and second most favoured dosage schedules of the main drugs taken by adults of the sample of the Lagos residential population are shown in Table V. The percentages in this table refer to the number of people taking the particular drug. The dosage for children is lower by approximately one half.

TABLE V

Drug	Modal Dose	Second Mode
Proguanil	7 tablets weekly—86%	14 tablets weekly—7%
Chloroquine	2 tablets weekly (300 mg.)—51%	3-4 tablets weekly (450-600 mg.)—42%
Pyrimethamine	1 tablet weekly—74%	2 tablets weekly—22%

Optimum Dose of Antimalarial.—It was found that there was no clear-cut correlation between the incidence of "malaria" and variation in the weekly dosage. Chloroquine, of which the most popular doses are two and three tablets a week for adults, and one and two tablets a week for children, shows the expected result—that is, 92.3% protection on the higher dose and 74.5% on the lower dose. This difference, however, just fails to reach statistical significance at the 5% level ($p=0.0543$ by Fisher's exact test). Amongst adults taking proguanil the converse is the case: those taking the modal dose of seven tablets a week are 77.2% protected, whereas those taking 14 tablets a week show 67.5% protection. This difference again just misses significance at the 5% level ($t=1.93$, with 1,051 degrees of freedom). Similar unexpected findings refer to samples of children taking proguanil at half-tablet (50 mg.) daily or one tablet (100 mg.) daily respectively. The same applies to two groups of adults: one on one tablet (25 mg.) of pyrimethamine and the other on two tablets (50 mg.) once a week. In children pyrimethamine shows the expected trend: 80.1% protection on the lower dose, and 84.7% on the higher.

The paradox of the higher dose giving the lower degree of protection is of interest though of limited importance. The ambiguous results of this part of the investigation are obviously due to neglect of numerous variables such as body weight, exposure to infection, and, last but not least, vagaries in the diagnosis of malaria.

Regularity in taking a drug is of prime importance for successful chemoprophylaxis, and a specific point was included in the questionnaire. Only 10 Europeans out of 2,022 confessed to irregularity in taking their antimalarials (from our personal experience, one might express some doubts about the reliability of this particular information). Amongst Africans, no fewer than 56 (32.7%) were irregular takers.

Reasons for choice of a particular drug were asked for, and the answers showed two primary reasons: proguanil was "officially recommended" to 57% of people by a doctor or an employer, while pyrimethamine was recommended to 11% and chloroquine to 16%. "Ease of administration" favoured pyrimethamine in 67% of its takers and proguanil in 33%.

(3) Toxic Effects of Antimalarial Drugs

Replies referring to side-effects of antimalarial drugs were of considerable interest. The results of the survey are discussed on the basis of data from the two questionnaires grouped separately for therapeutic and suppressive usage.

Medical observations on toxic reactions due to the therapeutic or protective administration of antimalarials are summarized below. It must be admitted that many side-effects associated with the prophylactic regimen (headache, insomnia, gastro-intestinal disturbances, depression, etc.) were so vague that the relationship between their frequency and the taking of a specific antimalarial was unconvincing.

Quinine.—The symptoms of cinchonism after high dosages of this drug are so well known that they need not be reported here. There was one case, however, of a sciatic nerve injury and paralysis after an intramuscular injection and one fatal case following an intravenous administration of the drug to a child. Intramuscular injections of quinine, nowadays much less common than before, were still advocated by 25 medical officers, particularly in severe malaria in children, apparently with very few local abscesses following the injection. There was one fatal case of blackwater fever following an intramuscular injection of quinine in a Syrian patient and five cases of "blackwater fever" in African children given irregular doses of quinine.

Mepacrine.—The most striking toxic effect of this drug, when given to infants and children up to 3 years of age, was an epileptiform seizure after the intramuscular injection of 100-150 mg. of mepacrine musonate. A total of 37 of these dramatic sequelae with 29 deaths were reported by 18 medical officers, including one case in the Army. The symptoms set off within 10 to 15 minutes after the injection, and consist of sudden clonic and tonic convulsions, dyspnoea, cyanosis, loss of consciousness, and either death or recovery within one to two hours. Two such cases with clonic convulsions of legs or one arm lasting for 20 minutes were observed in adults soon after the injection of 300 mg. of mepacrine. Cases of psychosis, mainly in adults, following the oral administration of mepacrine were reported by 36 medical officers. The incidence of this side-effect cannot be computed, but two correspondents assessed that it averaged 2% of people treated with mepacrine given at the standard dosage. In one small station four patients who were given rather high but not excessive doses of mepacrine developed mental symptoms, some of them of maniacal nature. Other side-effects ascribed to mepacrine were gastric symptoms with vomiting (4), gluteal abscess after intramuscular injection (3), and dermatitis (3).

Chloroquine.—Two epileptiform fits similar to those observed after parenteral mepacrine were reported following an intramuscular injection of 100 mg. of chloroquine—one in an infant, the other in a child of 18 months; one case recovered. The standard therapeutic regimen of chloroquine was followed by a number of side-effects. Vomiting and abdominal discomfort were most commonly reported; the next two common complaints were pruritus and blurring of vision (due probably to a paresis of accommodation). Either one or the other side-effect was seen, according to several correspondents, in 2 to 4% of all patients treated with chloroquine at full dosage. Pruritus seems to have been especially common in women, and was either general or localized in the perineal region or on hands and feet. Antihistamine drugs relieved this symptom, but in a few cases were without effect. Both these side-effects were temporary and abated within one week after the drug had been discontinued. Other minor complaints following

the administration of chloroquine were urticaria and oedema (4 cases), dizziness (8 cases), insomnia (3 cases), mental depression and abdominal discomfort (3 cases).

Amodiaquine.—Except for one case of vomiting, dizziness, and collapse in a child given 600 mg. of amodiaquine by mouth, no other side-effects were recorded, but the number of cases when this drug was used was small.

Proguanil and Pyrimethamine.—These are rarely used for treatment of malaria, and most of the side-effects reported were connected with the prophylactic regimen. Only 13 medical officers noticed any side-effects of proguanil taken in daily dosage of 100-200 mg. Most of these symptoms consisted of abdominal discomfort, diarrhoea, anorexia; there were, however, five cases in which proguanil was apparently causing stomatitis and mouth ulcers in adults, two cases of haematuria in children after an administration of 200 mg. of the drug, and one case of dermatitis resembling erythema nodosum. No side-effects were reported following the administration of pyrimethamine at standard doses, but there were seven cases of acute accidental poisoning of children. Five of these (four in European children and one in an African) proved to be fatal. The history of most of these cases was essentially the same: a child between 2 and 5 years of age found a bottle of pyrimethamine tablets and swallowed a number (15-25) of them. Within 30 minutes to 2 hours the child developed convulsions, occasionally vomited, collapsed, and either died one to three hours later or recovered. In one of these cases prompt medical action saved the child. In one case pyrimethamine could not be incriminated with any certainty. Apart from acute poisoning there were five cases of chronic toxicity of pyrimethamine given to one infant and four children at gross overdosage—for example, three tablets a week for six weeks or one tablet daily for three weeks). This was followed by asthenia, severe megaloblastic anaemia, and, in the case of two African children, death from a condition diagnosed tentatively as agranulocytosis.

Although the medical questionnaire brought some evidence of the type and frequency of side-effects in regular takers of antimalarial drugs for prophylaxis it was thought that more direct information could be obtained from the large residential group in Lagos. A few specific points in the questionnaire designed for the lay public called for definite answers which could be of value in this investigation.

As it was well known that some people keep changing their antimalarial prophylactic drug while others are faithful to one for a long time, an appropriate point calling for a reply was inserted in the questionnaire addressed to the residents in Lagos. The results are shown in Tables VI and VII.

A total of 527 residents of Lagos stated that they had changed at one time from one drug to another. This change was more frequent among adults (29%) than among children (17.5%) or infants (15%), with no significant difference between sexes.

Of all people changing drugs, the greatest number (279) changed from proguanil, forming 52.9% of those who changed drugs and 13.8% of the total in this survey; 75.6% of these went over to pyrimethamine—more children (87.0%) and infants (85.7%) than adults (72.5%). Chloroquine was the next most popular choice (55 persons, 19.7%).

TABLE VI.—Numbers of Residents in Lagos Changing Their Drug

Drug Changed from	Drug Changed to												Total	
	Proguanil		Chloroquine		Pyrimethamine		Mepacrine		Quinine		Amodiaquine			
	No.	%	No.	%	No.	%	No.	%	No.	%	No.	%	No.	%
Proguanil	17	3.2	55	10.4	211	40.0	6	1.1	6	1.1	1	0.2	279	52.9
Chloroquine .. .	10	1.9	8	1.5	5	0.9	—	—	1	0.2	—	—	23	4.4

Total ..	176	33.4	76	14.4	250	47.5	8	1.5	15	2.8	2	0.4	527	100.0

Mepacrine and quinine—the two "old-fashioned" drugs—were both abandoned by 19.5% of those who changed. Of those who stopped mepacrine, 75.7% went on to proguanil and 11.7% to pyrimethamine. Of the erstwhile quinine-takers, 68.9% preferred proguanil and 21.4% pyrimethamine. People who took chloroquine and pyrimethamine *ab initio* seem to be well satisfied with these drugs, changes occurring in only about 1% of the series.

The reason for a change of drug was also asked for. The answers were tabulated under the following headings: "Not effective," "personal preference or other reasons," "ill effects" (Table VII). Noticeable is the number of persons

TABLE VII.—Reasons for Changing Antimalarial Drugs in Lagos, 1956

Drug Changed from	Reason for Changing						Total	
	Not Effective		Personal Preference		Ill Effects			
	No.	%	No.	%	No.	%	No.	%

Total ..	116	22.0	160	30.4	251	47.6	527	100

Note.—The percentages refer to the relative proportions of the different reasons in the number of people changing from that particular drug.

who abandoned proguanil from personal preference—mostly for pyrimethamine, on account of the convenience of a weekly dose as opposed to a daily one, particularly in children. Nevertheless it is worth remarking that some people gave the contrary reason for changing from pyrimethamine to proguanil, because they found the daily dose easier to remember than the weekly one. As regards the incidence of ill effects, there were no significant differences between the various drugs, except in the case of mepacrine, which always was notoriously unpopular because it stained the skin yellow.

Gastro-intestinal upset was the commonest ill effect attributed to any drug; the usual symptoms were anorexia and nausea, often accompanied by dyspepsia and flatulence. Pyrimethamine appears to be the least offensive in this respect. Headache, insomnia, depression, together with lassitude, forgetfulness, and irritability—a syndrome for long popularly recognized as "coast-head"—was attributed to a drug by 40 people (15.9%) complaining of ill effects: all stated or implied that their symptoms disappeared on changing their drug. As was to be expected, mepacrine was the principal cause of skin trouble, and quinine of symptoms referred to the ears; other complaints, often vague and unconvincing, accounted for 10% of "ill effects," fairly randomly divided between the various drugs.

(4) Consumption of Antimalarial Drugs in Nigeria

A brief reference to the consumption of antimalarial drugs in Nigeria was made in a previous paper (Bruce-Chwatt, 1951), but the changing trends in the demand for these drugs can be assessed best from total amounts issued by the medical departments stores every year. Table VIII quotes the total number of tablets (in thousands) of each of the five main antimalarials indented during the period

1952-7 by medical officers of the Federal and the three Regional Governments. It should be pointed out that this table does not show the straight consumption of anti-malarials; during the past five years the number of hospitals and dispensaries opened in Nigeria had increased very considerably, and the figures in Table VIII reflect to some extent the ordering of new supplies for the greater number of treatment centres. Data concerning the consumption of drugs by private persons and commercial firms are not included in this table as they are not easily available.

Details of the consumption of parenteral preparations of antimalarial drugs are of less interest, but it might be added that the estimated number of ampoules of mepacrine (at 100 and 300 mg.) ordered by the governments in 1956 was 40,000, while the respective figure for quinine ampoules (at 6 and 10 gr. (400 and 650 mg.) was 30,000, and for ampoules of chloroquine 15,000.

The estimated cost to the governments of all antimalarial drugs used in 1956 for both prevention and treatment of malaria was approximately £60,000.

TABLE VIII.—Amounts of Antimalarial Drugs in Tablet Form (in Thousands) Purchased by the Government Medical Departments in Nigeria During the Period 1952-7

DISCUSSION

Difficulties in the correct diagnosis of malaria mainly from clinical symptoms, with little help from the blood examination, are considerable in West Africa, and are responsible to some extent for the unreliable malaria morbidity statistics of Africans and Europeans in Nigeria.

Information obtained through two questionnaires provided some new data on the incidence of malaria in the expatriate non-African population. It appears that the overall annual malaria morbidity of this population in the Federation of Nigeria fell from 225 per 1,000 in 1950 to 142 per 1,000 in 1956. Improvements in methods of malaria control in urban areas might have contributed to this gratifying decrease in morbidity, but the main cause of this is probably better individual protection and particularly the widespread use of more active prophylactic antimalarials. The disappearance of blackwater fever following the substitution of suppressive quinine by synthetic antimalarials is striking.

A survey of the therapeutic use of antimalarials in Nigeria revealed that as a whole the clinical medical practice in this country reflects creditably the remarkable advances achieved by experimental chemotherapy during the past ten years. Several interesting points were gathered from the answers to the medical questionnaire.

Chloroquine, given orally and parenterally, has become a drug of choice for the treatment of malaria in Nigeria. There can be little doubt that this drug is most effective and that the administration of the "loading dose," which averages two-thirds of the total dose, over three to five days is a correct procedure.

In spite of the popularity of chloroquine, quinine and mepacrine are still used; the former mainly for parenteral administration in severe malaria, the latter both by mouth and intramuscularly, somewhat indiscriminately, especially in rural areas.

The survey revealed a disturbing number of grave side-effects of intramuscular administration of mepacrine in

infants and young children. This disadvantage has been known for some time, but the frequency of these often fatal incidents was underestimated, as they were not widely known. It might be argued that 29 fatal sequelae of the intramuscular injection of mepacrine in children constitute a small proportion of all cases in which this treatment was beneficial, but it should be remembered that the number of accidents quoted above is probably only a proportion of all cases.

Similar observations were made in East Africa a few years ago (Dockeray, 1951) and confirmed in Uganda by Trowell (personal communication) and by Luder (1957). One such case, of toxic mepacrine encephalopathy in a child given a mepacrine injection in the absence of malaria, was described by one of us (Bruce-Chwatt, 1955). The experience in Nigeria is not in agreement with that of Covell *et al.* (1955), who maintain that mepacrine convulsions are alarming but seem to have no serious effects.

It must be admitted that chloroquine is not entirely blameless in this respect, and the two cases of acute toxic effects of intramuscular chloroquine, quoted by our medical correspondents, are similar to those described in Ghana by Harris (1955). Nevertheless at the present time the general consensus of medical opinion is that intramuscular chloroquine is safe when properly administered. It is certain that the danger of parenteral administration of any antimalarial will be greatly decreased if the drug is given in two or three fractional doses, over one to one and a half hours. Attention should be drawn to the importance of calculating the dosage of intramuscular chloroquine in relation to the actual weight of children and not by a rule of thumb referring only to the age of the child (Harris, 1957). Oral administration should be preferred whenever feasible.

Serious side-effects after chloroquine given by the mouth were uncommon; on a full therapeutic dose of about 2 g. over four to five days pruritus and temporary blurring of vision might be quite troublesome in about 1% of patients. Amodiaquine has gained some favour among the medical profession in spite of the fact that there is no evidence that it is superior to chloroquine. A comparative study of the schizontocidal effect of both drugs (Charles, 1958) confirmed Davey's (1955) opinion "that amodiaquine cannot be used in any way—that is, in any particular dosage regimen—which is significantly different from a way in which chloroquine might be used."

The results of the medical questionnaire were of interest with regard to some important points mentioned by Covell *et al.* (1955). (1) Dosage of antimalarial drugs necessary for treatment of malaria in semi-immunes was about one-third to a half of that needed for the non-immune subject, and a short treatment consisting of 600 mg. of chloroquine in a single dose or 800 mg. of mepacrine over two days was usually effective. Good effects were also reported by those who used single-dose treatment of 600 mg. of amodiaquine. (2) There was no evidence of any strain of *Plasmodium falciparum* in Nigeria being resistant to therapeutic doses of chloroquine, mepacrine, or amodiaquine. However, some indirect and inconclusive reports have been quoted of increased tolerance by malaria parasites of proguanil or pyrimethamine given as suppressives. (3) There were justified complaints of the ever-increasing confusion created by the profusion of various proprietary names for the same active drug and by the varying dosages expressed either as a salt or as a base. Need was expressed for a reliable active drug without a bitter taste, suitable for paediatric practice.

With regard to the latter point, attention might be drawn to the recent confirmation by Clyde and Shute (1958), in Tanganyika, of the failure of the chloroquine methylene- β -hydroxynaphthoate reported by Bruce-Chwatt and Charles (1957).

Respective Values of Suppressives

When it comes to discussing the recent trends in the choice of suppressive antimalarials and their respective

values the conclusions deriving from the two questionnaires are on less objective grounds. The use of antimalarial drugs for individual protection has been almost general in the expatriate population of West Africa for the past 50 years.* All senior Government officials and most of the senior staff in commercial undertakings, missions, etc., are supplied with antimalarials free of charge. A few years ago only quinine, mepacrine, or proguanil could be obtained on demand, but nowadays this extends also to chloroquine and pyrimethamine. Since the taking of an antimalarial is a normal feature of everyday life no wonder that the discussion of favourite antimalarial drugs is a popular conversational topic at any social gathering in Nigeria. There are unfathomable "fashions" in drug-taking, and many more or less imaginary complaints connected with them tend to obscure the real incidence of specific side-effects. All this, stimulated by an increasing amount of advertising, has led to an undesirable situation, as many expatriates are experimenting on themselves, using one or another drug, often at dangerously high dosages.

It appears from replies to both the medical and the "residential" questionnaire that proguanil is taken by nearly three-quarters of all expatriates and by an increasing number of educated Nigerians. Pyrimethamine and chloroquine are the next choice, with amodiaquine third. In comparing these findings with those of the 1950 questionnaire the remarkable though expected trend is the eclipse of the remarkable though expected trend is the eclipse of the quinine and mepacrine as protective drugs. The other interesting fact is the generally increased dosage of proguanil used with the modal dose in 1950.

The changing trend in prophylactic antimalarials taken by a representative sample of the expatriate population of Nigeria can be seen best from the comparative figures obtained successively by the Bruce-Chwatts (1950), Nicol (1953), and the present survey.

The percentages of expatriates taking one or the other prophylactic antimalarial were as follows:

	1950	1952	1956
Proguanil ..	65%	68%	70%
Quinine ..	23%	16%	3%
Mepacrine ..	10%	6%	0.6%
Chloroquine ..	1%	2%	5%
Pyrimethamine ..			20%

General Protection

The true comparative value of the main drugs for the "general protection," in the sense given to this term by Covell *et al.* (1955)—that is, suppression of clinical symptoms, suppressive cure of *P. falciparum*, and causal prophylaxis—cannot be established from replies given to the two questionnaires. Every drug, at whatever dosage taken, was alleged to have failed in approximately 6% of takers. This figure is in reasonably good agreement with the results obtained by Nicol (1953), who gave the percentage of "break-throughs" as 10.

Whether these break-throughs are genuine and due to the irregularity of drug-taking, or its underdosage, or an intercurrent gastro-intestinal illness interfering with the absorption of the drug, or unusually great exposure to infection, or the presence of a resistant strain of the malaria parasite or other unknown factors is impossible to tell, though the first suspicion is justified and the following two causes are most likely. The possibility of relapsing infections with *P. malariae* or *P. ovale* of local origin cannot be dismissed, but is likely only in sporadic cases and not in nearly 10% *P. vivax*, usually responsible for relapses of malaria, is so extremely rare in Nigeria that one or two imported cases

*It is generally believed that the regular use of prophylactic quinine was introduced into West Africa in 1835. According to the late G. M. Findlay (*In litt.*), however, the "preventive quinine" was initiated on the West Coast in 1772 by Robert Robertson, a naval surgeon and a friend of James Lind, the promoter of the administration of "the bark for the cure of ague" in India. Robertson later became a Fellow of the Royal Society.

would not account for more than a fraction of the incidence of malaria quoted above.

There is no factual evidence that proguanil- and pyrimethamine-resistant strains of *P. falciparum* might be responsible for some of the "break-throughs." A few personal comments of medical officers who had experienced an attack of malaria (with a positive blood slide) while on proguanil or pyrimethamine prophylaxis are insufficient to support this presumption. The incidence of malaria in regular takers of antimalarials generally and proguanil and pyrimethamine in particular has not increased in comparison with 1950, and it can be safely said that for the time being no drastic changes in the choice of suppressive drugs in Nigeria are necessary (Nigeria, 1949-54).

In Nigeria there has been an obvious trend to substitute pyrimethamine for proguanil, especially in children. The main, and good, arguments in favour of pyrimethamine are the lack of taste and the ease of giving a tablet once a week (usually on Sunday) instead of every day. It is of interest that in several replies to the questionnaires correspondents admitted that they reverted to the daily proguanil regimen, as they found it difficult to remember to take pyrimethamine on only one particular day of the week and felt that the daily routine left much less margin for any possible errors of individual prophylaxis. On the other hand, the use of pyrimethamine once a week was most convenient in hospitals, schools, labour camps, antenatal clinics, etc., whenever a collective prophylaxis is carried out in a reasonably stable or supervised group. The problem of the best routine of prophylactic drug-taking is far from simple and must "take into account economics, human desires, and human failings" (Davey, 1955). This is of considerable importance with regard to the routine administration of prophylactic chloroquine, which is usually given twice a week at 300 mg. base: it is probable that a daily routine of 50-75 mg. would be a far better choice for individual prophylaxis.

It is of interest, therefore, that Davey and Robertson (1957) carried out a successful field trial of chemoprophylaxis with a daily dose of 50 mg. of chloroquine base because the daily regimen has been favoured by the Army authorities. Several years ago French workers adopted the daily prophylactic dosage of 100 mg. of chloroquine base, and since 1953 this method has been used throughout French West and Equatorial Africa with considerable success.

It will thus be understandable why the method of individual prophylaxis by amodiaquine—two tablets twice a month—is quite unrealistic and of doubtful value.

There is little evidence that any of the three commonly used prophylactic drugs (proguanil, chloroquine, pyrimethamine) produce any serious and consistent side-effects when taken at standard dosage. Pyrimethamine is probably the least responsible for any gastro-intestinal or other complaints commonly referred to other drugs. It is therefore all the more regrettable that during 1956 there were five fatal cases of poisoning due to pyrimethamine left within the reach of toddlers, attracted by the small size of the tablets and their lack of bitter taste.

All these cases are much the same as those of accidental pyrimethamine poisoning in children described by Taylor (1953), Davidson (1954), Gunther (1954), Peake (1954), Abbott (1955), Davies (1956), and in the Belgian Congo by Montauban *et al.* (1956), whose paper contains the best clinical description of acute pyrimethamine poisoning.

It should be added, in all fairness to the drug, that these accidents happened in Nigeria in 1956, before the introduction of the modern plastic strip pack of pyrimethamine, which should effectively prevent children from swallowing more than one or two tablets.

Five cases of long-term toxicity of pyrimethamine (megaloblastic type of anaemia), given at doses far in excess of those normally used, were more serious, as they were due to an error of judgment of the medical practitioner or to irresponsible self-medication by laymen. The main cause

of the medical errors of judgment was the lack of appreciation of the differences between proguanil (which has a wide margin of safety) and pyrimethamine, remarkably active in small doses but toxic when given to children at several times its standard dose.

It appears that the conclusions of Myatt *et al.* (1953) about the reversibility of megaloblastic anaemia of adult volunteers on 25 mg. of pyrimethamine daily for several weeks do not necessarily apply to the blood-forming organs of children. The Federal Government of Nigeria, justifiably alarmed at the excessive dosage of pyrimethamine used in 1956 by some medical practitioners and by the lay public, circularized at the end of that year a warning to the medical profession in Nigeria. It appears that this warning was duly heeded, as only one case of overdosage of pyrimethamine came to light during the past year.

The replies to the medical questionnaire showed that there is a considerable measure of disagreement between medical practitioners in Nigeria regarding the value of drug prophylaxis in the indigenous population. The fact that out of 146 replies 100 did not express any definite opinion on this controversial subject indicates the gap in our knowledge of the problem of malaria immunity and its relationship with individual or collective chemotherapy. In view of the absence of a concerted opinion of the medical profession in Nigeria on the value of drug prophylaxis in the African population we express our own point of view.

In discussing the value of protective drugs in the indigenous population three groups of people must be distinguished. The first is a small but growing group of African infants and children either born in Europe or having been away for a long time and who are returning to the malarious areas. These should be treated, especially for some time after their return, as non-immunes and protected by the same drug regimen. The second group is constituted by antenatal clinics, infant welfare centres, schools, labour camps, etc. Such groups can be supervised; and here the value of antimalarial drugs is considerable, since they reduce the amount of sickness and decrease the infectivity of the human reservoir of infection.

An ideal drug in these conditions should have a combined curative and long protective action similar to that shown by pentamidine for prevention of trypanosomiasis. Unfortunately there is no such antimalarial at present, and all known drugs are excreted rapidly and have a short "carry over" value, so that a once-weekly or, at least, once-monthly administration is necessary whenever a long-term effect is sought. The choice lies between proguanil and pyrimethamine on the one hand and mepacrine, chloroquine, and amodiaquine on the other.

The first two have the advantage of low toxicity, low cost, and a potent sporontocidal effect, but they may induce parasite resistance, especially when used for treatment as well as prevention of malaria.

Chloroquine and amodiaquine are excellent for both purposes; their cost is still relatively high. Mepacrine has the advantage of being cheap, but it has several undesirable side-effects. The general consensus of opinion is still rather in favour of proguanil and pyrimethamine, but it is possible that in the long run chloroquine or amodiaquine will be the best in conditions where protection from malaria must start with its cure and especially where resistance to the first two drugs had appeared.

An indigenous child continuously exposed to malarial infection need not be given a continuous uninterrupted protective regimen from its early infancy through its whole life. There is no doubt that the administration to these children of adequate doses of active antimalarial drugs, particularly at the peak of the transmission season, will help the growing organism by easing the load of heavy parasitaemia without thereby hampering the progressive building up of the individual acquired immunity to malaria.

In the third group of the indigenous, large, and scattered rural population mass distribution of antimalarials could

hardly achieve any permanent results (Bruce-Chwatt, 1956). Moreover, administrative difficulties of such mass distribution are enormous, and with the exception of some special circumstances, such as stopping an epidemic, the prevention of malaria by residual insecticides remains the only possibility, though mass treatment will speed up the interruption of transmission.

SUMMARY

Reliable data on the incidence of malaria are difficult to obtain in Nigeria, and the reported figures do not reflect the true situation.

The malaria morbidity of the expatriate population in Nigeria, which was estimated in 1950 at 225 per 1,000, had decreased in 1956 to 142 per 1,000. In an expatriate population of nearly 18,000 there was one death due to malaria and one to blackwater fever.

Information on antimalarial drugs obtained from two questionnaires showed that chloroquine is the most popular therapeutic drug, with mepacrine second, and amodiaquine third. For severe malaria, quinine injections are still frequently used.

As a protective drug proguanil was the most favoured, followed by pyrimethamine and chloroquine. In about 6% of takers of all protective drugs "break-throughs" of malaria were reported, but the reasons for these break-throughs, as well as their diagnosis, are uncertain.

Intramuscular injections of mepacrine in infants and small children may be followed by serious and often fatal sequelae. Both mepacrine and chloroquine given at a full therapeutic dose may produce a number of side-effects which are usually transient. Side-effects due to protective drugs are rare, though in 1956 there were several cases of accidental fatal poisoning of children by pyrimethamine.

An assessment has been made of the amount of antimalarial drugs consumed in Nigeria in 1956.

We thank Sir Samuel L. A. Manuwa, Chief Medical Adviser to the Federation of Nigeria, for his permission to publish this paper. We are grateful to the medical officers in Nigeria and to the members of the public in Lagos who answered our questionnaires and whose contribution formed the main body of this report. We also thank the medical authorities of the Nigerian Military Forces for their co-operation and the Federal and Regional Chief Pharmacists for supplying information on consumption of antimalarial drugs.

MALARIA AND PREMATUREITY IN THE WESTERN REGION OF NIGERIA

BY

D. S. H. CANNON, M.R.C.S., D.Obst.R.C.O.G.
 Wesley Guild Hospital, Ilesha, W. Nigeria

The amount of information available in tropical Africa on the relationship between malaria infection and prematurity is still inadequate. An investigation based on nearly 400 single deliveries is of sufficient interest to warrant this preliminary note.

The Wesley Guild Hospital, where this work was carried out, is a Methodist Mission Hospital which has been established in Ilesha (a town of about 80,000 inhabitants) for 45 years. During 1956 there were almost 12,000 attendances of 2,683 patients at the antenatal clinics and 815 deliveries in the hospital. Not all of these deliveries were from our own clinics; a proportion of these patients were women coming in from the surrounding villages to be delivered, and some were referred from local clinics.

The major problem facing any worker on prematurity in Nigeria is to determine whether an infant is premature or not. The W.H.O. (1950) has defined a premature baby as one which weighs less than 5½ lb. (2,500 g.) at birth, but this standard is not universally accepted for Negro children. The average birth weight of infants born in the Wesley Guild Hospital is between 6 and 6½ lb. (2,720 and 2,950 g.), which is much below the average of 7 lb. (3,180 g.) for England. Most of the African women who attend the antenatal clinics have no record of the last menstrual period, and no accurate estimation of the maturity of the infant can be made on the duration of pregnancy.

Present Investigation

Relationship between the malaria infection of the placenta and the weight of the child at birth was investigated on 392 single deliveries. The above sample had to be selected so as to exclude women who had taken any antimalarial drugs during the late months of the pregnancy. Quinine, mepacrine, and other drugs are readily obtainable in the local market, and a number of women take the drugs during pregnancy for "fever" or for various real or imaginary ailments or as a "tonic."

Immediately after the delivery of the placenta a wedge-shaped piece of it was cut from the maternal aspect of the organ and a smear was made on a slide. The film was fixed with absolute methyl alcohol and stained for 45 minutes in 5% Giemsa diluted in buffered water at pH 7.2. All the films were first examined by the technician and then rechecked without reference to the clinical data. The infants were weighed as soon as possible after delivery. usually within two hours of birth. The results are shown in Table I. The weights of newborn babies were classified into four groups, and the numbers in each of these groups in relation to the infection of the placenta are shown in Table II.

Adopting the term "premature" for all babies weighing less than 5½ lb. (2,500 g.) at birth, with the reservation that not all such Nigerian babies are necessarily premature.

TABLE I.—Relationship Between the Malaria Infection of the Placenta and Birth Weight

	No.	%	Mean Birth Weight
Infected placenta	130	33	5 lb. 12 oz. (2,610 g.)
Non-infected placenta	262	67	6 lb. 7 oz. (2,920 g.)
Total	392	100	6 lb. 3 oz. (2,807 g.)

the percentage of premature babies is 37 in the infected group and 12 in the non-infected. The difference of 25% is 3.4 times its standard error and therefore statistically significant.

TABLE II.—Four Groups of Weights of African Newborn in Relation to the Infection of Their Placenta

Weights of Infants	Infected Placenta		Non-infected Placenta	
	No.	%	No.	%
Up to 3 lb. 4 oz. (1,474 g.)	2	1.5	—	—
3 lb. 5 oz. to 5 lb. 8 oz. (1,500 to 2,495 g.)	46	35.4	32	12.2
5 lb. 9 oz. to 7 lb. 12 oz. (2,523 to 3,515 g.)	76	58.5	215	82.1
More than 7 lb. 12 oz. (3,515 g.)	6	4.6	15	5.7
Total	130	100.0	262	100.0

It was thought to be of interest to analyse the proportion of infected placentae in relation to the parity of the mother, and the results of this investigation are shown in Table III, where all newborn babies below 5½ lb. (2,500 g.) are counted as premature.

TABLE III.—Relationship Between the Parity of the Mother, Frequency of Placental Infection, and Birth Weight

Para	Infected Placentae			Non-infected Placentae			Positive Placentae (%)
	No.	Premature		No.	Premature		
		No.	%		No.	%	
1	75	33	44.0	45	12	26.6	62.5
2	22	9	41.0	41	4	9.7	35.0
3	13	2	15.4	51	5	9.8	20.3
4	7	1	14.3	42	5	11.9	14.3
5	4	1	25.0	40	1	2.5	9.1
6 and over	9	2	22.2	43	5	11.6	13.5
Total ..	130	48	37.0	262	32	12.2	33.0

Of the infants born of the infected placentae, nine died in the first week of life (6.9%), but in the non-infected group only 3.4% died in the first week. These figures are in general agreement with the frequency of prematurity in each group.

In view of the interest in the problem of sickling and malaria infection (Livingstone, 1957), 306 mothers were tested for the presence of the sickle-cell trait, using 2% sodium metabisulphite solution mixed with a drop of blood under a sealed coverslip.

The overall sickling rate in 306 mothers was found to be 10%; the sickling rate of 100 women with infected placentae was 11%, and the corresponding rate in 206 women with non-infected placentae was 9.2%. The difference of 1.8 is less than twice its standard error, and this would suggest that sickling has little effect on the development of the malarial parasite in the placenta.

The problem of congenital malaria in Nigeria has recently been discussed (Atkins, 1957; Bruce-Chwatt, 1957), and the opinions expressed were quite contradictory. In an attempt to obtain some data from Western Nigeria 117 newborn babies were investigated for the presence of malaria parasites in their peripheral blood within 24 hours after birth. The corresponding placentae were also examined. It was found that 30 placentae were infected with malaria parasites, giving a percentage of 25.6. None of the 117 newborn were found to be infected.

Discussion

Prematurity is the commonest cause of neonatal death, and it has been suggested that malarial infection of the mother, and consequently the placenta, is one of the causes of prematurity in Nigeria. Bruce-Chwatt (1952) examined the placentae of 310 single deliveries in Lagos and its vicinity, and showed that 73 (23.6%) were positive, and that the average birth weight of babies born with these placentae was 145 g. (4 oz.) less than the average birth weight of those born with non-infected placentae. Archibald (1956), working at Ilaro in the Western Region of Nigeria, found malarious placentae in 77 cases (15%) out of a series of 463; the average birth weight of babies from infected placentae

was 6 lb. (2,720 g.), and from non-infected placentae 6 lb. 6 oz. (2,890 g.), a difference of 6 oz. (170 g.).

The present investigation confirmed these findings and showed that 130 African babies whose placenta was infected with malaria parasites had a lower mean birth weight than 262 whose placenta was not infected. The difference in birth weight between the two groups was 11 oz. (312 g.). The proportion of newborn with very low birth weights was greater in those whose placenta was infected.

It appeared that there is a negative correlation between frequency of infection of the placenta and the parity of the mother. The increasing resistance to the infection might be due simply to the increasing average age of the women at each successive parity and correspondingly higher degree of immunity. It is of interest, however, that the percentage of babies weighing less than 5½ lb. (2,500 g.) is increased in the malarious group at each parity. The comparison between the average birth weights and percentage of prematurity of South African babies of various races (Salber and Bradshaw, 1953) with Nigerian babies born in Ilesha is of interest. It will be seen from Table IV that the average birth weight of Nigerian infants is lower, and the percentage weighing less than 5½ lb. (2,500 g.) at birth higher than any of the four races, including the Bantu, which are of negro stock.

TABLE IV.—Birth Weights of South African Babies Compared with Nigerian Babies

Race	Average Birth Weight	Percentage Less Than 5½ lb. (2,500 g.)
European S.A.	7 lb. 8 oz. (3,400 g.)	4.2
Coloured S.A.	6 lb. 14 oz. (3,120 g.)	9.6
Bantu S.A.	6 lb. 12 oz. (3,060 g.)	11.5
Indian S.A.	6 lb. 7 oz. (2,920 g.)	18.3
Nigerian (Ilesha)	6 lb. 3 oz. (2,805 g.)	20.4

An investigation of the presence of congenital malaria in a sample of 117 newborn babies showed that, although 25.6% of them had infected placentae, no malaria parasites could be found within 24 hours after birth in any newborn infant. This confirms the results obtained by Bruce-Chwatt (1952) and indicates that congenital malaria is very rare in the indigenous population of Nigeria, in spite of the frequent infection of the placenta.

Summary

Out of 362 newborn African babies 30% had a placenta infected with malaria parasites.

The mean birth weight in the 130 newborn that had an infected placenta was 11 oz. (312 g.) less than the birth weight of 262 whose placenta was not infected.

There were 33% of premature babies in deliveries where the placenta was found infected with malaria parasites; in deliveries with non-infected placenta the respective figure was 12%.

There was no case of congenital malaria among 117 newborn, 25.6% of whom had an infected placenta. There appears to be a negative correlation between frequency of infection of the placenta and the parity of the African mother.

I thank Dr. C. A. Pearson, medical superintendent, Wesley Guild Hospital, Ilesha, for his co-operation. I am grateful to Dr. L. J. Bruce-Chwatt, Federal Malaria Service, Medical Department, Lagos, for his help and guidance; to Dr. D. C. Morley for his assistance; to Mr. Ladele and Mr. Fasuyi for laboratory and clerical work; and to Miss Lethbridge and staff of the maternity unit for their co-operation.

MECHANISM OF ACUTE HYPOTENSION FROM FEAR OR NAUSEA

BY

E. P. SHARPEY-SCHAFFER, F.R.C.P.

Professor of Medicine

C. J. HAYTER, B.Sc., M.R.C.P.

Lecturer in Medicine

AND

E. D. BARLOW, M.B., D.P.M.

Research Fellow

(From the Department of Medicine, St. Thomas's Hospital Medical School, London)

It is common knowledge that emotion, particularly fear, may cause syncope. There are great difficulties, however, in obtaining records of the circulatory events which precede the attack, and many situations, such as high-flying jet aircraft or the altar steps, are impossible to investigate.

There is a small amount of evidence that the final mechanism of syncope induced by fear of needles is the same as syncope induced by haemorrhage, for Brigden *et al.* (1950) and Greenfield (1951) each demonstrated vasodilatation of forearm vessels in a single subject during the phase of low blood pressure.

Further evidence has now become available. An investigation into the cause of cerebral damage following nitrous oxide anaesthesia for extraction of teeth was suggested by the clinical material collected by Bourne (1957). It was at first thought that reduction in arterial oxygen saturation might be the main factor, but it is shown in this paper that severe hypotension is not uncommon, and that a precipitating cause is the well-known fear of the dental chair.

Emotion is often associated with nausea, and either or both may cause syncope. The effects of spontaneous nausea have from time to time been recorded in this laboratory during the course of circulatory observations, and the treatment of alcoholic patients with apomorphine allowed an opportunity of obtaining control records before nausea was induced.

Material and Methods

The subjects were volunteers; the dental patients being young healthy males (21 to 39 years) in need of urgent extraction of one or, at the most, two teeth. The alcoholic patients were older males (40 to 60 years).

Intravascular and intrathoracic pressures were measured with capacitance manometers and changes in arterial oxygen saturation with a continuously recording photoelectric device on the ear. Forearm flow was measured by venous occlusion plethysmography and recorded on the same photographic paper as the measurements of vascular pressure. Plethysmography was unsuitable in the dental cases owing to the inevitable final phase of violent muscular movements. In some subjects, however, the vascular resistance of a limb was measured by an arterial "run-off" method (Hayter and Sharpey-Schafer, 1958). In this method the artery is suddenly occluded by a high-pressure cuff. The rate of fall of arterial pressure distal to the cuff varies with the vascular resistance in the limb. This resistance, calculated by an empirical method, shows a good correlation with the resistance calculated from simultaneous pressure and flow measurements. The method is rapid, as only 2 seconds' occlusion is necessary for calculation, and is relatively free from artifact when violent muscular movements are to be expected.

Results

Effects of Dental Gas

Twenty-one subjects were investigated, five developing hypotension and the remainder showing evidence of the effects of emotional stress on the circulation. Circulatory

Data From Continuous Records Just Before Administration of N₂O

Case No.	Heart Rate	Pulse Pressure (mm. Hg)	Arterial Pressure (mm. Hg)

14	90	43	115.72
15	94	66	126.60
16	112	60	126.66

data obtained from continuous arterial records just before administration of N₂O are shown in the Table. In many subjects both heart rate and pulse pressure were considerably increased.

On giving gas the mean arterial pressure and pulse pressure increased still further and the arterial oxygen saturation fell to about 60% (Fig. 1). With tooth extraction or severe asphyxia large changes in intrathoracic pressure were superimposed on the arterial pressure trace, while in some subjects violent pronation of the forearm interfered with recording in the brachial artery. During induction of anaesthesia the arterial "run-off" method showed constriction in the forearm.

FIG. 1.—Upper trace: arterial O₂ saturation. Lower trace: arterial pressure. N₂O was given at the black signal on the time marker. Calibrations in mm. Hg, % saturation, and time marker in seconds in this and subsequent figures.

FIG. 2.—Upper trace: arterial O₂ saturation. Lower trace: sub-arterial pressure. N₂O was given at the first arrow and the sub-arterial pressure at the second arrow. Arterial pressure was low before the anaesthetic was given. There is a gap of 15 seconds between the upper and the lower record.

Administration of N₂O was not the main factor in causing hypotension, since in four out of five subjects arterial pressure was low before the mask had been placed on the face (Fig. 2). Indeed, in two subjects the giving of gas raised the previously low blood pressure. One subject had hypotension and syncope when tipped into the erect sitting posture preparatory to proceeding with the dental gas, recovered when tipped into the supine position, again had syncope when erect, and was finally successfully anaesthetized and a tooth extracted while supine.

The final, or efferent, mechanism of the fall in arterial pressure is shown in Fig. 3. The vasodilatation in forearm vessels was similar to that found in syncope induced by haemorrhage (Barcroft *et al.*, 1944) or by fear of needles (Brigden *et al.*, 1950). Bradycardia was also present and pallor of the skin persisted afterwards for many minutes, suggesting discharge of posterior pituitary hormone.

There remains the problem of how this vasovagal fainting reflex is initiated. The evidence presented above suggests that emotion or fear is the main factor. Reduction in arterial oxygen saturation, which can also result in vasovagal fainting (Anderson *et al.*, 1946), would seem to be only a possible additional cause.

Effects of Apomorphine

Five alcoholic patients were investigated in the supine position. Effective right auricular pressure (right auricular pressure minus intrathoracic pressure) was measured by the differential manometer system described by Lee *et al.* (1954).

Arterial pressure and forearm flow were recorded on the same photographic paper. After a control period a suitable alcoholic drink was made available and 4 mg. of apomorphine was given intramuscularly. Some minutes later, when nausea and yawning appeared, effective right auricular pressure fell (3 to 7 mm. Hg), the heart rate increased, but the mean arterial pressure was maintained. Still later, in three subjects, the mean arterial pressure fell below 50 mm. Hg and there was bradycardia and vasodilatation of forearm vessels (Fig. 4).

FIG. 4.—Syncope after apomorphine. Upper trace: arterial pressure. Lower trace: forearm volume. The rate of rise of volume on applying a collecting pressure is proportional to the flow. Upper record: before apomorphine. Lower record: after apomorphine, showing hypotension, bradycardia, and dilatation of forearm vessels.

About 30 other cases of spontaneous nausea have been observed, in which right auricular pressure fell with the onset of nausea. Differential manometer systems were not used in these cases, so that possible changes in intrathoracic pressure were not taken into account. The evidence suggests that dilatation of the peripheral venous system precedes hypotension in syncope induced by nausea.

Effects of Emotion in Heart Failure

The vasovagal fainting reflex has not been recorded in patients with heart failure. Such cases have been bled up to 2,000 ml. without firing this reflex (Howarth *et al.*, 1946), while venesections of 1,000 ml. cause fainting in over 50% of normal subjects (Wallace and Sharpey-Schafer, 1941). Circulatory measurements of all kinds have been made by one of us in about 700 patients with heart failure. None fainted from emotion, nausea, or other cause. Any explanation, therefore, of the afferent mechanism of the faint reflex in normal subjects must take into consideration that it does not operate in heart failure.

Discussion

Emotional fainting might be mediated in a simple fashion from the central nervous system via the efferent vasomotor nerves, causing vasodilatation in muscle vessels. If this were so, there is no reason why subjects with heart failure should not faint; indeed, many of those with a low cardiac output might well develop hypotension more easily than normal subjects. So simple a mechanism, therefore, does not cover all the facts. The most attractive explanation at the present time is that there is an afferent pathway for this reflex fired from the heart itself and that diminution of the amount of blood and virtually complete emptying of a ventricular chamber during systole is the stimulus. (With a failing circulation ordinary procedures are unlikely to empty the heart completely and the faint reflex, therefore, is not brought into play.)

The results presented in this paper suggest that there are two ways in which emotion may tend to empty the heart in normal subjects. The first is by nervous stimulation of the contraction of the heart, initially increasing the stroke output; the second is reduction of filling pressure, possibly due to venodilatation in the splanchnic area. Stimulation of the contraction of the heart simultaneously with decreased filling pressure has been studied by Henry and Gauer (1950) in dogs. Following reduction in cardiac filling pressure by bleeding, they gave adrenaline and were able to show that large pressure transients developed during systole in the cavity of the left ventricle when that chamber was virtually emptied of blood. Such large transients might well stimulate receptors which are known to exist in cardiac muscle. It is suggested, therefore, that the effect of emotion is indirect, first causing a diminution of the amount of blood in the heart. Then impulses pass from the heart to the central nervous system. Thence the reflex is mediated via the efferent vasomotor nerves, causing vasodilatation of muscle vessels.

There are other events which support this theory. Recovery occurs in a very few seconds when the filling pressure of the heart is raised by tipping into the supine position (Fig. 2). Continuous records, too, may show conspicuous fluctuations of arterial pressure with respiration during the initial phases of fainting which suggest that reflex vasodilatation is occurring intermittently with small changes in filling pressure. Finally, there seems to be some truth in the popular belief that fainting may be prevented by "taking a grip of oneself," since muscular tensing, or movement, can cause the low arterial pressure to rise (Brigden *et al.*, 1950), presumably by increasing the amount of blood in the heart above the critical level. This last mechanism may explain the recovery that took place in some dental patients when nitrous oxide was given.

Effects of Forced Maintenance of an Upright Posture

Normally a person who faints falls to the ground and arterial pressure is restored in a few seconds. In the dental chair or the ejection seat of a jet aircraft the upright sitting posture is forcibly maintained, and arterial pressure can remain for many minutes below 40 mm. Hg at heart level. Of these two similar situations, the latter is clearly more dangerous. There is some evidence from pilots who have recovered and landed safely that a number of mechanisms may cause syncope. Fear and nausea, hyperventilation, coughing, and the Valsalva manoeuvre have been described, while heat at over Mach 1 and the immobile sitting posture are additional factors. Of these mechanisms, fear and nausea might produce the longest period of hypotension, for, provided no mechanical disaster occurred to the aircraft, baroreceptor constriction should restore consciousness in about 10 seconds in the others. A pressure suit is a complete answer to all these mechanisms, the difficulty being to blow it up when it is needed.

The dental chair is a simpler problem. Unfortunately our observations showed that the dental surgeon and anaesthetist did not recognize that severe hypotension was present and were apt to call this state "a nice quiet gas." They were clearly prepared to go on extracting teeth under relatively good conditions. Dental surgeons seem to be unwilling to extract teeth in the supine posture. They claim that their instruments are unsuitable, but it is more probable that they fear legal action should teeth or the effects of aspirated blood clot appear on an x-ray film of the chest. It is unlikely that the complete answer—extraction in the prone position—will be popular. At second best, patients might be pulled out of the chair on to their faces, on the floor, when palpation of the pulse suggests that severe hypotension is present.

Summary

Continuous circulatory measurements were made before and during N₂O anaesthesia for tooth extraction and the administration of apomorphine for chronic alcoholism. Five out of 21 dental patients developed acute hypotension with vasodilatation of forearm vessels, four of these before the anaesthetic was given. Fear appeared to be the main cause, with a fall in arterial oxygen saturation as a possible minor factor. Apomorphine-induced nausea caused a fall in the effective filling pressure of the heart which preceded hypotension and syncope.

It is suggested that emotional stimulation of the heart beat and a fall in cardiac filling pressure cause virtual emptying of a ventricular chamber during systole which fires the afferent mechanism of the faint reflex. There is strong evidence that subjects with heart failure, whose ventricles are not easily emptied, do not faint.

We are indebted to the anaesthetists and dental surgeons of St. Thomas's Hospital for their collaboration.

SEX HORMONES AND MAMMARY CANCER

EXPERIENCE WITH DURABOLIN

BY

J. TH. VAN DER WERFF, M.D.

Radiotherapist, St. Canisius-Ziekenhuis, Nijmegen, Holland

Whilst the effect of hormones on the growth of cancer cells in general is still completely unknown, some relationship between sex hormones and cancer of the breast seems highly probable—a relationship that clearly is exceedingly complex. This is at once evident from the various ways in which a patient suffering from mammary cancer may react to sex hormone therapy. Ira T. Nathanson (1949) said: "The point which comes to my mind is that we may have two people of the same age, with the same tumour histologically, with the same physiologic characteristics, with the same mode of spread, who, to all intents and purposes, are metabolically identical; we give them hormones of the same kind, from the same bottle, on the same day; but one patient goes on to death in a short period of time and the other patient has a nice regression and goes on for a year and a half or two years before death."

The fact that of two mammary carcinomas of the same histological structure the one metastasizes in an entirely different way from the other suggests the existence of different kinds of breast cancer. The above-mentioned statement concerning the experience that in spite of similar structure and metastases a different reaction to hormone therapy may occur shows that apparently there are various differences in the nature of these carcinomas which so far we have been unable to distinguish clearly by other means.

Statistics on the incidence of breast cancer in various age groups all show a kind of maximum in the climacteric, followed by a minimum and then a renewed increase. Pirquet (1930) inferred from this that there are two kinds of cancers (1930) inferred from this that there are two kinds of cancers—genital cancers and age cancers. I have recently (van der Werff, 1956) come to a somewhat different conclusion—that is, that two groups of breast cancer exist side by side: (1) oestrogen-dependent cancers which are stimulated by ovarian activity and can develop only in the reproductive period; and (2) age cancers which are independent of this period; and the disposition for which increases regularly with age (Fig. 1). This hypothesis explains why

FIG. 1.—Total chance of contracting mammary cancer, being the sum of the chances of age cancer and oestrogen cancer.

in some of the patients in the reproductive period oestrogen therapy results in a rapid exacerbation. In the menopause this seems to be not so, and sometimes oestrogens even have a favourable therapeutic effect.

As regards the androgens, they seldom seem to cause a rapid exacerbation, but have mostly either a clearly favourable, though merely palliative,

effect or none at all. The favourable response is seen mainly after administration of the most commonly used androgen, testosterone propionate, to patients with bone metastases.

Consequently, whereas it may be said of oestrogens that, according to the nature of the cancer, they have a positive, a negative, or no immediate effect on the growth of the tumour, it is far less clear whether androgens in certain cases can have a direct inhibitory effect on tumour growth or whether there is an indirect inhibition by means of the protein- and calcium-sparing action of these hormones, connected with stimulation of the general defence reaction.

However, in recent years it has become clear that, after prolonged administration and even in cases which originally showed a favourable response, androgens also in the end may stimulate tumour growth. This escapes observation because the impression is gained that the preparation has ceased to have effect.

Conversion of Steroids

In fact, according to recent research, the body is capable of gradually and to an increased extent converting certain androgens into oestrogens. This has long been suspected, not only from the similarity in structure of the oestrogenic and androgenic steroids but also from the fact that androgen therapy produced an increase in oestrogen excretion. While at first one might think of another process in which the production of oestrogens could be the result of stimulation by the administered androgens, recently more direct evidence has been obtained of a biological conversion of C19 steroids into C18 steroids by making use of radioactive ¹⁴C. For example, incubation of human ovarian tissue and testicular tissue from stallions with testosterone-4-¹⁴C resulted in the formation of oestradiol-17β-¹⁴C. Intravenous administration of the same labelled androgen to a pregnant mare gave rise to excretion of oestrone-¹⁴C. Finally the direct conversion of Δ⁴-androstene, 3,17-dione-¹⁴C into oestrogenic hormone could be demonstrated, for example, in the ovary, placenta, and adrenal (Meyer, 1955; Dorfman, 1956). It is clear, therefore, that for prolonged administration a steroid is needed which does not show this conversion and yet possesses the favourable properties of the androgens used for the treatment of mammary carcinoma. As already stated, it is not really known in precisely what way the androgen can favourably influence the carcinoma, but if we consider testosterone propionate we can say that the following properties are useful: (1) a pronounced protein-sparing effect; (2) an inhibitory effect on the decalcification process caused by the bone metastases and as a result a reduction in calcium excretion; and (3) an analgesic effect due to the action mentioned under (2). On the other hand, testosterone propionate has certain less desirable properties, the principal one being the virilizing action which becomes manifest in deepening of the voice and in beard growth.

Properties of Durabolin

Apparently the new compound, norandrostenedione phenylpropionate ("durabolin") compares favourably as regards all these properties with testosterone propionate, the first but until now the most important hormone for use in mammary carcinoma (Overbeek and de Visser, 1957). In the first place it seems that conversion in the body into oestrogen is not so easy or is perhaps even impossible, so that there is a possibility that far more prolonged administration is necessary (Meyer, 1955). In addition it has an anabolic effect 12 times more powerful than testosterone propionate, and the calcium excretion in patients with bone metastases can be greatly reduced after administration, while the virilizing effect is far less pronounced. The duration of action is long, so that weekly injections of 25 mg. are sufficient. The preparation is well tolerated, and patients who show a favourable response often begin to feel much better, acquire a good appetite, and look well. Although apparently conversion into oestrogen cannot be the cause, it has

unfortunately been found that in the case of durabolin the action wears off. From a certain moment the responsive patients also are seen to go slowly downhill and finally succumb.

Now, it is a significant fact that hormone therapy is almost exclusively instituted at an advanced stage, when the usual therapeutic measures have been exhausted and the patients show recurrences or generalized metastases, in which cases total recovery is no longer possible. It is feasible, therefore, that hormone therapy might have a curative effect if surgical and radiological treatments are immediately combined with the hormone therapy; but, on the other hand, in that case it will be very difficult to prove that this hormone therapy has been the decisive factor in the complete recovery. Without hormone therapy approximately one-third of the patients treated for cancer of the breast recover. A follow-up of a very large number treated in this way might produce the required evidence only after many years.

Results with Durabolin

The following results were obtained with durabolin in patients suffering from breast cancer. This group included 13 patients with such marked generalized metastases that recovery could not be expected. Eight of these have meanwhile died. In eight other patients the metastases were not yet very pronounced but other conditions made the prognosis very bad, and durabolin was administered to improve this. All are still alive.

In practically all 21 patients considerable improvement in the general condition was observed during weekly administration of 25 mg. of durabolin. This became manifest in alleviation of pain which was sometimes very severe as a result of bone metastases, in a good appetite which led to a considerable weight-gain, and in a general sense of well-being. This satisfactory condition, however, is often in complete contrast to the radiological findings. Although occasionally some slight calcification in bone metastases is observed, this is usually not clearly marked, and, in spite of a seemingly good general condition, the bones prove to be in a deplorable state.

In contrast to testosterone propionate, the durabolin is well tolerated for many months and the unpleasant symptoms of virilization occur only sporadically. The most striking of these is the inability to sing. Van Dommelen (1956) noticed that the administration of a single large dose of durabolin gave rise to such a severe calcium retention in the bones that there was a grave risk of hypocalcaemia and tetany. This was not so in any of the 21 patients, though the blood calcium usually fell slightly. In a number of cases the alkaline phosphatase was determined regularly. Here also varying reactions were found. In responsive cases in which this level was raised it fell fairly soon and continued to vary around a value which often was still too high. In one patient durabolin had no effect and the alkaline phosphatase continued to rise. When finally ethinyl-oestradiol ("lynoral") was given, this level fell critically. The case is discussed below. This patient belonged to the group of 13 of whom it was known beforehand that they could not be saved and of whom eight have died. Some of them, however, showed a dramatic improvement which, though of a temporary nature, was quite unexpected. Two of these cases are discussed in detail.

Case 1

A woman aged 43 had an operation in June, 1953, for carcinoma of the left breast and post-operative irradiation. In November she complained of "rheumatism" and stayed in bed for two months. Her doctor then treated her with testosterone phenylpropionate, and in March, 1954, she felt well and had gained 10 kg. in weight. However, gradually "shooting pains" began to occur again, and on January 1, 1955, having already given radiotherapy to the patient, I was called in for consultation and found her in a deplorable condition. She was suffering excruciating pains as a result

of generalized bone metastases and vomited after administration of morphine or other potent analgesics. The vomiting could be stopped immediately by injections of chlorpromazine. The pain could then be relieved with analgesics and the patient could again take food, after which the general condition improved. This improvement continued for a considerable time, but in July she was again in a hopeless condition. There were widespread metastases throughout the skeletal system.

In August durabolin therapy was instituted, first 25 mg. in a fortnight, then 25 mg. weekly, and still later 50 mg. a week. In September she was already feeling much better. The pain had gone and morphine was no longer needed. There was only a certain feeling of stiffness in the back, which was not surprising considering that the skeletal system was riddled with metastases. The alkaline phosphatase level fell from 39 King-Armstrong units in September, 1955, to 19 in January, 1956, and then remained at that value. An increase in the durabolin dosage was of no avail (Fig. 2). In March, 1956, the pain suddenly became very severe again, and her condition gradually deteriorated. While about Christmas the patient had been so well that she could travel by train and stay with her relatives, she was now confined to bed, began to decline slowly, and died on July 21, 1956.

In the last few months durabolin was no longer tolerated. Virilization symptoms caused by durabolin were present only in a very slight degree.

Case 2

A woman aged 41 noticed a lump in the right breast in January, 1955, but did not go to the doctor until March. when there was also a lump in the axilla. The condition was complicated by a three-months pregnancy. She had an immediate operation, followed by irradiation, but in July there were supraclavicular nodules on the other side. Premature birth was induced and a healthy child was born.

On August 5, five days after parturition, large masses of nodules were observed in the neck. The neck was very painful, owing to a metastasis in C 2. There were also skin metastases around the vulva. Radiotherapy was given to the neck. Early in September the neck was still very painful but the nodules had disappeared. Unfortunately a tumour could now be felt in the left breast. Durabolin therapy was instituted, 25 mg. weekly. By the end of September the general condition had greatly improved. Only the tumour in the left breast was still present, but it had not grown larger. Mobility of the neck was much better. On October 11 her general condition was very good and the tumour in the left breast stationary.

Her general condition continued to be good. She could again do light housework and even ride her bicycle. She

FIG. 3.—Case 2. Alkaline phosphatase during treatment with durabolin.

FIG. 2.—Case 1. Alkaline phosphatase during treatment with durabolin.

was troubled only by a repeatedly recurring erysipelas, which could be easily suppressed with sulphonamides and penicillin. In May, 1956, she was looking very well indeed and felt well. The tumour in the left breast was still present, but was smaller and mobile. An ablation now took place, which healed without difficulty. All this time the patient was given durabolin, one dose of 25 mg. a week. The alkaline phosphatase level, which in September, 1955, was 20 K.A. units, had fallen, and in December, 1956, it was normal (Fig. 3). Unfortunately in January, 1957, her condition began to worsen and ascites developed. Durabolin began to lose its effect, and in late February it seemed as if the end was near. In connexion with an article by Goldsbrough (1957) a course of chorionic gonadotrophin was given (500 units three times a week). It has been reported that the patient is beginning to improve once more. She was still alive in April, 1957.

Case 3

This case, referred to above, shows that sometimes durabolin has no effect at all.

In April, 1953, a woman aged 42 felt a strand with three small lumps in the right axilla. When in the course of that year the nodules grew larger she went to see her doctor, and after a biopsy specimen had been taken she had an operation. She had never felt anything in her breast. Post-operative radiotherapy was given and she remained in good condition till July, 1955, when she began to complain of pain in her back and lack of appetite. An x-ray picture showed a shadow in the right lung. The blood sugar was 50-94 mg./100 ml. In the evenings the temperature was subfebrile. After a few weeks' rest in bed her condition had slightly improved, but the subfebrile temperature remained.

FIG. 4.—Case 3. Alkaline phosphatase during treatment with durabolin and ethinyl-oestradiol.

temperature was subfebrile. After a few weeks' rest in bed her condition had slightly improved, but the subfebrile temperature remained.

Durabolin therapy was now instituted—first 25 mg. every fortnight, later every week. As a result the patient began to look better, but the pain in the back did not diminish. In January, 1956, this pain had increased. In an x-ray film the shadow in the right lung had gone, but there were now clear metastases in the ninth and tenth ribs. The temperature had gone up to 38.5° C. No metastases were observed in the vertebral column. An increase of the durabolin dosage to 50 mg. weekly produced no results.

As regards the alkaline phosphatase level, this had shown a continuous increase ever since October, 1955, till it reached the nearly 60 K.A. units in March, 1956. In addition to the durabolin, 0.05 mg. of ethinyl-oestradiol was now given daily. It is remarkable that the alkaline phosphatase then fell to 17 K.A. units (Fig. 4). However, the pain in the back remained and the patient's condition deteriorated rapidly. Skin metastases began to develop also, and she died in May, 1956.

Comment

The three cases described here, and also the other 10 with marked metastases, show that in such cases we cannot expect a cure with durabolin, but, with the exception of a

single case, mentioned above, durabolin temporarily had an excellent effect. In one case calcification was observed in some of the metastases, as is sometimes seen after administration of testosterone propionate. Virilization symptoms were practically absent, and in no case did they bring inconvenience. Whether it is possible by means of durabolin to suppress metastases right at the beginning is, as already stated, obviously very hard to prove.

All eight patients who had no marked metastases but who gave cause for anxiety—for example, because the carcinoma was present during pregnancy or because they complained of vague and varying "rheumatic" pains—showed an excellent response and at the time of writing were free from cancer symptoms. All things considered, durabolin may justifiably be regarded as a valuable aid in the struggle against mammary carcinoma and as a preparation with clear advantages over testosterone propionate, the palliative value of which is established.

Summary

After a discussion on the effect of certain hormones used so far in the treatment of mammary carcinoma, including the new preparation durabolin (norandrostolone phenylpropionate), some clinical results obtained with this preparation are reported.

It has been found that durabolin is usually a powerful and long-acting palliative which, owing to its very slight virilizing action, is a real asset in this treatment.

ANTIBIOTICS IN ACUTE TONSILLITIS AND ACUTE OTITIS MEDIA

BY

JOHN FRY, M.D., F.R.C.S.

General Practitioner, Beckenham, Kent

Antibiotics are absolutely necessary in the treatment of serious bacterial infections. It is questionable, however, whether these expensive and potentially dangerous drugs are really necessary to treat all the much more frequent infections of the respiratory tract that abound in general practice. When and how should antibiotics be used for these common and relatively minor infections? Opinions differ greatly on the needs and indications, but apart from "opinions" there have been no planned studies into the matter.

This paper is an attempt to assess in a general practice the proportions of patients suffering from two readily definable and very common respiratory infections—namely, acute tonsillitis and acute otitis media—who required antibiotics in order to achieve satisfactory results, and at the same time the proportions who recovered equally well on non-specific treatment.

Methods

In carrying out this investigation the patients' interests were always of the first importance and no risk was taken or sacrifice made for the sake of the experiment. In any case of doubt the specific antibiotics were used, but where possible the aims were to withhold the antibiotics for 24 to 48 hours unless there were certain definite indications.

connected directly to the endotracheal tube. The bellows was compressed at a rate of 16 times a minute and each stroke delivered a tidal volume of 2 litres of air, as calculated from the known volume of the bellows. It was not possible to measure the actual volume of air expired from the subject, neither were any samples taken for carbon dioxide analysis, as there was no rebreathing.

This method of resuscitation was also used for ventilating a further series (53) of patients undergoing surgery under thiopentone and tubocurarine anaesthesia for 30 minutes and upwards.

Results

Manual Methods.—As measured by oximetry, the blood saturation in all these subjects remained above 90%. There was, however, a slight fall during the experiment in practically every case. The mean tidal volumes obtained by the Schafer and Holger Nielsen methods were 262 ml. and 575 ml. respectively (see Table).

Tidal Volumes			
Subject	Sex	Tidal Volumes (ml.)	
		Schafer	Holger Nielsen
1	M	230	580
2	F	300	900
3	M	200	450
4	F	350	500
5	F	240	450
6	F	170	320
7	F	350	750
8	F	360	800
9	F	170	590
10	F	250	410

Intermittent Positive-pressure Methods.—(1) With mouth-to-mouth respiration oximetric studies were undertaken on the first few patients in each group—that is, with and without the carbon dioxide absorber in the donor expired air circuit. As the oxygen saturation never dropped below 96%, oximetry was discontinued for the remainder of the experiments. The mean results of the carbon dioxide and oxygen concentrations of the expired air of the donor are shown in Fig. 3, and those of the recipient, with and without canister, in Fig. 4. With the canister the expired oxygen concentration of any patient did not fall below 14.15%, and the carbon dioxide did not rise above 5.7%. Without the canister the lowest expired oxygen concentration was 11.4%, and the highest carbon dioxide concentration 6.4%. (2) With the bellows resuscitator oximetry showed that no change occurred in the blood oxygen saturation of the eight subjects during the period of ventilation, and clinically there was no deterioration in their condition.

In the larger series ventilated by the bellows during surgery it was in no case possible to distinguish their clinical condition from that obtained with an ordinary, controlled respiration, anaesthetic technique.

Discussion

In this investigation all four forms of artificial respiration were found to be adequate for maintaining oxygenation of the anaesthetized, curarized subject under ideal conditions, but, whereas there was a slight fall-off in oxygen saturation with manual methods in five minutes, no such fall occurred with either form of positive-pressure resuscitation in 30 minutes. This suggests that the tidal volumes obtained with the manual methods were not completely satisfactory, as was in fact confirmed by the experimental measurements. No such deficiency could be attributed to intermittent positive-pressure artificial respiration, where the limiting factor in mouth-to-mouth ventilation was simply the vital capacity of the donor, and that with the resuscitator the 3-litre capacity of the bellows, both these volumes being considerably in excess of the requirements of any subject. Therefore, in an emergency, when conditions are not ideal, positive pressure would be more effective. Moreover, the pressure differential obtainable with mouth-to-mouth respiration, or with the resuscitator, enables better ventilation in the presence of respiratory obstruction, such as bronchospasm.

It has been argued, with little if any evidence, that positive-pressure ventilation inflates the stomach to the detriment of the lungs. There is evidence that this is not so at pressures up to 20 cm. of water (Mushin and Morton, 1958). Even if it were, a state of equilibrium would ultimately be reached in which both the lungs and the stomach would be ventilated. Positive-pressure respiration has also been criticized on the grounds of impairment of the venous return to the heart, but if the respiratory pressure is dropped to zero in between each breath venous return is not impeded, as judged by the absence of any change in mean venous pressure. The essential feature of any form of resuscitation is that the blood reaching the left side of the heart should be well oxygenated, even if the amount is a little reduced.

In the two methods of intermittent positive-pressure respiration used in this investigation there was found to be little difference if the carbon dioxide canister was included in the donor line of the mouth-to-mouth apparatus. When normal expired air was used the patients showed the typical clinical picture of respiratory acidosis under anaesthesia—namely, a flushed skin and a raised pulse rate and blood pressure—and needed an increased amount of barbiturate to maintain the same level of anaesthesia. Such a state has been shown by several authors to predispose to shock (Beecher and Murphy, 1950; Lucas and Milne, 1955). With a canister this form of resuscitation is satisfactory, but, in practice, any suitable canister would soon become exhausted and so replacements would have to be an integral part of the equipment. Apart from aesthetic considerations, an overall disadvantage of mouth-to-mouth ventilation is that there is a tendency on the part of the donor to overventilate, which must ultimately produce fatigue. The bellows resuscitator, on the other hand, has been shown to be entirely satisfactory: there are no components which have to be exchanged, fresh atmospheric air is used for each breath, there is minimal fatigue, and the complete apparatus is extremely simple.

Summary

The relative merits of manual and intermittent positive-pressure artificial respiration have been investi-

FIG. 3.—Mean carbon dioxide and oxygen concentration of expired air of donor.

FIG. 4.—Mean carbon dioxide and oxygen concentration of expired air of recipient (with and without canister).

gated in the unconscious, curarized subject. The Schafer and Holger Nielsen methods have been compared with mouth-to-mouth ventilation and a simple bellows resuscitator.

Manual methods have the advantage of requiring no apparatus, but they do require space. They are not so efficient for the oxygenation of the subject and may be relatively ineffective in the presence of bronchoconstriction.

Intermittent positive-pressure methods require apparatus, but are superior in terms of ventilation and oxygenation. The bellows resuscitator, a simple, compact apparatus, was still more efficient than the mouth-to-mouth apparatus.

The bellows resuscitator used in this investigation was designed and supplied by the Chemical Defence Experimental Establishment, Porton, Salisbury.

CLINICAL EVALUATION OF "MIRADON"

BY

GAVIN KELLAWAY,* M.B., M.R.C.P., M.R.C.P.Ed.
Registrar, Department of Cardiology,
Royal Infirmary, Edinburgh

The value of anticoagulants in the treatment of certain thrombo-embolic conditions is now well established. Since the introduction of dicoumarol about 17 years ago (Butt *et al.*, 1941; Wright and Prandoni, 1942; Overman *et al.*, 1942), a number of hydroxycoumarin and indanedione derivatives, causing depression of the prothrombin activity of blood, have become available for use as anticoagulants. In addition to dicoumarol, these include ethyl biscoumacetate ("tromexan") (Tulloch and Gilchrist, 1951; Burke and Wright, 1951), phenindione ("dindevan") (Jaques *et al.*, 1950), phenylpropylidene ("marcoumar") (Bourgain *et al.*, 1954), cyclocoumarol ("cumopyran") (Hanson *et al.*, 1951), and, more recently, warfarin (Clatanoff *et al.*, 1954) and nicoumalone ("sintrom") (Weiner *et al.*, 1956). They all suffer the disadvantage of being potentially dangerous and require frequent estimations of the prothrombin time for their control. As yet, however, they remain the best available drugs for treatment where prolongation of the prothrombin time is desired.

The purpose of this paper is to report the clinical trial of a new anticoagulant, 2-p-anisyl indanedione—1,3(C₁₆H₁₂O₃), called "miradon" (anisindione). It appears to be more rapidly effective than and just as readily controlled as any anticoagulant in current use.

Material and Methods

Miradon has previously been tested in animals (P. L. Perlman and P. C. Giordano, unpublished work) without evidence of toxicity. It has the following chemical structure.

*Now at Green Lane Hospital, Auckland, New Zealand.
D

Like phenindione, to which it is chemically related, miradon exercises its therapeutic action by depression of the prothrombin activity of the blood. In the presence of alkaline urine an orange colour is often detected, the result of katabolites of miradon.

Miradon was supplied in 50-mg. tablets for oral use, and the clinical trial was divided into three parts.

Part I.—A loading dose of 300 mg. was given to 12 healthy subjects, and the onset, rate, degree, and duration of prothrombin activity depression were recorded. None of these patients required anticoagulant therapy and all were free from known renal or hepatic disease. Estimations of the prothrombin time were performed according to the Quick one-stage method (Quick, 1942), using a phenol-saline preparation from human brain as a source of thromboplastin. Each batch of thromboplastin was diluted to obtain prothrombin % activation curves, and the results presented here are given as prothrombin % activity. The normal control using this method varied from 11 to 14 seconds. Prothrombin activity of 10 to 20% was regarded as a satisfactory therapeutic range; this corresponds approximately to two to three times the normal plasma prothrombin time. Prothrombin activation curves were obtained for each patient.

Part II.—This constituted a therapeutic trial in 25 patients in whom anticoagulant therapy was thought to be necessary. These patients comprised 25 consecutive admissions who would otherwise have received therapy with another anticoagulant. Of these patients, 20 were suffering from a recent myocardial infarct, two from acute coronary insufficiency of increasing severity, two from deep venous thromboses of the legs (one of these had also suffered a pulmonary infarct), and one patient was given anticoagulant therapy while he received treatment to convert auricular fibrillation to normal rhythm. The aim in treatment was to maintain the prothrombin activity between 10 and 20%, and the dose for patients was ordered each day by the one observer. Estimations of the prothrombin time were performed before treatment began, 24 hours later, and thereafter daily between 9 and 10 a.m. for the first two weeks and for two out of every three days thereafter until treatment had been completed. During the course of this trial, random 24-hour periods were studied more closely to observe variations in prothrombin activity. The initial dose was 300 mg., except in three patients suffering from myocardial infarction in whom cardiac failure was present. (In these patients the initial dose given was 250 mg.) After 24 hours a further dose of 100 mg. was given, and thereafter the single daily dose depended upon the prothrombin times.

Part III.—The effect of oral vitamin K₁ on the prothrombin time was observed in a number of patients in whom "therapeutic levels" had been maintained for at least three days. The effect of vitamin K₁ was assessed further by the simultaneous oral administration of 20 mg. together with 300 mg. of miradon.

Results

Part I

In 11 of the 12 subjects given 300 mg. of miradon orally there was an effect upon the prothrombin time within six

TABLE I.—Effect of a Loading Dose of 300 mg. of Miradon

Subject	Duration of Effect (Hours)	Prothrombin % Activity at Start	Prothrombin Activity Less than 25% (Hours)	Maximum Effect	
				Prothrombin %	Time (Hours)
1	6-64	40	24-52	12	34
2	8-106	50	26-58	17	50
3	4-58	100	—	30	26
4	6-58	60	26-38	17	34
5	6-96	40	20-52	14	28
6	6-72	40	26-38	17	34

11	6-58	80	—	30	30
12	6-52	100	—	28	26

hours (Table I). In one subject no effect was evident before eight hours, while in another prolongation of the prothrombin time occurred within four hours. After a sharp fall in prothrombin activity to the region of 50 to 70% of the original level there was a slower decrease over the ensuing 4 to 10 hours, followed again by a steeper fall to the maximum effect, which was present between 20 and 50 hours (average 34 hours). The average duration of effect was from 6 to 70 hours, with an overall range of 4 to 106 hours. Seven of the 12 subjects were within the average range. Typical prothrombin activation curves are illustrated in the Chart. The trial dose was sufficient to produce the desired therapeutic level of 10 to 20% prothrombin activity in 8 of the 12 subjects, while in the other 4 the lowest level produced was between 21 and 30%.

Effect of 300 mg. of miradon upon prothrombin activity in four subjects.

By way of comparison, 12 similar subjects were given 200 mg. of phenindione. The average duration of effect was from 10 to 60 hours, with an overall range of 8 to 100 hours. Eight of the 12 subjects were within the average range, while the average maximum effect occurred at 30 hours. In these subjects the lowest level of prothrombin activity produced by this loading dose varied from 16 to 49%. This may be compared with the range of 12 to 30% observed above with miradon.

Part II

A satisfactory therapeutic effect upon the prothrombin activity was obtained in all patients (Table II). The prothrombin activity was within the therapeutic range (10-20%) within 24 hours of the initial dose in 16 of the 25 patients. When these results are combined with those obtained in

Part I, 56% of the 37 subjects had prothrombin activity within the therapeutic range at 24 hours, and a further 30% had a prothrombin activity between 21 and 24% (Table III). After the first 24 hours, 86% of the 472 estimations of the prothrombin time performed were within the therapeutic range, 7% were narrowly outside this range (21-24%), and only 2% occurred in the 25 to 30% group. There were no estimations showing less satisfactory control than this, and, of the 5% recorded as having a prothrombin activity of less than 10%, the most prolonged prothrombin time was one of 62 seconds at a time when the control was 14 seconds.

The uniformity of prothrombin activity as a result of single daily doses of miradon was demonstrated by closer observation of random 24-hour periods in eight patients (Table IV). Little significant variation was evident throughout these periods.

Once therapeutic levels had been obtained, the daily maintenance dose varied from 25 to 350 mg. In two-thirds of the patients the variation between maximum and minimum doses required to maintain therapeutic levels was 100 mg. or less. The average maintenance dose was 100 mg. a day. One instance of mild resistance was noted in a patient in whom there was an initial satisfactory response to 300 mg. and subsequent doses of 100 mg. a day. It became necessary to increase the dose by stages to 350 mg. a day to maintain control. This patient was later treated with phenindione, to which he showed a more marked degree of resistance, and doses of 550 mg. daily were necessary to produce therapeutic levels. In the remaining 24 patients the maintenance dose varied from 25 to 250 mg.

The time taken for the prothrombin level to return to normal on discontinuation of therapy was observed in 10 of the 25 patients. In all instances at 24 hours the prothrombin activity was within 3% of the previous reading. At 32 hours the prothrombin time of two patients had returned to normal, and by 72 hours normal prothrombin times were recorded in all 10 patients.

Throughout these trials toxic side-effects were not observed, there were no haemorrhagic episodes, haematuria was not encountered, and in those patients in whom liver-function tests were performed prior to treatment no change was observed after therapy.

Part III

Vitamin K₁ given orally in doses of 20 mg. produced an appreciable response on the prothrombin time within four to six hours, and in six subjects normal levels were produced within 10 to 12 hours. Vitamin K₁ in 20-mg. doses given intravenously resulted in a fall to normal levels within four hours. A similar oral dose of vitamin K₁ given together with the loading dose of miradon resulted in an absence of subsequent hypoprothrombinaemia. Miradon was thus satisfactorily antagonized by vitamin K₁.

Discussion

In general, anticoagulants may be used therapeutically either in short courses of 14 to 28 days, as in deep venous thrombosis and recent myocardial infarction, or for more prolonged therapy in the prophylactic treatment of coronary thrombosis or embolic phenomena.

Ideally, anticoagulants must be free from toxic side-effects. In addition they should be readily metabolized and excreted. They should maintain the prothrombin time within therapeutic levels and without wide variations. In the event of spontaneous haemorrhage a rapid reversal of the anticoagulant action with vitamin K₁ is necessary. In these circumstances of increasing Health Service costs they should also be reasonably priced. In short-term therapy the requirements mentioned, a rapid, uniform, and predictable response to a standard dose is highly desirable. Equally important is the uniformity of prothrombin time response from day to day, so that any doctor unaccustomed to the daily regulation of anticoagulant dosage may not find control difficult.

The relative merits of the various hydroxycoumarin and indanedione anticoagulants have been fully discussed by previous workers (Brodie *et al.*, 1952; Scarrone *et al.*, 1952; Coon *et al.*, 1953; Weiner *et al.*, 1956; Prior, 1957). For long-term therapy the rapid production of therapeutic levels and early uniformity of response are not essential. Once the initial difficulties of stabilization, most anticoagulants prove satisfactory for this form of treatment. The longer-acting anticoagulants (phenylpropylhydroxycoumarin, warfarin, and cyclocoumarol) are suitable for prolonged prophylactic therapy, but the time taken to acquire therapeutic levels and the delay in returning to these levels when the control is unsatisfactory make them less desirable than the shorter-acting anticoagulants ethyl biscoumacetate and phenindione for short-term therapy.

Although ethyl biscoumacetate is very rapidly absorbed the considerable variation in dose required to produce therapeutic levels tends to offset this advantage (Weiner *et al.*, 1953; Vander Veer *et al.*, 1953). Coon *et al.* (1953) thus found that a greater percentage of patients treated with phenindione were within the therapeutic range at 24 hours than with ethyl biscoumacetate, despite its slower absorption. They found also that there was less difficulty in maintaining constant levels with phenindione, and these factors, coupled with the excessive cost of ethyl biscoumacetate, have led to the more general use of phenindione. As phenindione is, in our experience, the most satisfactory anticoagulant at present in use for short-term therapy it is important to compare this drug with miradon. With phenindione, therapeutic levels are obtained within 24 to 48 hours (Sise *et al.*, 1957), although in the majority of patients these levels take 32 to 48 hours to be produced (Blaustein *et al.*, 1950). Coon *et al.* (1953) found that 18% of their patients were controlled at the end of 24 hours, 70% at 36 hours, and 95% at 48 hours. Our own experience with phenindione is in agreement with this finding.

With miradon, 56% of patients were found to have prothrombin times in the desired range of 10 to 20% prothrombin activity within 24 hours, and 30% were narrowly outside this control. The average time taken for production of maximal effect with miradon and phenindione is very similar (miradon 34 hours, phenindione 30 hours), and for the numbers considered the difference is not significant. With miradon, however, there is a narrower range of response to the initial loading dose (prothrombin activity 13-30% compared with phenindione, 15-49%). As compared with phenindione, therefore, the response to a given dose of miradon is a little more predictable. This allows a larger initial dose to be used with safety and leads to a greater number of patients in whom therapeutic levels of prothrombin time are produced within 24 hours. In addition, in the majority of patients, miradon produces some effect upon the prothrombin time within six hours, compared with 10 hours taken by phenindione. Control from

day to day appears very satisfactory with miradon, and only 14% of the estimations in this trial were not within the desired range. Our own experience with phenindione is very similar, and 15% of estimations have been found to be outside this control.

Sise *et al.* (1957) found on stopping phenindione that the prothrombin time of their patients returned to normal levels in 36 to 72 hours in the majority of patients. Miradon was found to take a similar period of time, and, as with phenindione (Guttas *et al.*, 1953), there was a rapid response to vitamin K₁.

It appears, therefore, that miradon has certain advantages over phenindione in the speed and predictability of initial response and subsequent rapidity with which therapeutic levels can be obtained. It is apparently just as readily managed from day to day, and has the advantage that a single dose produces striking uniformity of response, while most workers consider that phenindione requires to be given in divided daily doses to produce satisfactory uniformity of response (Blaustein *et al.*, 1950).

Summary

A new anticoagulant, miradon, has been assessed clinically and used therapeutically in the treatment of 25 patients requiring anticoagulant therapy.

The initial response to a loading dose of 300 mg. was rapid and some effect upon prothrombin time was evident in most subjects in six hours. Over 50% of patients had prothrombin levels within the desired therapeutic limits (prothrombin activity of 10 to 20%) at 24 hours, and 86% of subsequent estimations of the prothrombin time were within similar limits. Normal prothrombin levels were recorded between 36 and 72 hours after cessation of treatment and a very even response was evident during therapy. Vitamin K₁ produced a rapid reversal of anticoagulant action.

Compared with other anticoagulants miradon appears to approach more closely to the "ideals" for a short-term anticoagulant than other preparations at present in common use. The uniformity of response to a single daily dose suggests that it would prove satisfactory also in long-term therapy.

I thank Dr. A. Rae Gilchrist for his help and advice in conducting this trial, and Dr. C. P. Stewart for the laboratory facilities which he made available. I also thank Dr. R. M. Marquis and Dr. M. F. Oliver for criticism in preparing this paper. Miradon was generously supplied by Schering Corporation, who also provided an expense grant.

CLINICAL EXPERIENCE WITH
WARFARIN SODIUM

BY

M. TOOHEY, M.D., M.R.C.P., D.C.H.
Physician, New End Hospital, London

Several reports (Shapiro, 1953; Wolff *et al.*, 1953; Pollock, 1955) are now available on the use of the anti-coagulant warfarin sodium ("coumadin" sodium), and all are very favourable. Indeed, it has been stated that warfarin sodium is the "anticoagulant of choice" (Shapiro, 1956). This paper records the results of using warfarin sodium in 175 patients, most of whom had cardiovascular disease (myocardial infarction or cardiac failure) and the remainder phlebothrombosis and pulmonary embolism. Treatment was controlled by the simultaneous use of Quick's and Owren's "P and P" methods. A therapeutic level of between two and three times the normal control time (ideally two and a half times) was maintained when assessing results by Quick's method. For Owren's technique a level of between 10 and 14% was aimed at. This percentage prothrombin concentration is lower than that advised by Owren—10 to 30%—but I believe that a lower proportion than 30% is desirable, as I have seen fresh thrombo-embolic episodes develop between levels of 20 and 30%.

The same thromboplastin was used for both Quick's and Owren's methods—that is, a saline extraction of human brain stored at -20°C ., where it keeps stable indefinitely. The Quick prothrombin time with pooled plasma from normal controls was 11 to 12 seconds with this thromboplastin.

Initial Dosage

Warfarin sodium is a unique coumarin compound in that it can be given intravenously as well as by mouth. The initial dose was given intravenously to 32 patients and orally to 143. No appreciable difference in rapidity of action was noted between the intravenous and the oral administration; therefore, except for exceptional circumstances—for example, persistent vomiting—the oral route was preferable. The usually recommended initial dose of 60 to 75 mg. was given to the first 42 patients treated. This dose, however, in nearly all instances led to a pronounced rise in the prothrombin time to above the upper limit (three times the normal control time) for therapeutic control. Small doses of vitamin K₁ had to be given to six patients to bring the prothrombin time down to a safe level. For the remaining 133 patients the initial dose was therefore sharply reduced to between 35 and 50 mg., and the latter dose was never exceeded. With these lower doses the results were much more satisfactory and made the whole control of the treatment much easier.

If too big an initial dose of most coumarin-type anti-coagulants is given the peak effect of the drug may be delayed for several days and a sustained effect will still be present for many days thereafter, during which time no further dose of the anticoagulant must be given. This sustained effect is obtained even with the shorter-acting drugs such as warfarin sodium and phenindione, because to some extent sustained action depends on dosage; the larger the dose the longer the effect. If too big an initial dose is given, with the resultant marked sustained effect, it takes much longer to arrive at the correct daily maintenance dose necessary to maintain a steady prothrombin time. By keeping the initial dose to the minimum effective amount, the first maintenance dose can usually be given on the third day of treatment (about 36 to 48 hours after starting therapy). Also, by avoiding the pronounced sustained effect of too large an initial dose, the early maintenance doses will give a good

approximate indication of the correct subsequent doses necessary to maintain a steady prothrombin level throughout the course of anticoagulant treatment.

Very satisfactory results were obtained with the following initial dosages of warfarin sodium: doses of 35–40 mg. were never exceeded for patients over the age of 75 years; doses of 42–50 mg. were given to all patients under 75 years. The smaller doses were given to the frailer and more seriously ill patients. An initial dose of more than 50 mg. is not advised.

The first prothrombin time was taken routinely on the morning of the third day after starting treatment (usually 36 hours after the initial dose), by which time the maximum effect of the initial dose was apparent in most patients.

Rapidly and Duration of Action

With initial doses of 35 to 50 mg. a therapeutic prothrombin time was reached in 36 hours in 95% of cases, whilst a noticeable effect on the prothrombin time was achieved in about 18 hours in most instances. The effect of daily maintenance doses of a size sufficient to maintain an adequate therapeutic level usually lasts for 36 hours. If large doses of warfarin are given, however, there is a pronounced sustained effect and the prothrombin times may remain high for much longer than 36 hours, and often for three to four days.

Warfarin sodium is therefore a rapidly acting drug with a moderately short-lasting action if large doses are avoided. In rapidity of action and duration of effect it is remarkably similar to phenindione and can be classed with that drug as a short-acting anticoagulant, in contrast to the long-acting drugs such as diphenadione ("dipaxin"), dicoumarol, and phenylpropylhydroxycoumarin ("marcoumar"). However, if large doses are given it has a much more pronounced sustained effect than phenindione.

Maintenance Therapy

It was possible to arrive at a very accurate assessment of the daily maintenance dose of warfarin sodium (to within 3 to 5%) in 158 patients (see Table). The average daily maintenance dose for all patients was 9 mg. In 68% the maintenance dose was between 5 and 12 mg., and in only 20% was the maintenance dose outside the range of 5 to 15 mg.

Dose	No. of Patients
2 to 5 mg.	20
5 to 12 mg.	107
12 to 15 mg.	19
15+ mg.	12
Overall average = 9 mg.	

The first maintenance dose was usually given on the third day of treatment. The following scheme provided a good average indication of the first maintenance doses to be given:

Prothrombin time over 3 times the normal (or below 7% by Owren's method)	Nil
Prothrombin time $2\frac{1}{2}$ to 3 times the normal (7 to 9% by Owren's method)	3 to 5 mg.
Prothrombin time 2 to $2\frac{1}{2}$ times the normal (9 to 15% by Owren's method)	4.5 to 10.5 mg.
Prothrombin time $1\frac{1}{2}$ to 2 times the normal (15 to 20% by Owren's method)	10.5 to 15 mg.
Prothrombin time less than $1\frac{1}{2}$ times the normal (above 20% by Owren's method)	15 to 20 mg.

Warfarin sodium acts rapidly enough for any appreciable change in dosage to be quickly reflected in the prothrombin times. The great advantage of rapidly acting drugs, such as warfarin sodium and phenindione, over the long-acting drugs for the treatment of acute thrombo-embolic episodes is that rapid and large changes in dosage can be quickly made, with the result that the correct maintenance dose can be rapidly determined. In the first few days of anticoagulant

therapy, because of the great individual variation in response to all anticoagulant drugs, it is impossible to know whether the patient will need small or large maintenance doses. Regulation of dose has therefore to be by trial and error guided by the results of the blood tests. Thus it is a great advantage to use an anticoagulant whose action is rapid enough for any material change in dosage to be reflected in the prothrombin times the following day.

After the first few doses of maintenance therapy, and once the prothrombin time is in the required therapeutic range, it is rarely necessary to alter the daily maintenance dose of warfarin sodium by more than 1.5 to 2 mg. When the prothrombin time has been steady for three or four days it should be realized that a change in the daily dose of more than 0.5 mg. will lead after a few days to considerable fluctuations in the prothrombin times, owing to the cumulative effect of the drug. Once the approximate daily maintenance dose has been ascertained and the prothrombin times have been steady for three or four days, a good approximate guide to any further changes in the maintenance dose which may be necessary to maintain a steady unfluctuating prothrombin time is not to alter the amount of the dose by more than 5%.

To determine the appropriate small variations in dose at this stage, bearing in mind the cumulative effect of anticoagulants, it is essential not just to consider the effect of a single dose on the prothrombin time the following day. A much clearer picture of the exact daily maintenance requirements of any anticoagulant will be obtained if the treatment is assessed over, say, a three-day period. By taking such a three-day period the full cumulative effect of small changes in dosage in the region of 5 to 10% can be readily seen and the exact daily maintenance requirements easily ascertained with a minimum of blood tests.

Ease of Control

Warfarin sodium is a remarkably easy drug to control, as the response to a given dose can almost invariably be reliably predicted. In this trial 25-mg., 10-mg., 5-mg., and 3-mg. tablets were made available. The 25-mg. tablet was used for initial dosage and the 10-mg., 5-mg., and 3-mg. tablets for maintenance therapy. For the initial doses of 35 to 50 mg. maintenance therapy, the 25-mg. tablet is unnecessary. To prescribe small variations in dose of the order of 5% the strength of tablet available is, however, of great importance. Indeed, to-day, with several good anticoagulants available, what makes one anticoagulant much easier to control than another is often the ease and convenience with which very small variations in dose may be prescribed.

The overall average maintenance dose of warfarin sodium is about 9 mg. and a 5% variation of this amount about 0.5 mg. In assessing the exact daily requirements, as mentioned earlier, it is essential to take a three-day period so that the full cumulative effect of the drug on the prothrombin times can be taken into account. For warfarin sodium one-half of a 3-mg. tablet, more or less, each three-day period, would give the necessary 0.5-mg. variation a day. A tablet strength exceeding 3 mg. makes it much more difficult to prescribe small variations in dose. To cater for initial doses of 35 to 50 mg., and for those patients who need daily maintenance doses of 12 mg. or more, a second tablet of 5 to 6 mg. or so is necessary. With two such strengths of tablet (3 mg. and 5 mg.) accurate assessment of dosage can be quickly and easily made. For long-term therapy a tablet strength of approximately 3 mg. is essential.

Conclusions

Warfarin sodium was used in the treatment of 175 patients with thrombo-embolic diseases. It is a rapidly acting drug, and 95% of all patients reached a therapeutic prothrombin time in 36 hours. With daily doses of the drug just sufficient to maintain a therapeutic prothrombin time the duration of action is approximately 36 hours. However, in large doses warfarin sodium has

a very sustained effect, with a duration of action up to four to five days. It is important, therefore, to avoid large doses. The usually recommended initial dose of 60 to 75 mg. proved far too much in this series; 35 to 50-mg. doses proved perfectly adequate for initial therapy, and it is inadvisable to exceed 50 mg. as an initial dose. The overall average maintenance dose was 9 mg., and 80% of all patients were maintained on daily doses between 5 and 15 mg.

Warfarin sodium proved extremely easy to control, and it probably ranks with phenindione as one of the two best anticoagulant drugs available for short-term therapy. Initial experience with warfarin sodium shows that it is also a very useful anticoagulant for long-term therapy. Great care must be taken in prescribing the anticoagulant to allow for the very definite cumulative effect of the drug. In this respect warfarin sodium resembles in its action that of phenylpropylhydroxycoumarin, which has proved a very reliable anticoagulant for long-term therapy.

To obtain the best results with warfarin sodium it is necessary to have available a strength of tablet with which to prescribe variations in dose of 0.5 mg. easily and quickly. It is considered that scored 3- and 5-mg. tablets would be ideal.

Thanks are due to Dr. Samuel M. Gordon, of Endo Laboratories Inc., New York, for his most helpful advice and for making available the various strengths of coumadin tablets which I have used, and also to Evans Medical Supplies Ltd. for supplying warfarin sodium ("marevan") in 3 mg. and 5 mg. strengths.

STAPHYLOCOCCUS AUREUS TYPE 80
AND HUMAN INFECTIONS IN UGANDA

BY

R. S. F. HENNESSEY, C.M.G., M.D., F.R.C.P.I.
Dip. Bact.

AND

R. A. MILES, A.M.I.L.T.

Wellcome Laboratories of Tropical Medicine, London

The differentiation of cultures of staphylococci by phage-typing has contributed notably towards an understanding of the epidemiology of staphylococcal disease. As well as being of value in tracing infections to particular sources, the method has provided useful information about the distribution and spread of strains of different phage types. Studies of strains isolated from healthy persons and hospital patients have shown that some phage types occur more frequently than others in certain environments, while an association between phage type and antibiotic resistance has been widely observed.

The high prevalence of antibiotic-resistant strains of phage group III in hospital infections is of special clinical interest (Blair and Carr, 1953; Rountree, 1953; Jackson, Dowling, and Lepper, 1954; Knight and Holzer, 1954). Again, some phage types seem to spread readily, while others are associated with infections possessing distinctive features. Examples of these tendencies are the recovery of type 52A strains from

hospital infections of newborn infants (Barber, Hayhoe, and Whitehead, 1949; Colbeck, 1949) and of type 71 strains from impetigo contagiosa (Spittlehouse, 1955; Parker, Tomlinson, and Williams, 1955; Barrow, 1955) and pemphigus neonatorum (Gillespie, Pope, and Simpson, 1957). Staphylococci of phage type 80 have recently been found in serious infections, often of an epidemic nature; this report is concerned with the relatively high incidence of such strains in a series of cultures from Uganda.

Infections caused by *Staphylococcus aureus* type 80 were first encountered in Australia in 1954 (Rountree and Freeman, 1955; Clarke, McGeoch, and Sippe, 1956). Strains of this type were lysed by a phage adapted from typing phage 52A, the adapted phage being designated typing phage 80. They have been isolated from an epidemic of furunculosis among hospital workers and from many outbreaks of neonatal infection in hospitals throughout Australia. Skin lesions were numerous and some infants developed pyothorax. Nearly all strains were penicillin-resistant and appeared to be of relatively high virulence.

Since 1955, type 80 strains have been identified in Europe. They have been observed in several extensive hospital outbreaks in Britain (Anderson and Williams, 1956). Ruys (1957) has remarked upon their prevalence in the Netherlands, where they have been recovered from a considerable proportion of infective conditions. As in Australia, the strains were generally penicillin-resistant, and Bijlmer (1957) recovered them from some fatal infections.

In view of the association of type 80 staphylococci with virulent infections in Australia and Europe, it was of interest to find that about 40% of 248 strains recently sent to us from East Africa belonged to this type. The strains had been recovered from pus and other specimens collected from patients at two hospitals in Uganda. The results of phage-typing and antibiotic sensitivity tests are given below.

Materials and Methods

Between November, 1955, and March, 1957, batches of staphylococci isolated at the Central Laboratory, Kampala, were sent to us at intervals of a few months for study of their lysogenic properties. These strains, which were unselected, came from routine cultures of material collected in the wards and out-patient departments of two general hospitals at Kampala; one (Mulago Hospital) served Africans and the other (Nakasero Hospital) served mainly Asians and Europeans. Strains were tested for coagulase production in tubes with 1/5 dilution of human plasma. Coagulase-positive strains were phage-typed by the method of Williams and Rippon (1952) and tested for antibiotic sensitivity on agar plates by means of "sentest" tablets.

Phage-typing

A total of 248 strains proved to be coagulase-positive. They all produced yellow pigment and were taken to be *Staph. aureus*. Table I gives the numbers of strains belonging to the various phage groups and to phage type 80 which were recovered from specimens received from each hospital.

TABLE I.—Phage-typing of Strains of *Staph. aureus* from Two Kampala Hospitals

	Group I		Group II	Group III	"Mixed" Groups				Total
	Type 80	Other			I-II	II-III	III-IV	Not Typable	
Mulago Hospital	73	23	13	22	19	1	1	9	161
Nakasero Hospital	25	16	12	22	2	0	0	10	87
Total	98	39	25	44	21	1	1	19	248
	40%	15%	10%	18%	8%	1%	1%	8%	100%

ing to the various phage groups and to phage type 80 which were recovered from specimens received from each hospital.

The proportions of type 80 strains derived from Mulago and Nakasero Hospitals were thus 73/161 (45%) and 25/87 (29%) respectively. Type 80 strains were by far the commonest single phage type in the whole series; as shown in the Chart, they were frequently recovered from all sources except "sundry specimens" (sputa, urines, blood cultures, swabs from the upper respiratory tract). They made up 45% of 103 strains from "deep" infections which included 80 abscesses (23 classed as "pyomyositis," 6 cases of osteomyelitis, and 4 of empyema); 48% of 29 strains from wounds, burns, and fractures; and 35% of 69 strains from miscellaneous pyogenic infections which could not be allocated to the "skin" or "deep" category on the clinical data.

The incidence of type 80 infections among patients of different races was 45% (73 out of 161) in Africans, 30% (10 out of 33) in Asians, and 28% (15 out of 54) in Europeans.

When type 80 strains were tested for lysogenicity, it was found that 9 out of the 98 strains released phage which lysed the remaining strains of this type. Except for these nine strains, no other type 80 strain yielded phage which could be detected on any of the indicator strains used. A non-typable strain released a phage which formed plaques on all type 80 strains; strains which were made lysogenic with this phage became resistant to typing phage 80.

Antibiotic Sensitivity

The results of tests for antibiotic sensitivity are given in Table II. The proportion of penicillin-resistant strains was highest among staphylococci of phage groups I (90%) and III (64%). Strains resistant to both penicillin and streptomycin were much more frequent in group I, where 41 strains (30%) belonged to this category.

TABLE II.—Sensitivity of 248 Strains of *Staph. aureus* to Antibiotics*

	No. of Strains	No. of Strains Resistant to						No. of Strains Sensitive to P S A T C E
		P	S	A	T	C	E	
Group I (Type 80)	98	95	30	3	3	0	0	3
Group II (Others)	39	28	15	0	0	0	0	10
Group III	25	2	0	0	0	0	0	23
"Mixed" groups	44	28	7	6	6	4	0	16
Not typable	23	3	0	0	0	0	0	20
Total	19	6	3	1	0	0	1	9
Total	248	162	55	10	9	4	1	81

* P = Penicillin. S = Streptomycin. A = Chlorotetracycline. T = Tetracycline. C = Chloramphenicol. E = Erythromycin.

Table II shows the extent of penicillin resistance in strains of each group and of type 80. Resistance to both penicillin and streptomycin was present in 28% (27 out of 98) of type 80 strains.

Discussion

Information about the phage types of staphylococci which are responsible for human infections in tropical Africa seems to be lacking. This series of strains from Uganda is of interest in that the predominant phage type (type 80) is one which has displayed marked pathogenicity in Australia and Europe. Type 80 strains made up 40% of the series, the remainder showing a wide range of differing lytic patterns. Among the staphylococci of phage group I, which

Medical Memoranda

Arteriovenous Fistula Following Blunt Trauma

Recently we had occasion to treat an arteriovenous fistula which seemingly resulted from a non-penetrating wound and had no features to suggest a congenital origin. A review of the modern literature failed to reveal a similar fistula following trauma by a blunt instrument which did not penetrate the tissues.

Post-traumatic arteriovenous fistulae and false aneurysms are a frequent complication of penetrating wounds in war. In civilian life congenital arteriovenous fistulae are often encountered, but an arteriovenous fistula or false aneurysm following a non-penetrating wound is a rarity. The case under discussion represents another form of aetiology of arteriovenous fistulae which is uncommon enough to be of interest to others.

CASE REPORT

A man aged 21 was referred because of a history that he had been struck on the left temple by a hockey ball. He was not rendered unconscious, but noted the immediate formation of a swelling at the area of impact, which in three to four hours' time had assumed the size of half a goose's egg. The skin was not broken nor was there any bleeding. On the evening of his injury he noticed a "buzzing" sensation just in front of the left ear. Within the next few days the swelling disappeared, but he continued to be aware of a whirring sensation in the area of trauma, noted when recumbent with the head turned so that the left side was down. It was only the persistence of this annoying buzzing in front of the ear for four months that led him to seek medical attention. Close questioning failed to disclose any history of previous penetrating injury in the left temple area or any skin lesion such as a capillary naevus or angioma.

On examination the pulse rate and volume were normal; blood pressure 130/80 mm. Hg. The significant physical findings were limited to the left temporal area, where there were several conspicuous subcutaneous veins anterior to the ear. Light palpation disclosed a systolic thrill, and on auscultation there was a continuous murmur with a crescendo in systole. Firm pressure upon the superficial temporal artery abolished the bruit; lighter pressure over the dilated veins caused marked engorgement of the veins of the scalp, and the bruit again disappeared. In view of the history and findings a diagnosis of post-traumatic arteriovenous fistula of the superficial temporal artery and vein was made, and at operation the superficial temporal artery and vein were exposed and found to have a fistulous communication. Accordingly a quadruple ligation was performed with excision of included vein, artery, and fistula. Recovery was uneventful and the patient has noted no further symptoms.

COMMENT

The pathogenesis of the fistula presents the point of major interest in this case. The patient absolutely denied any abnormal prominence of the veins of his temple, peculiar vibrations, or whirring prior to the traumatic episode. In fact, there was nothing to suggest that he might have had a small arteriovenous fistula which was enlarged by the blow. It seems most likely that the two vessels lying in close proximity must have been ruptured partially by the severe force, forming a communicating haematoma between them. A vascular channel subsequently developed and remained patent after resorption of the confined haematoma. Owing to the anatomy of the temporal region the haematoma was enclosed in a small space limited by the epicranial aponeurosis and its attachments to the zygomatic arch. There was little chance of dissection of the extravascular blood such as would be allowed in the areolar tissues surrounding vessels in most parts of the body.

outnumbered those of group III by more than 3 to 1, the proportion of type 80 strains was 72%.

Type 80 strains were associated with a variety of infective conditions, some of which may have been acquired in hospital. The proportion of type 80 strains among staphylococci recovered from different sources ranged from 32% (skin lesions) to 48% (wounds, burns, and fractures). There was no indication that type 80 infections occurred as part of a definite "outbreak"; between 20% and 60% of each of five batches of strains received over 17 months were of this type.

The high incidence of penicillin resistance among type 80 strains accords with experience elsewhere. These staphylococci, possessing a distinctive lytic pattern and a marked insensitivity to penicillin, seem to form a group of considerable pathogenic potentiality. From the lysogenic standpoint, the 98 strains classed as type 80 were not homogeneous, nine strains liberating a phage to which all the remaining type 80 strains were sensitive. It would appear that type 80 strains, like type 52A strains, possess properties which favour their growth and spread in man; further data relating to their prevalence among the patients and staff of hospitals in tropical Africa would be valuable.

Summary

Strains of *Staph. aureus* type 80 formed 40% of 248 cultures of coagulase-positive staphylococci recovered from patients suffering from various infective conditions in Uganda. Type 80 strains were by far the commonest phage type in this series, and nearly all (97%) were penicillin-resistant. Strains of this type appear to be responsible for serious infections; their prevalence among hospital workers deserves study.

We are indebted to Dr. A. B. Raper and Dr. E. C. Buck for strains of staphylococci, and to Dr. R. E. O. Williams and Dr. Joan E. Rippon for typing phages and helpful information.

Speaking at the conference of the National Society for Clean Air on October 1, the Minister of Housing and Local Government, Mr. HENRY BROOKE, said that on the industrial side we ought to see a substantial improvement within the next five years or so. The period allowed by the Clean Air Act for alterations to plant expired in the middle of 1963. During this time all the necessary improvements to the furnaces and boilers would have to be carried out—the fitting of mechanical stokers, and the provision of instruments for observing and checking smoke. There ought also to be a steady growth in the fitting of dust and grit arrestors to be a steady growth in the fitting of dust and grit arrestors to furnaces. In the processes which came under the Alkali Act there should also be improvements coming along by then. For instance, in the gas and electricity and pottery industries the process of shutting down older works would have gone yet a stage further; and it was the older works which so often were responsible for the most smoke.

Large haematomas are, of course, frequent after blunt trauma, and it is surprising that more arteriovenous fistulae do not develop. As stated above, a special anatomical situation must necessarily exist in which vessels rupture into a confined space. The open venous channel affords the line of least resistance for the blood under arterial pressure, rather than diffusion of the blood into the tissues such as normally occurs. If the vascular shunt is maintained the channel will gradually become organized and lined with endothelium, and an arteriovenous fistula will have been established.

I thank Professor Sir James Paterson Ross for allowing me to publish this case and for advice and help in the preparation of this paper.

PHILIP H. FRANDSEN, M.D.,
Clinical Research Assistant, Surgical Professorial Unit,
St. Bartholomew's Hospital.

Empyema Caused by *Pasteurella septica*

In the fatal case of empyema described below, *Pasteurella septica* was isolated both during life and after death. This organism is not infrequently isolated from the upper respiratory tract in man, but its importance as a pathogen is extremely difficult to assess. In Britain it has only twice been incriminated as the causal agent in infection of the respiratory tract—once in a case of sinusitis (Bartley and Hunter, 1947), and once as the cause of repeated exacerbations in a case of bronchiectasis (Cawson and Talbot, 1955). Elsewhere, cases of empyema caused by *P. septica* have been described, but only nine reports can be regarded as adequately substantiated by the bacteriological findings.

CASE REPORT

A 76-year-old woman was admitted to hospital on December 20, 1955, complaining of pain in the right hypochondrium and vomiting for three days. On examination she was dyspnoeic and pyrexial—99.2° F. (37.3° C.). Right subcostal tenderness and guarding were present, but there were no other abnormal findings. She had a remittent pyrexia for two days, and then developed grunting respirations and a rust-coloured sputum. Signs of a right lower-lobe pneumonia with pleural effusion were confirmed by x-ray examination. A blood count revealed a leucocytosis of 22,900/c.mm. Treatment with penicillin (crystalline) intramuscularly, 500,000 units six-hourly, produced temporary improvement, but after two more days signs of congestive cardiac failure developed. There now seemed to be an effusion only at the right base, and, in view of the continued deterioration, chest aspiration was performed. A small volume of blood-stained pus was withdrawn, which contained numerous polymorphonuclear leucocytes and minute Gram-negative coccobacilli. Culture yielded a heavy pure growth of *P. septica*. Penicillin was instilled into the loculus entered, and chlortetracycline was given orally, but in spite of all supportive therapy the patient became increasingly feeble, dying on January 16, 1956.

Necropsy Findings.—Necropsy was performed four hours after death. A fibrino-purulent pleurisy involved the lower lobe of the right lung. In the right costophrenic recess there was a collection of 50 ml. of thick yellow pus, walled off by dense fibrous tissue. No gross consolidation was detected in the lungs, but histological examination showed the right lower lobe to be the site of an organizing pneumonia. Other positive findings were confined to the kidneys, which were contracted and coarsely scarred, and the large intestine, which presented an appearance compatible with a uraemic colitis. Cerebrospinal fluid taken at necropsy gave a urea level of 322 mg./100 ml. A specimen of the empyema pus produced, as before, a heavy growth of *P. septica*. The organism was not recovered from material taken from the lungs, trachea, fauces, liver, spleen, heart blood, or cerebrospinal fluid, nor did Gram stains on all organs sectioned show any evidence of Gram-negative coccobacilli. The

final post-mortem diagnosis was "chronic pyelonephritis, pneumonia with empyema occurring as a terminal event."

Bacteriological Findings.—In films prepared from the empyema pus the organism was seen to be a coccobacillus measuring approximately 1.5 by 0.5 μ . Bipolar staining was easily demonstrable, but capsules were not seen. The organism was Gram-negative and non-acid-fast. Its cultural characteristics were typically those of *P. septica*. It grew easily on blood agar and on nutrient agar, but not at all on MacConkey's agar. Two notable features were a peculiar brownish discoloration produced on blood agar after 48–72 hours' incubation, and a semen-like odour given by cultures on this medium. Biochemical reactions were again typical, with the single but important exception of the production of acid from lactose. The antigenic structure and pathogenicity of the organism were investigated by Dr. G. H. Tee. He found it to be agglutinated to a titre of 1:5,120 by an antiserum prepared against a lactose-fermenting organism which had been isolated from a cat-bite and which appeared to be *P. septica*. He also inoculated two mice intraperitoneally with 0.1 ml. of an 18-hour broth culture of our organism diluted 1:100. Both mice died within 24 hours, and were found to have peritonitis with free fluid in the abdominal cavity. A pure growth of an organism with similar properties was recovered from their spleens. Finally the organism was tested against antibiotics, using a standard dried-disk technique; it was found to be sensitive to penicillin, streptomycin, chloramphenicol, the tetracycline group, and polymyxin, but resistant to erythromycin.

COMMENT

Two features in this case are noteworthy. First, it adds to the slowly accumulating body of evidence implicating *P. septica* as a definite potential pathogen in the respiratory tract in man. When Schipper (1947) reviewed human infections with *P. septica*, he divided them into two main groups—local infections due to animal bites, and infections, usually systemic, not obviously attributable to any direct cause. It seems to us, however, that cases of respiratory infection might well be separated from this second rather vague group, with consequently increased emphasis on their frequency and importance. The relatively large series of cases of bronchiectasis, including two complicated by empyema, reported by Olsen and Needham (1952) lends support to this view.

The second feature is of primarily bacteriological interest, and concerns the unusual property possessed by our strain of *P. septica* of producing acid from lactose. There is no published reference to a lactose-fermenting strain being isolated from man. However, such strains have often been described by veterinary workers (Jones, 1921; Rosenbusch and Merchant, 1939), and were referred to by Allin (1942) in a review of cat-bite infections. Moreover, Tee (1956, personal communication) has obtained from sputa several strains of lactose-fermenting organisms which otherwise seemed typically *P. septica*. There is therefore strong evidence that the production of acid from lactose is a property of certain not uncommon strains of *P. septica*, and that such strains may on occasion be pathogenic for man.

We are indebted to Dr. G. H. Tee for his invaluable assistance in carrying out the serological and pathogenicity tests; to Dr. C. S. S. Don for permission to publish the clinical details of the case; to Dr. A. Nicol for the necropsy report; and to Dr. R. W. Fairbrother for his advice and encouragement.

Reviews

HYPERTENSION

High Arterial Pressure. By F. H. Smirk, M.D., F.R.C.P., F.R.A.C.P. (Pp. 764+xxxvi; illustrated. 75s.) Oxford: Blackwell Scientific Publications. 1957.

The recent recognition of Sir Frederick Smirk's contribution to medicine was well timed in relation to the publication of his most important work. In this monumental volume he describes in detail virtually all that a clinician could want to know about hypertension, and few have studied it clinically so exhaustively or treated it more successfully. The book is essentially clinical and will be appreciated most by those who have to look after the patients.

While a monograph of this size must be classed as a reference book—and there are, incidentally, some 2,500 references—it is very readable and has that desirable conciseness so often lacking in books of multiple authorship. The first four chapters are concerned chiefly with the relationship of blood pressure to environment, diet, or reaction of the blood pressure to environment, diet, or somatotype, race, and daily activities, and constitute an excellent introduction. Chapter V., on the clinical manifestations of hypertension, is less convincing, but how unimportant these seem in relation to the whole! Known causes of hypertension, including psychiatric factors, are then considered in detail, and this is followed by chapters on the physiology of blood-pressure regulation and on experimental hypertension. All this leads up to the author's views on the pathogenesis of essential hypertension: very briefly he contends that all the clinical manifestations are the results of high pressure itself, however produced or maintained; that a wide variety of neurogenic and non-neurogenic factors may be responsible for the rise of pressure; and that certain mechanisms exist which tend to make hypertension self-perpetuating. It is interesting to reflect that quite independently almost exactly similar views have been expressed recently in relation to pulmonary hypertension after a very much shorter period of study.

Apart from a chapter on prognosis, the rest of the book (330 pages) is devoted to treatment. Far from engendering respect for such careful, complete, and detailed work, this elaborate therapeutic section has excited a curious reaction in some quarters: remarks such as, "What treatment that in some quarters: remarks such as, 'What treatment that is any good requires 330 pages to describe?' and, 'Devil's brew,' illustrate this reaction. But it is both stupid and churlish to deny the value of this therapeutic section, because hypertension is not as well treated as it should be, and successful management demands close attention to detail and familiarity with the potency and side-effects of a fairly large range of hypotensive agents.

While many books have been written about hypertension, there is no other that provides so much practical information, and it is therefore highly recommended to all who have to deal with this common and troublesome condition.

PAUL WOOD.

HORMONES AND BREAST CANCER

Endocrine Aspects of Breast Cancer: Proceedings of a Conference held at the University of Glasgow, 8th to 10th July, 1957. Edited by Alastair R. Currie, B.Sc., M.B., F.R.C.P.E.D. Foreword by C. F. W. Illingworth, C.B.E., M.D., Ch.M., F.R.C.S.E.D., F.R.F.P.S. (Pp. 340+xvi; illustrated. 37s. 6d.) Edinburgh and London: E. and S. Livingstone Ltd. 1958.

This book deals with the proceedings of a conference held at the University of Glasgow from July 8 to 10, 1957, in which there were over 90 participants from Great Britain and other countries. This should not, however, deter the reader, because by skilful editorship Dr. A. R. Currie has managed to give the book a continuity which is rare in volumes of this kind. A discussion follows the reading of most papers. The first part deals with the clinical aspects of breast cancer, and the remaining three sections are on

hormone studies and experimental pathology. In conclusion there is a comprehensive review of the work discussed at the conference, ably presented by Professor C. F. W. Illingworth.

During the last decade some interesting facts have been brought to light on the role of hormones in carcinogenesis. Not only have new hormones been recognized and isolated, but knowledge of the mechanisms which regulate these secretions has also been extended. It is therefore heartening to find that many of the discoveries which have been achieved in the laboratory are now applied clinically. This is especially true in the case of breast cancer, for it is now firmly established that the sex hormones of gonadal and adrenal origin play an important role in the development of breast cancer. Unfortunately at the present moment the role of the pituitary gland is less well understood, though one reads in this volume of promising researches on pituitary function which might have important clinical applications. Certain types of breast cancer, following application of endocrine therapy, undergo remission, and, even if the improvement is only of temporary duration, this in itself is a stimulating achievement. Recurrences of tumour growth after periods of remission following both gonadectomy and adrenalectomy suggest that the anterior pituitary may be capable of stimulating adrenal rests to secrete oestrogens to a degree sufficient to reactivate the neoplasm, or it may even be that the recurrence of some breast carcinomas is due to a pituitary hormone or hormones acting in addition to oestrogen. Clinical results following hypophysectomy without previous gonadectomy and adrenalectomy for patients with breast cancer suggest that this might be so. As Professor Illingworth rightly emphasizes in his concluding remarks, oestrogens may not be the only offenders in the induction of breast cancer. More research should still be done on the possible influence and sources of other hormones, such as progesterone and gonadotrophins, as well as prolactin and the growth hormone.

This volume is to be recommended particularly because it links together a vast mass of data on the endocrine induction and control of breast cancer in a way that can be appreciated by the medical practitioner and scientist alike. It is also a most useful book of reference for those interested in the general subject of hormones and cancer.

E. S. HORNING.

PSYCHOTHERAPY

Psychotherapy: A Modern Theory and Practice. By E. Lakin Phillips, Ph.D. (Pp. 334+xviii. 30s.) London: Staples Press Limited. 1957.

In a study of communication Ruesch and Bateson¹ note the remark of a Freudian, "The more experience I have in psychiatry the more convinced I become that it is impossible to verbalize what I do." It is indeed a characteristic of psychotherapists of all persuasions that they are unable to describe how their results are achieved, coupled with a certain reluctance to consider critically the efficacy of their efforts. This is an attitude which one cannot expect scientifically trained psychologists to tolerate, and, as they become interested in psychotherapy, a situation which obtains in the United States, so it is to be expected that they will examine the theories, assumptions, and results of psychotherapy in the same way as, say, intelligence or personality testing.

The author of this book notes, for example, that psychotherapists seem to get much the same sort of results though they hold very different theories and employ different methods. What effects the improvement in the patient—if, indeed, there is any improvement beyond that which would occur spontaneously—would seem to lie, not in the particular nature of the theories held by the individual psychotherapist, but in some other factor or factors common to all psychotherapy. It is obviously a matter of some interest and importance to consider these common factors, but this

¹ Ruesch, J., and Bateson, G., *Communication: The Social Matrix of Society*, Norton, New York, 1951.

is a task for which the clinician, engrossed with the particular aspects of his own brand of psychotherapy, is unfitted.

The author's attitude towards the critical study of psychotherapy is a most salutary one, whether or not one agrees with his views on the particular nature of psychotherapy which should be followed. He criticizes depth therapy on the grounds that it is fundamentally unsound, that its concepts are unnecessary, and that its duration is protracted because the psychotherapist is dealing with irrelevancies rather than tackling the present problems. He comes out in favour of a conflict theory and of a short-term directive psychotherapy consisting in bringing to the patient's notice his immediate conflicts which are responsible for his symptoms. On this basis he discusses the applicability of the work on experimental neuroses, much of which, however, he regards as naive. He attempts to evaluate the results of his therapy and claims that it is more effective than grubbing around in the unconscious for years; indeed, the whole concept of the unconscious comes in for sharp scrutiny.

The author devotes a chapter to the controversy between the monothetic approach—that is, the analytic approach in search of general laws which are statistically verifiable—and the idiographic or intuitive approach. He does not decry the intuitive approach, which would seem to be indispensable in dealing with particular problems ("no monothetist can tell what his wife would like for a Christmas present by applying the general laws of psychology"), and he regards the method of the clinician as that of adding an idiographic touch to the monothetic data he obtains from the patient.

Apart from the views expressed in this book, its main importance is that it emphasizes the lively nature of psychology in the U.S.A. Psychotherapy is in great need of a critical scrutiny of its basic assumptions and its *modus operandi*. Such a study is more likely to be made by psychologists than clinicians, and this book demonstrates the sort of contributions that psychologists can most valuably make to psychiatry. It is a book which should be read by all psychiatrists, not only for the views of the author on his short-term directive psychotherapy, but for the insight it gives as to how psychology might truly come to bear the relationship to psychiatry that pathology bears to medicine—still a very distant ideal.

A. W. BEARD.

MODERN ENDOCRINOLOGY

Modern Trends in Endocrinology. Edited by H. Gardiner-Hill, M.D., F.R.C.P. (Pp. 298+x; illustrated. 65s.) London: Butterworth and Co. (Publishers), Ltd. 1958.

Dr. Gardiner-Hill is the doyen of English clinical endocrinologists, and those of us who have followed him must ever be grateful for the aura of respectability which he cast around a specialty which a quarter of a century ago was not quite "a profession for a gentleman." He re-emerges now as editor of what must be the most star-spangled of all books on endocrinology. The late Michael Todd hardly did better when he collected his cast for "Around the World in Eighty Days." To list the authors would be merely to name two dozen from amongst the most distinguished endocrinologists from the laboratories and wards of the English-speaking world. To pick out any from such a company may be unfair, but at the risk of being so I would say that no one (however learned) who treats thyroid diseases can fail to learn something from the masterly chapters by Dr. Rosalind Pitt-Rivers, Dr. E. E. Pochin, and Dr. G. C. Kennedy and Professor R. A. McCance.

Of course there are omissions which strike the eye. In a book called "Modern Trends" dated last October and containing five chapters on the thyroid it is surprising to find no reference to auto-immunization. The authors of the chapter on tests of thyroid function, by what was obviously a momentary lapse of memory, forgot to say that patients with goitres without thyrotoxicosis often have a great avidity for radio-iodine. There is no mention of the valuable part played by triiodothyronine in the control of

patients with thyroid carcinoma. Dr. P. J. Randle, who writes with admirable clarity about diabetes mellitus, expressly excludes a discussion of the importance of the thyroid, obesity, and heredity, which is a pity. Space should have been found for the recent work of Kekwick and Pavan, who have succeeded in proving (what so many of us have long believed) that there are more things in heaven and earth than calories in the diet of the obese. And of course there are bound to be points of disagreement between any reviewer and any author, but reviewers are not, as once they were assumed to be, omniscient, and such matters are best left unnoticed unless a brick has been dropped large enough to be a stumbling-block. There are no such bricks here. Indeed, the only criticism which is likely to be general is that the book lacks balance. Though all parts are very good, the whole is less than their sum. The editor's answer, and a satisfactory one, is that this is not intended to be a textbook of endocrinology, but a series of essays planned to indicate some of the salients on the endocrine front. He says himself—and he should know—that the book "will be a helpful addition to the library of physicians, endocrinologists, postgraduates and others." I agree.

RAYMOND GREENE.

SANCTITY OF LIFE

The Sanctity of Life and the Criminal Law. By Glanville Williams. (Pp. 319. 30s.) London: Faber Ltd. 1958.

Concealed behind the pedestrian title of this book lies a topical volcano bubbling with ideas founded on a profound substratum of legal and historical knowledge. You begin with a placid first chapter on the protection of human life. This investigates the medico-legal niceties of birth and death—when the unborn child can be considered as alive, and when in the light of resuscitative techniques you should be regarded as really dead. It deals with the associated problems of concealment of birth, child destruction, infanticide, and what is to be done about monsters. From this you pass to the topical and controversial—to the control of conception, to sterilization, to artificial insemination, to abortion, to suicide, and to euthanasia. Professor Glanville Williams examines each of these problems against its historical background and in its present social context. Lawyers and politicians, Protestants and Popes, come in for searching criticism. He reviews the law as it is in England and in the American jurisdictions. On suicide, for example, he reminds us that the Christian attitude originates not from the Gospels or St. Paul but from St. Augustine's condemnation of the Circumcelliones. These cast themselves by the hundreds in ecstasy from lofty cliffs, for "to kill themselves out of respect for martyrdom is their daily sport." On eugenic sterilization he reminds us of Justice Holmes's observation in the United States Supreme Court in *Buck v. Bell*, decided in 1927, "Three generations of imbeciles are enough."

Not all will agree with all of Professor Williams's criticisms and suggestions for improvement; but this is a stimulating and instructive book which will give all but the most firmly closed minds considerable food for thought.

"A BARRISTER."

A second edition of Mr. J. C. Adams's *Outline of Orthopaedics* has appeared only two years after the first (reviewed in this *Journal* on May 12, 1956, p. 1089). This book, intended primarily for senior students, gives an adequate outline of orthopaedic conditions and their management. It is published by E. and S. Livingstone, Ltd., Edinburgh (pp. 428, 300 illustrations; 35s.).

Professor Oliver E. Byrd, of Stanford University, has selected 254 articles from 78 journals to form the basis of *Health Yearbook, 1956* (pp. 278; London, Oxford University Press, 1957; 40s.). These articles "represent the research, experience, and opinion of approximately 300 authors, committees, organizations, and other groups in the fields of public health, medicine, and allied scientific areas," but only nine come from outside the United States, and none from foreign-language journals.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY OCTOBER 11 1958

FAINTING

A wide variety of conditions may precipitate fainting. It may occur after prolonged standing in the erect posture, sympathectomy, violent coughing, or the administration of ganglion-blocking drugs and nitrites, and it may be a complication of haemorrhage or pregnancy. Arterial hypotension is a constant feature of it. Now Professor E. P. Sharpey-Schafer and Drs. C. J. Hayter and E. D. Barlow show in an article at p. 878 this week that severe hypotension is not uncommonly precipitated by fear before the administration of nitrous oxide for dental extraction. Nausea caused by apomorphine was also found to lead to a similar vascular reaction.

Since arterial pressure is a product of total peripheral resistance and cardiac output, it follows that acute hypotension is due to a profound fall in one or both of these factors. The normal slight fall in venous filling pressure and cardiac output which occurs with a change to the upright posture in man is balanced by vasoconstriction; this "baroreceptor constriction" has been observed in the vascular reactions accompanying squatting and performing the Valsalva manoeuvre.¹⁻³ Fainting occurs when normal vascular reactions are inadequate and fail to maintain arterial pressure above some 50 mm. Hg. The constituents of the faint reaction, apart from the hypotension and resulting syncope, are independent of the cause, and include sudden bradycardia, pallor, sweating, and hyperpnoea, suggesting that the whole is a reflex phenomenon. Sudden vasodilatation, as shown by an increase of blood flow in the forearm, has been observed in fainting reactions accompanying haemorrhage,⁴ tilting to the upright posture, spinal anaesthesia, and pregnancy.⁵ Thus fainting will be enhanced in susceptible subjects by any factors which tend to increase vasodilatation, such as a warm atmosphere or thick clothing.

In most types of fainting there is evidence that inadequate filling of the heart, and consequently a

reduced output and lower pulse pressure, is a crucial factor. The inadequate filling is due to venous pooling, which is why fainting is usually associated with the erect posture and is more likely to occur when the subject is in the lordotic position or has been standing for long. In pregnancy venous pooling is probably due to partial occlusion of the inferior vena cava by pressure of the gravid uterus.

Nitrites readily produce faintness because they cause venous dilatation as well as arteriolar relaxation. Venous pooling may be stopped by an anti-gravity suit, which thus prevents syncope.⁶ Diminished filling of the right atrium is also an important factor in the mechanism of cough syncope.⁷ Professor Sharpey-Schafer and his colleagues now suggest that the whole faint reflex may be initiated from afferent nerves stimulated by a relatively empty heart, this being caused not only by venous pooling but by vigorous systolic emptying owing to emotional stimulation. This ingenious hypothesis explains the strange absence of faint reactions in patients with congestive heart failure, when a residue of blood remains in the ventricles in diastole.

In a rare form of idiopathic postural hypotension there is syncope on standing, anhidrosis, and impotence.⁸ These are the result of a central paralysis of vasoconstriction, and the effect is similar to that caused by extensive sympathectomy or an overdose of ganglion-blocking drugs. In these conditions syncope may occur before the full picture of vasovagal fainting develops; unconsciousness may supervene without bradycardia. However, the contributions of Sharpey-Schafer and others have shown that, apart from minor differences in degree of vascular reaction, in all forms of fainting the final mechanism is similar. There is sudden vasomotor failure in conjunction with reduced filling of the heart. The only homeostatic feature of the reaction appears to be final collapse from the upright position, which leads to restoration of the venous filling pressure.

INFECTIOUS MONONUCLEOSIS

Infectious mononucleosis, or glandular fever, is still a baffling disease. It is presumed to be a viral infection, though no causal organism has yet been found. A. Nyfeldt,¹ C. A. Pons and L. A. Julianelle,² and R. A. Webb³ all thought that *Listeria monocytogenes*, a Gram-positive motile bacillus occurring naturally in rodents and ruminants, was the likely aetiological agent. *L. monocytogenes* is being found with increasing frequency in human infections,^{4 5 6} and B. H. Chaiken and D. T. Michaud⁷ report a case of infectious mononucleosis from which this organism was

isolated in 6 out of 8 blood cultures: the heterophil antibody titre was 1:448. But in the majority of cases *L. monocytogenes* has not been isolated, nor have positive agglutinins appeared. It seems possible that this is a syndrome with more than one cause. K. F. Girard and E. G. D. Murray⁸ summarized the evidence in favour of a viral cause and of the view that *L. monocytogenes* was responsible, and suggested that the heterophil antibody was not directly produced by either organism but by some other non-specific immune mechanism set in motion by the affected lymphatic or liver tissue and by alteration in serum globulin. D. A. Goldthwait and J. W. Eliot⁹ regard infectious mononucleosis as a disease presenting the triad of lymphatic hyperplasia, circulating abnormal lymphocytes, and the appearance of heterophil antibodies that are absorbed by ox red-blood cells but not by guinea-pig kidney. Heterophil antibodies of this pattern are generally regarded as occurring only in infectious mononucleosis,¹⁰ and absorption tests are therefore essential in assessing the significance of a positive Paul-Bunnell reaction.

A. Bernstein,¹¹ in a comprehensive review, suggested that a negative Paul-Bunnell test almost excluded a diagnosis of glandular fever. C. E. Bender¹² was of a similar opinion, but pointed out that in certain forms, notably the "febrile" type and those cases with neurological manifestations, heterophil antibodies appear only in the later stages or even in convalescence. A rising titre of antibody is stronger evidence of the disease than an arbitrarily chosen level such as 1:64¹³ or 1:56.¹² S. Leibowitz¹⁰ originally regarded a positive Paul-Bunnell test as "almost an absolute yardstick of infectious mononucleosis": in 1956 he revised his opinion and said that "the validity of the diagnosis of infectious mono-

nucleosis in sero-negative cases still remains to be established with certainty and will continue in some doubt until the aetiological agent is identified and an unquestioned diagnostic test results." In a field survey of 498 cases suspected on clinical grounds to be cases of glandular fever F. G. Hobson, B. Lawson, and M. Wigfield¹⁴ found 242 had a positive Paul-Bunnell reaction, 100 were negative to the test but showed haematological evidence of the disease, and 156 had illnesses due to other conditions. It was not possible to differentiate sero-positive and sero-negative cases on purely clinical grounds except in retrospect, but the former tended to be more severe, while, though infectivity was low in both groups, the latter appeared to be the more infectious. There were notable differences in the two groups in seasonal onset and in the age and sex incidence, and glandular-fever cells were found to persist twice as long in the cases with a positive Paul-Bunnell reaction. The authors' conclusions supported the findings of S. Shubert and his colleagues¹⁵ that sero-negative cases should be regarded as examples of a different disease. More detailed investigation of sero-negative cases is clearly required.

Serological surveys for toxoplasma antibodies in Britain¹⁶ and in America have shown that by adult life between one-quarter and one-half of the entire population have become infected,¹⁸ while the close resemblance of some cases of acquired toxoplasmosis to infectious mononucleosis has often been noted.¹⁹ M. Bateman²¹ has reported three cases in which an initial diagnosis of infectious mononucleosis had been made but subsequent Paul-Bunnell tests were negative and serological tests for toxoplasmosis were positive. In a more recent survey of 30 cases of toxoplasmosis in Sheffield, J. K. A. Beverley and C. P. Beattie²² report that four were proved by isolation of the parasite and the remainder showed significantly high antibody titres. While lymphadenopathy appeared to be the commonest manifestation, the severity and duration of the illness varied enormously; five of their patients were never really ill, whereas in others the illness dragged on for months. All had negative Paul Bunnell reactions. It is clear, therefore, that routine investigation for toxoplasma antibodies should be made both in cases resembling infectious mononucleosis with negative Paul-Bunnell tests and in cases of pyrexia of unexplained origin.

Evidence of widespread visceral disease in infectious mononucleosis has accumulated in recent years. Hepatic, cardiac, or neurological symptoms may predominate. Jaundice is a well-known development in proved cases (Leibowitz¹⁰ found it in 28% of his series of 25 cases), but R. S. Nelson and J. H.

Darragh²³ have shown by serial liver biopsies that non-icteric hepatitis is present in most cases. L. E. Rennie and F. Wroblewski²⁴ found that alterations in serum glutamic pyruvate transaminase (S.G.P.-T.) reflected most sensitively the presence and extent of hepatic infection, while the subjective manifestations of the disease appeared to coincide with the S.G.P.-T. levels, suggesting that fluctuations and variations in the symptoms of the disease might be explained in part by the amount of hepatic inflammation. B. H. Webster,²⁵ in a report on five cases of infectious mononucleosis—confirmed by increasing absorption titres of heterophil antibody with beef cells—which showed electrocardiographic as well as clinical evidence of severe cardiac complications, believes that the heart is more often affected than is generally suspected. D. M. Roseman and R. M. Barry²⁶ describe what they consider to be the eighth reported case of acute pericarditis occurring in association with infectious mononucleosis, and it is noteworthy that the signs of pericardial inflammation preceded those of mononucleosis by one week. Neurological complications of infectious mononucleosis are being reported with increasing frequency. Leibowitz¹⁰ suggests that in the majority of cases the symptoms become manifest in the first to third weeks but that the clinical picture may be confusing; he noted that in the 71 cases recorded in the literature the mortality rate was 11%. E. P. Frenkel and his colleagues²⁷ have claimed good results with steroid therapy.

In the absence of notification the incidence of the disease cannot be calculated, but in common with some other viral infections it seems to be on the increase, and in semi-closed communities like the Army may be as common as infectious hepatitis and poliomyelitis. So varied is the symptomatology and mode of onset that infectious mononucleosis should be kept in mind in any infection of unexplained origin. The development of exudative tonsillitis after a variable period of febrile disturbance with malaise and possibly lymphadenopathy is one of the commonest patterns of the disease; while macular rashes, clinically indistinguishable from rubella, are often seen. The study of a blood film is thus an indispensable procedure in all such cases. Many references have been made to the enanthem of glandular fever,²⁸⁻³⁴ and F. I. Caird and P. R. Holt³⁵ have made a detailed study of this phenomenon. They describe five types of lesion, the most important being multiple pin-point petechiae at the junction of the hard and soft palate. Red macules, linear macules, white macules, and vesicular lesions may also be seen. Caird and Holt maintain that such lesions are not generally found in diseases which infectious mononucleosis may simulate and may therefore prove helpful in a diagnosis which

so often remains in doubt until the results of the Paul-Bunnell test are known. Much more might be learned about the aetiology and epidemiology of this infection if it was made notifiable, at least temporarily, in areas where the incidence is believed to be high.

WAITING FOR DOCTOR

To a patient already worried about his ill-health a long wait in the out-patient hall can seem uncommonly irksome. He may be suffering loss of earnings as a result of it, or the housewife may have trouble over getting her children looked after. It can be no surprise if they, like Marvell, are sometimes obsessed with the thought of "time's winged chariot hurrying near." Marvell was addressing his mistress, not his doctor (and hence in verse), but many people do find it a frustrating experience to fidget about for an hour or more in strange company waiting for their slightly alarming turn to come before the doctor. A number of investigations have by now been carried out into the various causes of long waits at the hospital clinic; a considerable literature on it has appeared; and last week a further contribution, partly reviewing previous work but adding fresh observations, was published by the Ministry of Health.¹ "Waiting in the clinic before seeing the doctor," says the report, "is the most frequent and most irritating cause of complaint."

As the report recognizes, many kinds of disturbance can upset the smooth running of an appointments system. The authors found that on the average about 10% of patients booked do not attend (though some give warning), and, though most patients come early, "there are often enough late comers to jeopardize the efficiency of an appointments system." The doctors in charge of the clinic may themselves be late, or have to leave suddenly to deal with an emergency, or to go off for a few minutes to consult a colleague. Again, the length of each consultation may vary enormously. To the statistician—and most studies of these problems have been executed by statisticians—these problems appear as measurable variables which, after some technical processing, can provide data from which to deduce the framework of a scheme. An appointments system may thus be constructed by which, for example, in 19 out of 20 successive out-patient sessions not more than 5 out of 100 patients would, on the average, have to wait more than one hour. The objective recommended in this report is that 75% of patients should be seen within half an hour of their appointment time, and that no more than 3% should have to wait over an hour.

It is possible by this approach to provide a scheme that is helpful to everyone concerned, though sometimes the variables are distributed in an exceedingly complex and irregular manner; in other words, the unexpected is apt to happen. Moreover, chronic overworking of the clinic staff by too many patients coming along can cause difficulties that no appointments system will satisfactorily resolve. The best thing to do here, as the report says, is to hold more sessions, but it unaccountably omits to add that more consultants would be needed to do that.

Though waiting for the doctor can be a worry, it is possible to make too much of it. The problem happens to be one that can readily be cast in terms of measurement, so that analyses of it are tempting to anyone handy with a slide-rule. That it should be a cause of complaint among patients is natural—travellers complain about delay on the railways, litigants about delay in the courts, and babies about delay in getting the next feed. As is well known in hospitals, these are often as much problems of human personality as of administrative machinery, and in the great majority of hospitals a proper concern for the patients' welfare is never allowed to become obscured on the one hand by forgetfulness, on the other by over-zealous supervision. And has it escaped the investigators' notice that for many people the regular visit to the out-patient department is the equivalent of going to a club for a good gossip?

ANTISERUM AGAINST CANCER

A report has been published in Canada¹ of the treatment by means of an antiserum of patients with cancer. Though no cures are claimed, considerable palliative effect is reported. The patients treated were all in the terminal stages of the disease after surgeons, radiotherapists, and others had done what they could. Two main forms of cancer were treated, breast and stomach, and an antiserum against each was prepared by injecting horses with suspensions of the appropriate human cancer tissue. A globulin fraction of the horse serum, presumably the gamma globulin, was used to treat the patients, and was injected intravenously until the equivalent of 300 ml. of serum had been administered over three or four weeks. Only patients who gave negative responses to skin sensitization tests were treated. Some of these developed later adverse reactions to the injections of serum, but many did not.

Three patients with metastatic breast cancer had secondaries in the brain, and experienced a return of eye function on serum therapy. In 9 out of 24 cases with metastatic gastric carcinoma there was a disappearance of symptoms for four to eight months. Patients with severe bone pain obtained relief, often complete, and there was radiographic evidence of recalcification of the osteolytic metastatic bone lesions. In some cases of breast

cancer in which radiation treatment had combined with the malignant disease to give a massive ulceration, the author reports healing, epithelization, and relief of pain following serum therapy. A group of patients with mediastinal infiltration, who had extreme difficulty in breathing and swallowing, were said to have obtained great relief, apparently owing to a reduction in size of the mediastinal tumour mass. A similar improvement was found in some cases with multiple pulmonary metastases and there was x-ray evidence of a diminution or disappearance of nodules. In a group with pulmonary and pleural metastases with massive pleural effusion, there was reduction or disappearance of the effusion following serum treatment. In the gastric carcinoma group there was considerable relief of symptoms and a suggestion of increased survival in those patients who received the full course of serum.

These results are surprising and promising. They are surprising because they appear to be at least as good as anything produced experimentally in the serum therapy of spontaneous or induced animal tumours (except the virus tumours). The results are also surprising in that they were obtained with such an unrefined preparation. The horse serum would almost certainly contain antibodies to the normal plasma and tissue proteins, and there was no attempt to remove them. These may have caused some of the adverse reactions. The results are promising because they were obtained in such unfavourable conditions—namely, in advanced cases. The anti-serum preparation can be greatly improved, especially by the use of certain fractions of the cancer cells, as was recently reported in this *Journal* by J. G. Makari.² However, this may be looking too far ahead, since there is no good evidence in the report that immunity plays any part. No patients were injected with normal horse serum, and in the absence of such controls it is reasonable to speculate whether the effect may be due simply to the injection of heterologous serum. R. Schrek,³ for example, has recently reported that normal rabbit serum is far more toxic to human leukaemic lymphocytes than to normal lymphocytes *in vitro*.

Whether the effect is an immune one or not there can be little doubt that some palliation was achieved, and this may be capable of improvement by further research. If the effect is found to be one of immunity, this would be of great theoretical importance, since the whole rationale of immune cancer therapy depends on the existence of specific cancer antigens. Evidence for such an antigen or antigens, discussed in these columns recently,⁴ has been forthcoming from several countries in the last two or three years, though few would regard the case as established. The final proof, or certainly the general acceptance, of this idea will probably come only when primary tumours are removed or inhibited through such an agency. It is salutary, therefore, to remember that so far the results of such attempts have been disappointing, and that the present effect may not get further than palliation.

INHERITANCE OF RHEUMATOID ARTHRITIS

Though rheumatoid arthritis sometimes affects more than one member of a family, this disease is fairly common if all grades of severity are considered, and to the casual observer the distribution might seem to be one of chance. The great majority of patients with rheumatoid arthritis are the sole sufferers of their immediate kindred. However, all studies which have compared the incidence of the disease in relatives of patients suffering from it with the incidence of it in control groups variously chosen have agreed that there is a familial tendency: in five separate studies, between twice and five times more rheumatoid arthritis was found in the relatives of patients than in those of the controls.

A new weapon for the more detailed analysis of such a tendency has been in our hands since 1948: the Rose-Waaler test depends upon a factor in rheumatoid sera which agglutinates particles such as erythrocytes coated with gamma globulin. It is nearly specific for rheumatoid arthritis sera and is found to be positive in about 60–70% of adults with that disease. With this addition to clinical and radiological assessment J. S. Lawrence and J. Ball¹ have recently re-evaluated the familial distribution of "rheumatoid arthritis" in a series of relatives of patients with rheumatoid arthritis, comparing them with an equal number of randomly chosen controls from the general population matched for age and sex. Clinical assessment showed severe, moderate, and minimal rheumatoid arthritis (three of the five grades chosen) to occur in 16 out of 183 relatives but in only 4 out of 183 controls; radiological assessment showed specific changes in 12 relatives and in 6 controls; serological assessment showed a positive Rose-Waaler titre in 13% as against 5% in controls. On the American Rheumatism Association's grading of rheumatoid arthritis, minimal, moderate, or severe changes were found in 14 relatives and 9 controls.

These figures agree in general with previous ones; though the incidence of rheumatoid arthritis in relatives is small, it is about two to four times as great as in controls. More detailed analysis disclosed that families of patients with rheumatoid arthritis but with a negative Rose-Waaler test had no more radiological or serological evidence of rheumatoid arthritis than the controls but did show more clinical rheumatoid arthritis (8% as against 2%). This discrepancy might perhaps be due to the lower proportion of older people in the sero-negative group. It is well known that both radiological and serological changes increase with age, and it is likely that the relatives of patients with sero-negative rheumatoid arthritis would be younger than those of patients with sero-positive rheumatoid arthritis and would also have less serological change themselves.

On the assumption that by the age of 65 all who are liable to develop this serological change will have done so, the authors calculate that the gene responsible for it occurs in one in three of the population. How this serological change is related to the changes in the connective tissues of the joints remains completely un-

known, but it was found that morning stiffness was more frequent than in the control population only in the sero-positive persons with rheumatoid arthritis and not in those with a negative Rose-Waaler test. In such ways studies of the population, besides their intrinsic interest, serve also to indicate further fields of useful inquiry.

MARFAN'S SYNDROME

Eponymous titles are, in general, to be deprecated, but there are some disease syndromes which are so well known that their eponym has passed into current usage, and indeed sometimes the use of the name is often easier than the descriptive title. One example of this is Marfan's syndrome. In his original paper Marfan¹ reported the case of a girl aged 5 years with spider fingers and skeletal deformities, and he called the condition "dolichostenomelia." Achard² first suggested the name "arachnodactyly." Ophthalmic abnormalities have long been recognized as being closely associated with the bony deformities, and cardiac lesions are also common. This triad of arachnodactyly, dislocation of the lens, and congenital morbus cordis constitutes Marfan's syndrome, but there are many variations which have loosely been included under this title, although Marfan did not describe them.

Though the condition is rare, it is easily recognizable on sight, even in early childhood. The long thin fingers and toes, the hypermobility of the joints, the pigeon or funnel chest, and the dislocated lenses and marked myopia (necessitating very thick glasses) make an unforgettable picture. The heart lesion, which is usually acyanotic, has generally been considered as predominantly a septal defect, but R. K. Piper and E. Irvine-Jones³ found that aortic abnormalities were commoner, particularly medial sclerosis, and this has been confirmed by further necropsies. As a dissecting aneurysm is a likely sequel to such a lesion, sudden death is no rarity. Because of the incidence of "formes frustes" of the syndrome some authors^{4,5} have suggested that unexplained aortic aneurysms should lead to a search in the family for other congenital anomalies, even if there are no overt signs of Marfan's syndrome.

Almost every system has been affected in association with arachnodactyly, and the various abnormalities have been surveyed by C. C. Booth and colleagues.⁶ The latest study, by M. A. Lynas,⁷ has emphasized the genetic aspects. She investigated all the families in Ulster which were known to have any members suffering from the condition, either in its complete form or as "formes frustes," and found 13 families with a total of 31 affected subjects in several generations. The complete clinical syndrome was present in 11 of the 20 patients she examined. The genetic studies suggested that the disease was inherited as a dominant trait acting irregularly. There was no consanguinity in any of the families

studied. Yet despite all the cases now recorded, and the work involved in their investigation, the aetiology of Marfan's syndrome remains unexplained.

PULMONARY TUBERCULOSIS AND PEPTIC ULCER

Pulmonary tuberculosis occurs more frequently in patients, especially men, after partial gastrectomy than in the general population.¹⁻⁴ This finding has been confirmed by J. A. Balint in a recent survey of mortality in a follow-up of 2,413 patients after gastrectomy.⁵ The higher incidence of tuberculosis in men than in women after gastrectomy is due to the fact that the majority of men have this operation before they reach the most dangerous age for phthisis (55-65 years), while women have already passed what is for them the most dangerous age (20-30 years) before the operation.

Some workers have claimed that pulmonary tuberculosis is more prevalent among patients with peptic ulcer not treated by operation,^{6,7} but others have disagreed with this view.⁸⁻¹⁰ Balint in his survey examined the incidence of tuberculosis among 1,886 patients with peptic ulcer seen at the Central Middlesex Hospital during 1953-5 inclusive, and found no significant difference between this and the incidence in all other out-patients seen during the same period. However, his patients were new cases of peptic ulcer and therefore mainly of recent onset.

The increased incidence of tuberculosis after partial gastrectomy has been most commonly attributed to malnutrition,¹¹⁻¹⁴ yet there is much evidence that nutrition after gastrectomy is not usually severely impaired.^{5,15-17} Furthermore, it has been shown that tuberculosis is just as likely to develop in patients whose partial gastrectomy is a success as in patients with bad results.^{1,18} D. M. Kissen¹⁹ has recently suggested that the increased prevalence of tuberculosis among patients with peptic ulcer has a psychological origin. While many doctors would agree that emotional disturbances often lead to recrudescence of ulcer symptoms, there is still much doubt about their significance in the aetiology of peptic ulceration. Other factors are known to be of importance in determining the increased incidence of tuberculosis in ulcer subjects. One of these is social class. W. R. S. Doll and colleagues²⁰ have shown that gastric ulcer is much more common in social class V than in social

classes I and II. Tuberculosis is also more common in the lower social classes. Again, C. R. Lowe²¹ has shown that there are an excessive number of heavy smokers among adult patients with pulmonary tuberculosis, while Doll and colleagues²² have shown that peptic ulcer is more common in smokers than non-smokers. Thus smoking may be another important factor in the development of tuberculosis in patients with peptic ulcer.

Firm evidence of an increased incidence of pulmonary tuberculosis among patients with peptic ulcer is at present lacking, except that the incidence after partial gastrectomy is undoubtedly higher. Balint has calculated that cases of tuberculosis arising after partial gastrectomy may account for 5-10% of all new notifications of pulmonary tuberculosis in men. The explanation for this increased incidence appears to lie in the social class of the patients (mainly social class V), their heavy cigarette smoking, the age at which the operation is performed, and the slight malnutrition following partial gastrectomy.

AFTER DINNER

The medical schools are beginning the new session. Notable men make edifying speeches. And everyone dines. Usually the dinners are good, and also the wines. Everyone eats too much on these occasions. Surfeit is the rule. A medley of middle-aged men—with a few ancients around—sit uncomfortably with starched shirtfronts and become flushed and even purple as the evening wears on; and all this at the end of a long day in the operating theatre or consulting-room. For those who have to join the circus of presidents of the square dozen of metropolitan medical societies, dining out can become quite a habit between the autumn of one year and the spring of the next. And they all have to pay the same price for this hazardous privilege—making or listening to speeches. No one likes it—neither the speaker nor the listener. It is an intolerable infliction on all. There may be three or at the most four medical men in London, for example, who can make a speech that entertains. The rest conscientiously grind out their little stories or attempt displays of cleverness. Then comes the climax of after-dinner futility—the toast to the guests. The proposer, plainly, has met the most distinguished of them for the first time that evening; but he bravely hints at familiarity with their past, hoping he has not by error got hold of the wrong entry in *Who's Who*. On one memorable and even funny occasion the proposer brought a prompter with him in case he missed his cues. After-dinner speakers are mostly as dull as dish-water. It is not their fault. Surgeons have been taught to take life seriously, and physicians to look knowing and grave. Apart from their intrinsic demerits, after-dinner speeches prevent the diners moving round to meet old friends over the port. They all get stuck in their places next to and opposite the same old faces. If there must be speeches after dinner there should be two only—one for and one against, the choice of subject being open to the first speaker—and a time limit of seven minutes each.

Drug Treatment of Disease

ASTHMA

BY

R. S. BRUCE PEARSON, D.M., F.R.C.P.
Physician, King's College Hospital

The main advances in the symptomatic treatment of asthma lie in the use of corticoid substances and their derivatives. The older bronchodilators, however, remain the drugs of choice in cases of mild or moderate severity. Their effectiveness in some cases has been improved by modification in their structure, in their physical state, or by the combined use of more than one preparation, so that side-effects have been reduced or the rate of absorption modified. The use of the following preparations in asthma will be discussed:

- (1) Bronchodilators: (a) Sympathomimetic drugs.
(b) Xanthine derivatives.
(c) Miscellaneous.
- (2) Corticoid preparations and corticotrophin.
- (3) Sedatives.

Sympathomimetic Drugs

These include adrenaline, isoprenaline, methoxyphenamine, and ephedrine. Ephedrine (30 mg.) and methoxyphenamine (100 mg.) are given by mouth and may be used in the treatment or prophylaxis of mild attacks. They are also useful in emphysematous patients with bronchospasm. Though they are less potent than isoprenaline or adrenaline, their action persists for a longer time. Isoprenaline can be prescribed sublingually in doses of 10-20 mg. or as an aerosol means of pressure from an oxygen cylinder or electric motor may be continued for 15-30 minutes in exceptional circumstances. Adrenaline hydrochloride (1:1,000) 0.5-1.0 ml. or bitartrate (1:2,000) 1-2 ml. are given subcutaneously in severe attacks. Repeated doses of 0.05-0.1 ml. every 1-2 minutes may be given in status asthmaticus up to a total dose of 3.5-5 mg. of the adrenaline salt, unless there is relief of symptoms or evidence of hyperadrenalinism before the maximum dose is reached.

The side-effects of these drugs are mainly cardiovascular. Ephedrine, adrenaline, and isoprenaline are all cardiac stimulants and may cause extrasystoles or over-action of the myocardium, with unpleasant subjective sensations. Ephedrine is also a central stimulant and may make patients feel so tense and excitable that they are unwilling to continue taking it; for the same reason it may prevent sleep if administered at night. It is remarkable that this effect is rarely observed in children, who can usually tolerate ephedrine in doses of 8-15 mg. ($\frac{1}{4}$ - $\frac{1}{2}$ gr.) up to 5 years and 15-30 mg. ($\frac{1}{4}$ - $\frac{1}{2}$ gr.) after this age when it is given at bedtime, without any disturbances of sleep habit. Its prolonged action makes it a particularly valuable nocturnal prophylactic. The following linctus is often beneficial for children, and is suitable for a child aged 5 years:

R. Tinct. camph. co.	minims 5 (0.3 ml.)
Oxymel scillae	minims 15 (0.9 ml.)
Ephedrin.	gr. $\frac{1}{4}$ (16 mg.)
Pot. iodid.	gr. $\frac{1}{4}$ (100 mg.)
Aqua chloroform	to 1 dr. (3.5 ml.)

One drachm to be taken before going to bed.

Methoxyphenamine ("orthoxine") is an analogue of ephedrine but produces considerably fewer cardiovascular or central nervous side-effects. When given to 7 patients who were unable to tolerate ephedrine, no side-effects were experienced in 6; and, of 24 patients who were asked to compare the effects of the two preparations, 15 preferred orthoxine (100 mg.) and 3 ephedrine (30 mg.). The broncho-

dilator effects of the two preparations were judged to be approximately equal.

The side-effects of ephedrine may be reduced by prescribing it with phenobarbitone 30 mg. ($\frac{1}{2}$ gr.) or sodium amytal 50 mg. ($\frac{1}{2}$ gr.). Its action can be further prolonged by giving it in the form of a resin ephedrine complex, so that the ephedrine is liberated slowly by ion exchange as it passes down the alimentary tract. It has been shown that the active part of a combination of this type is in fact absorbed steadily into the blood stream over a period of 6-8 hours. The action of adrenaline can be prolonged by injecting a combination of adrenaline in an emulsion of nut oil ("hyperduraline"). Although these modifications of adrenaline and ephedrine may make them more effective under certain circumstances, the unmodified preparations are adequate for most patients and considerably cheaper.

Xanthine Derivatives

These consist of theophylline and caffeine. The former is the more effective and may be given orally, intravenously, or intramuscularly. Oral theophylline exerts a relatively weak bronchodilator action when given alone in the usual dose of 200 mg. (3 gr.). In severe asthma or in status asthmaticus, intravenous aminophylline (theophylline with ethylenediamine) 250-500 mg. should always be given if adrenaline has not been effective; it may cause dramatic relief in such patients. Rectal suppositories (250 mg.) are sometimes useful, especially at night. Side-effects are due to gastric irritation, especially when taken orally, and to cardiac stimulation (rarely with ventricular fibrillation) when injected intravenously. Administration by rectal suppository, though inelegant, seldom gives rise to unpleasant symptoms.

Various means have been adopted to avoid the irritating effects of theophylline on the gastric mucosa, of which the most obvious is to prescribe it after food. A combination with choline (choline theophyllinate) which increases its stability and is highly soluble appears to be the most effective; it is available in tablets of 100 and 200 mg. A preparation in which theophylline and aluminium hydroxide are given together is also well tolerated. The cardiac side-effects of intravenous aminophylline can easily be overcome by slow administration, and in status asthmaticus it may be given in a saline drip up to a total dose of 3 g. in 24 hours. The inconvenience of intravenous administration can be avoided by intramuscular injection, but this is painful because of the acid reaction of aminophylline. Modification of theophylline by replacing the hydrogen-containing amine with a hydroxy-propyl chain, diprophyllyne ("neutraphylline"), renders it neutral in reaction and relatively painless. The effect produced is somewhat slower than after intravenous administration. Caffeine is not administered alone for its bronchodilator action, but the *National Formulary* preparation, caffeine iodide elixir, is sometimes of value when bronchial infection is associated with asthma.

Although it is generally regarded as bad practice to prescribe more than one drug at a time, the effect of a combination of sympathomimetic and xanthine substances may be superior to that of either drug alone. The further addition of a sedative not only reduces the side-effects of ephedrine but may help to relieve nervous tension. Clearly, however, to be effective these drugs should be given in adequate quantities—that is, theophylline 130-200 mg.,

ephedrine 20–30 mg., and phenobarbitone 20–30 mg. The addition of a keratin coating will delay absorption of the active principles and makes such preparations particularly valuable in preventing nocturnal attacks.

Other Bronchodilators

The belladonna alkaloids and the nitrites, both pharmacological bronchodilators, are of no significant value in the treatment of asthma. Stramonium is sometimes given in the form of mist. pot. iod. and stramonium (N.F.) $\frac{1}{4}$ fl. oz. (14 ml.) three times a day. Kheilin, a smooth-muscle relaxant with irritant effects on the alimentary tract, has no advantage over better-known preparations. The antihistamines, though highly effective in many cases of hay-fever and urticaria, are disappointing in asthma. The sedative side-effects of promethazine and diphenhydramine, combined with their antihistaminic action, may render them effective in the nocturnal asthma of children, and in Great Britain their use in asthma is almost limited to this type of case. Diphenhydramine may be prescribed as an elixir as follows:

B. Diphenhydramine ..	0.08 g.
Chloroform ..	0.1 ml.
Lemon flavouring ..	0.12 ml.
Liq. ext. liquorice ..	0.3 ml.
Soln. of bordeaux B ..	(B.P.C., 1949) 0.08 ml.
Soln. burnt sugar ..	(B.P.C.) 0.1 ml.
Syrup ..	to 28.5 ml.
4 ml. to be taken at bedtime.	

Corticoids

Corticoid preparations are highly effective in asthma. They are, however, merely symptomatic remedies and in no sense to be regarded as a "cure." While there is little objection to their use for short periods as a means of helping a patient through an exacerbation, their continuous exhibition, though justified in some cases, has certain serious disadvantages and should be avoided unless the patient's way of life is disorganized by his asthma.

Corticoids should be given only under the closest supervision and in exceptional circumstances if a patient has a history of peptic ulcer or pulmonary tuberculosis. Haematemesis from an ulcer, or perforation, with masked symptoms, are not uncommon even with short courses of treatment. The author is aware of three fatal cases and has seen others who survived. Reactivation of quiescent pulmonary tuberculosis may also occur. In diabetes, corticoids should be employed with circumspection and the dose of insulin may need adjustment. Signs of heart failure should also be regarded as a contraindication to the administration of cortisone and hydrocortisone; prednisolone or prednisone, which do not cause excessive retention of sodium and fluid, are relatively safe in this respect.

Intermittent Therapy

My own practice is to supply patients who are subject to intermittent severe attacks of asthma which may lead to status asthmaticus with an emergency supply of 20 tablets of prednisolone (5 mg.) or cortisone (25 mg.), and instructions to take these if their asthma fails to respond to the bronchodilator drugs they habitually use. The course of treatment is as follows:

Prednisolone 5 mg. or cortisone 25 mg.	
Days 1 and 2 ..	1 tablet four times a day.
Days 3 and 4 ..	1 tablet twice a day.
Days 5 and 6 ..	1 tablet twice a day.
Days 7 and 8 ..	1 tablet at night.

This is effective in controlling exacerbations in a high proportion of cases, but patients with more severe attacks may need a larger initial dose—say, $7\frac{1}{2}$ mg. four times a day for the first two days, thus prolonging the treatment to a period of ten days. Short courses of this type, even if repeated every month or so, are preferable to continuous or long-term treatment.

In status asthmaticus an initial daily dose of 60 mg. of prednisolone or 300 mg. of hydrocortisone should be given in divided doses on the first day. An initial administration of hydrocortisone hemisuccinate (100 mg.) intravenously is valuable in severe cases: this may be repeated after 3–4 hours if necessary. It must be remembered that immediate relief is not always obtained; corticoids do not act directly as bronchodilators, and improvement may not take place for 48 hours or more. Bronchodilator drugs such as adrenaline and aminophylline must therefore be given in the usual way until relief is evident. Death from asthma can still take place on full doses of corticoid substances. It is also important to remember that if bronchial infection is present antibiotics should be given in full doses.

Long-term Treatment

The long-term treatment of severely disabled asthmatics should be undertaken only after complete hospital investigation has been carried out with trial periods on corticoids and dummy tablets. It is important to bear in mind that patients who have been on even small doses of corticoids for more than a few weeks will have complete suppression of their suprarenal activity, and recovery of function will develop only slowly after the administration of corticoids has ceased. This means that under conditions of unusual physical or mental stress—for example, following surgery or during infection—such patients are unable to produce the additional secretion of corticoids which takes place under natural conditions when their output may be increased four or five times above the normal value. Inability to do this may lead to shock and sudden death, if additional corticoid substances are not provided on the day of and for some days after operation. Every patient on long-term corticoids will be well advised to carry a card stating the nature of the corticoid being used and the dose prescribed, with instructions to increase this by three or four times for 2–3 days in the event of emergency surgery, with gradual decrease to the usual maintenance dose over the next week.

.....Hospital	
CORTICOID THERAPY	
Name.....	Hospital No.....
Address	
.....	
This patient is taking regularly. It is important that the dose should not be decreased suddenly because the activity of her own suprarenal cortex is almost certainly depressed. In the event of any surgical emergency, the dose should be increased considerably for 48–96 hours after operation and then gradually reduced to the basic level.	
Signed	Date.....

In the same way during respiratory infection the dose of cortisone may need to be increased and antibiotics should be used at the same time.

If these precautions are kept in mind cortisone or prednisolone in small doses can transform the life of a severely incapacitated patient. In a number of cases under my care, a dose of 5 or 10 mg. of prednisolone has enabled them to carry out their occupation with only occasional loss of time from asthma over a period of two years or more, whereas previously they had required repeated admission to hospital in status asthmaticus and were disabled between attacks. Other cases may require 100 mg. of cortisone or 20 mg. of prednisolone to obtain reasonable relief, but side-effects will be proportionately increased. In some cases the effect of the preparation appears to diminish after a few months. Prednisolone has the advantage that salt is retained only to a small extent, and the tendency to put on weight is much less than with cortisone.

ORAL PENICILLIN IN GENERAL PRACTICE

BY

DAVID WHEATLEY, M.D.

Northern Home Counties Faculty, College of General Practitioners

Oral penicillin preparations have been in use for nine years, and yet the value of this method of giving the antibiotic is still the subject of considerable controversy. The reason for this may lie in the fact that oral penicillin therapy is almost exclusively administered by general practitioners rather than by hospital specialists. The former encounter innumerable obstacles in making public their observations, and hence there are few reports on the clinical use of oral penicillin. The paper by Chapple *et al.* (1956) is a notable exception to this.

On the other hand, from our hospitals have emanated a number of reports on the blood levels achieved with different oral penicillin preparations administered to healthy volunteers (Fairbrother and Daber, 1954; Laurance and Alder, 1954; Holborow *et al.*, 1956; Henry *et al.*, 1957; to mention but a few). The scarcity of reports on blood levels in ill patients is remarkable. In any case, blood levels are not necessarily related to therapeutic effect (*Brit. med. J.*, 1953). An article on the use of penicillin in sore throat included the statement that intramuscular penicillin rather than oral antibiotics was commonly used in practice for this complaint (Brumfit and Slater, 1957). In subsequent correspondence I suggested that, on the contrary, oral penicillin was probably used far more in general practice than penicillin by injection (Wheatley, 1957). Through the co-operation of the research committee and members of the Northern Home Counties Faculty of the C.G.P., I have now had an opportunity to verify this statement and to collect further information on the subject from those most intimately concerned with it.

Objects of the Investigation

The objects were to find out how much general practitioners use oral penicillin, for what purposes they use it, and in what form and dosage. It is difficult to assess objectively the merits of this form of treatment, yet I feel that after this length of time general practitioners are unlikely to go on using oral preparations if in fact they are useless.

The faculty consists of some 180 members and associates distributed throughout the four counties—Middlesex, Hertfordshire, Bedfordshire, and Essex. Therefore all types of practice ranging from rural Essex to suburban Middlesex are included in the area, which constitutes a fairly representative cross-section of the country as a whole. These doctors were all circulated with a questionnaire asking the following questions:

1. Do you use oral penicillin? Yes/No.
2. Do you use it for Adults/Children/Both?
3. For which of the following infections do you use it therapeutically? Tonsillitis. Acute otitis media. Pneumonia. Acute bronchitis. Any others? (please state which).
4. Do you use oral penicillin combined with a sulphonamide, and if so, for what infections?
5. What preparation(s) do you use?
6. What is your dosage regime?

	(a) Dose	(b) Interval Between Doses	(c) Average Length of Treatment
Adult ..	 units or mg.	 hours	 days
Children 0–5 ..	 units or mg.	 hours	 days

When once corticoid treatment has been instituted for some months, the problem of weaning the patient becomes a difficult one. After such treatment it can be taken that the suprarenal cortex will cease to function. Heavy stimulation with corticotrophin in such cases will produce a temporary rise in corticosteroid output, but even this may lead to exhaustion of the cortex, with symptoms of acute Addison's disease. Abrupt termination of treatment will often lead to severe status asthmaticus, and all patients should be warned of this. Reduction of the maintenance dose when it has been given for six months must be very gradual—say, $2\frac{1}{2}$ mg. of prednisolone every 2–3 weeks. In many cases the patient must be prepared to continue on maintenance corticoid therapy for life. For this reason it is obviously a form of treatment rarely advisable for children, who will, however, tolerate short courses well.

Long-acting corticotrophin given intramuscularly is an alternative form of treatment which is not complicated by suprarenal suppression. It has the disadvantage that it must be given by injection and that obesity like that in Cushing's disease, with increase of several stones in weight, often develops. In rare cases sensitization to the animal proteins which are present as an impurity may occur, with production of anaphylactic shock. Death from anaphylaxis, however, usually follows only intravenous administration of corticotrophin. 20–40 units of corticotrophin may be given daily or on alternate days with benefit, and many cases have been kept relatively free from attacks in this way.

Sedatives

The well-recognized fact that emotional factors play an important part in asthma suggests that sedative drugs may be useful. There is some evidence that sodium amytal or phenobarbitone in small regular doses may help the nervous asthmatic, but their main value appears to be in combating side-effects of sympathomimetic agents. In status asthmaticus paraldehyde 5 ml. intramuscularly, or 2–4 dr. (7–14 ml.) by mouth remains the safest and most effective sedative for use at night. Morphine is contraindicated because of its depressing action on the respiratory centre. Pethidine, though a less effective sedative, is a mild bronchodilator with some depressing effect on respiration; its total effect is to reduce the tidal volume in the majority of cases. It is, however, reasonable to give it in association with nalorphine (4 mg.) when discomfort is great and other treatment has failed.

Conclusion

In conclusion it may be said that drug therapy, though valuable in asthma, should never be used as an excuse for avoiding the careful investigation of the important precipitating factors in each case, nor should the use of drugs replace measures to improve the general health. The recognition of allergic sensitization, emotional stress, or infection, and their treatment, are always of primary importance, and may lead to long-lasting relief that drugs cannot achieve. In particular the use of corticoids as the first choice of treatment cannot be deprecated too strongly.

The wise administration of bronchodilators is a useful accessory to other forms of treatment. They help to give the patient confidence in relieving symptoms, and may help to break an "asthma habit." Sometimes, because of our ignorance of the underlying pathogenesis, they may provide the only effective treatment available. In the same way corticoids may be used to prevent attacks of status asthmaticus or to control them when they have developed, and in a few cases may convert a disabled, unhappy patient into a relatively normal person capable of carrying out a full day's work.

It must be remembered that the objective in treating asthma to-day is to teach the patient to control and live with his disease. To do this intelligently he must be taken into the doctor's confidence and given some explanation of the rationale of the treatment recommended.

7. Do you consider that oral penicillin as given by you for the infections stated is: (a) Better than, (b) comparable to, (c) worse than penicillin by injection.
8. Will you kindly record over a 20-day period the number of cases for which you prescribe sustained penicillin treatment: (a) orally, (b) by injection.

N.B.—By "oral penicillin" is meant penicillin to be swallowed in the form of tablets, capsules, or mixtures. This does not include penicillin lozenges or other forms of local medication.

Participants were asked to return the forms, whether or not they were oral-penicillin enthusiasts.

Eighty-five (47%) doctors agreed to take part in the investigation and sent in completed questionnaires, with the following results.

Use of Oral Penicillin

Eighty doctors (94%) replied that they used oral penicillin, against five who replied that they did not. Of the 80 doctors using it, 66 (82%) used it for both adults and children and 14 for children only. The number of patients treated orally and parenterally over a 20-day period were summated with the following totals: oral, 1,043 (73%); injections, 379 (27%). So that, for every two cases treated with penicillin by injection, five cases were treated orally.

The number of cases treated with penicillin over this period varied enormously from practice to practice. Thus one doctor treated the staggering total of 92 cases orally and 12 by injection, an average of five cases a day. At the other extreme one doctor treated only one case by injection during the period. Most replies, however, fell in the proportion shown by the total number of cases, with an average of 17 treated during the period. This amounts to almost one case a day, so it is apparent that a considerable amount of penicillin is used in general practice. It must also be pointed out that the survey was conducted during the month of May, which was a fairly slack period, and the figures would doubtless be higher for the winter months.

Infections Treated with Oral Penicillin

The four infections named in the questionnaire were correctly chosen as those for which oral penicillin was most often used, with furunculosis and boils coming very close to them. These and other conditions noted by the participants are shown below. The percentage of doctors treating each condition with oral penicillin is also shown:

Tonsillitis	91%
Acute otitis media	88%
Acute bronchitis	69%
Pneumonia	47%
Furunculosis and boils	44%
Finger infections	20%
Carbuncles, dental sepsis, acute sinusitis, scarlet fever, cellulitis (each)	6-10%
Upper respiratory infections, impetigo, phlebitis, mastitis, erysipelas, cervical adenitis, P.U.O., Vincent's angina (each)	3-5%
Urinary infections, bronchiectasis, acute pleurisy, acute conjunctivitis, acute laryngitis, vaginitis, Bartholinitis (each)	1%

Fifteen doctors volunteered the information that they used an initial "loading" dose of parenteral penicillin in the treatment of pneumonia or other infections if they were severe.

With regard to the use of oral penicillin combined with a sulphonamide, 17 (21%) doctors replied that they used this combination whereas 63 (79%) did not. Those using the combination did so for the following conditions:

Pneumonia	8 (47%)
If penicillin alone fails	5 (29%)
Acute bronchitis, acute otitis media (each)	5 (29%)
Boils and carbuncles	2 (11%)
Acute sinusitis, puerperal pyrexia, and chronic bronchitis (each)	1 (6%)

Choice of Preparation

Some doctors replied that they used more than one of the main varieties of oral penicillin, while some used one kind

for children and another for adults. As a result the figures shown below do not represent percentages of the total numbers replying, but the proportionate figures for the different preparations:

	Children	Adults
Penicillin V (phenoxymethyl-penicillin)	52 (65%)	60 (75%)
Benzathine penicillin	29 (36%)	8 (10%)
Penicillin G (benzylpenicillin)	16 (20%)	11 (14%)
Penicillin + probenecid	5 (6%)	3 (4%)
Penicillin V + sulphonamide combination	2 (2%)	3 (4%)
Benzathine penicillin + sulphonamide combination	1 (1%)	1 (1%)
Penicillin G + sulphonamide combination	3 (4%)	3 (4%)

It is seen, therefore, that penicillin V is "sweeping the field," since more doctors used this than they did all the other preparations put together. Three-quarters of the participants used penicillin V for adults, although for children benzathine penicillin still remained fairly popular. This is doubtless due to the fact that penicillin V was first introduced in the form of tablets and capsules, whereas the palatability and stability of benzathine penicillin mixtures had been established before the introduction of the former.

There is no clinical evidence that penicillin V is any more effective than penicillin G in twice the dosage. Certainly the latter, even in twice the dosage, remains less expensive than penicillin V, although the price of this preparation may fall with continued usage. Nevertheless it is obvious from this investigation that penicillin V is almost completely ousting penicillin G for oral therapy. Undoubtedly this is due to the fact that penicillin V is more acceptable to the profession owing to reports of higher and more consistent blood levels after its administration. However, as has already been pointed out, these reports have been mainly on healthy volunteers. There remains a need for a therapeutic trial in ill patients.

With regard to penicillin and sulphonamide combined preparations, it is apparent from the previous section that this form of therapy is not particularly popular. Of those using it, 47% made use of the proprietary combinations available, although it might be thought that the dose of penicillin in these is somewhat on the low side.

Dosage Schedules

The only distinction which need be made between the different preparations is between penicillin V and the others. Since approximately twice as much penicillin V is absorbed as either benzathine penicillin or penicillin G, lower dosage schedules would be expected for the former. Therefore various dosage schedules were tabulated for penicillin V and the others, with the numbers of doctors using each scheme.

The most important results from these tables can be summarized thus: *For children*: 66% of doctors used penicillin V in a dosage of 60 mg. three to six hourly, while 65% used the other preparations in a dosage of 125-187 mg. three to six hourly, which is two to three times the dose of penicillin V. Only 5-6% used an eight-hourly scheme for either preparation. *For adults*: 61% of doctors used penicillin V in a dosage of 125 mg. three to six hourly, which is precisely double the most popular dosage scheme for children. Only 4% used an eight-hourly schedule for penicillin V, and the numbers for the other preparations were too small for analysis.

With regard to duration of treatment, the following results were obtained:

	Children	Adults
3 days	6	4
4-5 "	53 (78%)	47 (78%)
6-7 "	7	7
10 "	2	2

In other words, 78% of doctors favoured treatment for four to five days, without distinction between children and adults.

Impressions of the Effectiveness of Oral Penicillin

The results were as follows:

Better than penicillin by injection	1	(75%)
Comparable to " " " "	59	
Worse than " " " "	20	(25%)

Of the 25% who considered oral penicillin to be less effective than penicillin by injection, one doctor stated that he was giving up using it orally. Of the others, several added their reasons for continuing to use it, the main one being dislike of giving injections to children. One doctor stated that he was allergic to injection solutions and so could not use them.

It is interesting to compare the dosage schedules used by those doctors who considered oral penicillin to be less effective than penicillin by injection. We can assume that an adequate dose of penicillin V is 60-125 mg. three to six hourly (the smaller dose corresponding to the shorter interval) for children, with double these doses for adults. For other penicillin preparations the doses are double those for penicillin V. We can also assume that at least four to five days' treatment is required for the simpler infections. By these criteria, eight out of these 20 doctors (40%) were using inadequate dosage, which might account for inferior results.

It is also instructive to see whether these 20 doctors were "practising what they preached," by noting whether they treated more cases by injection than by mouth. The results are illuminating: more by injection than orally, 6; more orally than by injection, 8; question not completed, 6. Of those treating more cases orally, the proportion of oral to injection recorded by three of them was very high—namely, 29:2, 92:12, and 7:0. The reason for this apparent anomaly is probably summed up in the words of one of these doctors: "Oral penicillin is only slightly less effective than intramuscular penicillin, a disadvantage greatly outweighed by its greater convenience, particularly with children."

Conclusions and Summary

The Northern Home Counties Faculty of the C.G.P. has some 180 members distributed in all types of practice. Of these, 85 (47%) agreed to answer a questionnaire on the use of oral penicillin in general practice.

It was found that oral penicillin was used by 92% of these doctors, of whom 82% used it for both children and adults and the remainder for children alone. The total proportion of cases treated orally to those by injection over a 20-day period in May was 5 to 2. It would seem likely that these results, coming from such varied practices as they do, are representative of national custom. This being so, it may well be that more penicillin is now given by mouth in this country than by injection.

Of the infections commonly treated with oral penicillin, tonsillitis (91%) and acute otitis media (88%) came first, with acute bronchitis (69%), pneumonia (47%), and minor boils (44%) next. Finger infections accounted for 20% and a large number of other miscellaneous conditions fell into the 1-10% range. These results reflect the common penicillin-sensitive infections met with in general practice, with the exception of severe deep-seated infections, such as carbuncles, which are probably best treated with penicillin by injection.

With regard to the preparations used, it is apparent that penicillin V (75% for adults, 65% for children) is "sweeping the field," although benzathine penicillin in its palatable liquid form still retains a place in the treatment of children (36%). Combined penicillin and sulphonamide therapy would not appear to be particu-

larly popular, only 21% of the participants using it. The indications were for serious infections such as pneumonia or other infections which had failed to respond to penicillin alone.

Dosage schedules used by the participants showed very wide variations. However, 66% of doctors used penicillin V in a dosage of 60 mg. three- to six-hourly for children of 0-5 years and 61% used double this dose for adults. The dose used for other preparations was two to three times the above for adults, the numbers being too small to analyse for children. This would seem to reflect fairly accurately the difference between the amount of penicillin V absorbed from the gastrointestinal tract and that absorbed from other penicillin salts. 78% of the participants favoured four to five days' treatment for the infections listed.

One doctor thought that oral penicillin was better than penicillin by injection; 75% of the participants found the two forms comparable. Of the 25% finding oral medication not as good as injection, 10% were probably using inadequate dosage. More of these doctors continued to use oral rather than injected penicillin, despite their impressions of the relative efficiency of the two methods. This is probably because they found oral penicillin to be effective enough to allow its advantages to overcome any slightly diminished therapeutic effect. However, it is apparent that the majority of general practitioners taking part in this survey were completely satisfied with the effectiveness of oral penicillin therapy.

This investigation could not have been undertaken without the co-operation of the following doctors who took part in it: G. S. Adams, M. S. Adams, E. Anthony, C. D. Baker, D. M. Baker, G. O. Barber, L. J. Blay, W. N. Booth, O. B. Brears, H. M. Brunt, R. B. Chalmers, D. S. Chowdhary, J. R. C. Clarke, M. B. Clynne, G. H. R. Curnock, J. A. Currie, D. Craddock, J. R. Dennis, H. B. Dykes, G. W. Everett, R. A. Fisher, E. D. Fox, R. P. Gammie, J. Z. Garson, J. C. Graves, J. D. Granger, D. Gregory, R. A. Haes, A. A. Hamza, B. H. du Heaume, J. E. Heggart, R. N. Herson, E. R. Herst, S. F. Hewitson, F. N. Hicks, H. Jarvis, J. D. S. Knight, M. Latner, R. Lawson, A. J. Levine, I. M. Librach, C. R. Lynn, G. McDonnell, J. H. Macpherson, G. Melotte, P. J. Mitchell, J. R. Mortimer, T. M. Moylett, P. D. Mulken, H. M. Murray, B. E. H. Neal, J. O. Newman, N. G. Nicholson, N. O. Patterson, N. L. Paros, J. T. Pemberton, A. G. Philip, P. B. Poole, S. M. Pruss, B. S. Quinn, W. Radcliffe, D. The Excerpta Medica Foundation, Amsterdam, announces the publication of a new monthly abstracting journal, devoted to rehabilitation. This forms Section XIX of the *Excerpta Medica* series. Its cost of production is aided by a grant from the Department of Health, Education, and Welfare of the U.S. Public Health Service. Annual subscription is \$15.

self that a definite danger to life or health exists, and should whenever possible have his opinion corroborated by at least one other practitioner. The effect of the operation must be fully explained to the patient, whose written consent should be obtained; if the patient is married, it would also be wise to explain the position to the spouse with a view to obtaining his or her consent.

However trivial or unjustified a practitioner may consider a complaint to an executive council, he is strongly advised, in the Society's report, to attend the Medical Service Committee hearing. "We know of instances when the practitioner has failed to attend, with the result that the evidence of the complainant, in the absence of the practitioner's rebutting evidence or explanation, has been accepted by the Committee."

NEW ACADEMIC YEAR

WELSH NATIONAL SCHOOL OF MEDICINE

The inaugural address for the new academic year at the Welsh National School of Medicine was given by Professor G. I. STRACHAN, emeritus professor of obstetrics in the School, at Cardiff on October 8. He reviewed some aspects of past professional life, and traced the factors—partly in the nature of the doctor's work and partly due to increasing Government control—that have led to its modification.

The Profession of Medicine

In the early nineteen-hundreds ours was a free profession, said Professor Strachan. The patient chose his own doctor and changed him when he thought fit, while an account for professional services was rendered from time to time. A doctor assumed a partner or an assistant at will, and on retirement or death the goodwill of his practice was sold to an appropriate successor. The doctor-patient relationship of mutual regard and trust was then an important feature of British medicine.

In 1911 the National Health Insurance Act was introduced. This required the wage earner and also his employer to contribute a weekly sum, and for this the former was entitled to receive appropriate medical treatment from the doctor of his choice. The Act was opposed by the British Medical Association, as it implied Government interference between patient and doctor. But only the wage earner was provided for; his family was not included under the benefits, neither were specialist or maternity services. For these reasons Government interference was not marked and a substantial degree of private practice persisted.

But in 1943 at the request of the Government Sir William Beveridge presented his report on national insurance as an integral part of the Welfare State. This established a comprehensive national health service which embraced everyone, rich and poor, and which provided for every kind of investigation and treatment—general, consultative, or hospital—together with all necessary drugs and appliances. These provisions were embodied in a Bill which became an Act of Parliament on July 4, 1948, the appointed day. The National Health Service represented a great upheaval in medical life and practice. The new Service was contributory, and, as it was taken advantage of by about 96% of the population, the Government now stood in a commanding position between doctor and patient. The doctor had now to look to the Government for all or almost all of his remuneration; he could not practise under the Service or take a partner or assistant without Government permission, while on death or retirement his successor was appointed by a committee. The Government took over all the public hospitals and became responsible for their maintenance. The honorary status of consultants ceased, and they were now remunerated on a sessional basis and at an annual salary. Rich and poor now sought hospital treatment, so that out-patient attendances rose sharply while waiting-lists became correspondingly congested. In general practice the "free" aspect of the Service stimulated patients literally

to storm the surgeries of their doctors, often for the most trifling of complaints.

One result of the National Health Service had been a degree of deterioration in the doctor-patient relationship as shown by unreasonable demands on the doctor's services and for particular remedies, by a tendency to lodge complaints against the doctor before the executive council, and by a grave increase in litigation. The effect of this had been to cause reference to hospital of minor cases, often unnecessarily, while hospital officers now tended to carry out their work under conditions of uncertainty and apprehension. Again, prescribing was to some extent supervised, and, while great latitude was allowed in this respect, undue prescribing of the more expensive drugs might result in a heavy fine if it was considered that a less expensive drug would have been equally effective.

Medical life had altered materially in the last half-century. The doctor's responsibilities had increased while his status had to some extent decreased; he was more open to criticism, and his choice of place to practise in might be restricted. On the other hand he had better facilities for diagnosis and treatment and he was still held in regard. The material rewards in medicine had never been great, and the main reward must always be in work well done. In spite of altered conditions a medical man could still lead a full and happy life.

CHARING CROSS HOSPITAL

The importance of maintaining private practice was stressed by Sir HARTLEY SHAWCROSS, Q.C., when he gave the inaugural address at the opening-day ceremony of Charing Cross Hospital Medical School on October 2.

Value of Private Practice

Sir HARTLEY said he had been impressed by the great changes which had taken place in the position of the medical practitioner in the last thirty years. His prospects to-day were much more encouraging. "It is sometimes said that the National Health Service is a danger to the integrity and independence of doctors," he said, "and of course there are doctrinaire people who would like to abolish private practice and to do away with pay beds, just as they would like to abolish the public schools in an effort to reduce us all to a rather dull and drab equality. These are dangers which will be guarded against. I believe that the possibility of private practice and the existence of the independent schools is something which it is vital to maintain against the encroaching power of the almighty State. It is most important that the medical profession and the teachers should not become the slaves of a bureaucracy or the pawns of politics."

In the last thirty years the concept of social service had become so widely recognized that the medical practitioner could to-day call on the assistance of many ancillary services. The medical profession was the most satisfying of all, offering the greatest prize of all. Indeed, Sir Hartley had himself contemplated a medical career in his youth and had visited one of the London teaching hospitals with this in mind before turning to the law. Referring to the decision to rebuild the hospital in Fulham, Sir Hartley recalled that when Charing Cross Hospital was established 100 years ago it had dealt with the sick poor in a very crowded area. Since then there had been a great move of population. Fulham was now the centre of a thickly populated area, but it was near enough to the centre of London and the University to offer the facilities of the other scientific studies at London University.

In his annual report the dean of the medical school, Professor W. J. HAMILTON, said that in August last year the board of governors had been asked by the Ministry of Health whether they would be prepared to build the new Charing Cross Hospital and Medical School on the site of the present Fulham Hospital, incorporating in the new hospital Fulham Maternity Hospital, the West London Hospital, and the present Charing Cross Hospital. They had

agreed, and in July the Minister of Health had given final approval. "The board are convinced," he said, "that with the good will and co-operation of all concerned, the new hospital and medical school will constitute a landmark not only of local pride but also of national and indeed international significance. Assurances have been given to the Ministry that an adequate hospital service can be provided for the Fulham area and that the staffs of the Fulham Hospital, Fulham Maternity Hospital, and West London Hospital will be welcomed to the new Charing Cross staff without the slightest detriment to their existing contracts and conditions of service." It was the intention of the board of governors that, when the building of the new hospital was completed, the residents of Fulham would have a fully comprehensive medical service backed by all the resources of a modern teaching hospital. The general practitioners of the Fulham district would have the opportunity of becoming closely associated with the hospital by taking advantage of the facilities available to them for x-ray and pathological examinations.

The prizes were then presented by Lady SHAWCROSS, and the appointment of Dr. N. F. MORRIS as professor of obstetrics and gynaecology was announced.

ROYAL FREE HOSPITAL

At the Royal Free Hospital School of Medicine prize-giving, held at the Senate House of London University on October 3, the inaugural address for the new session was delivered by Professor DOROTHY RUSSELL. Her subject was "Belief and Unbelief." After presenting the prizes and congratulating the winners, Professor RUSSELL emphasized that those who had not distinguished themselves academically knew perfectly well that in future life many non-prize-winners made extraordinarily successful doctors. This was where the important factor of personality came in. There were many who knew of the brilliant scholar who tragically failed to gain some coveted post which would seem well within his grasp, because for some reason he was felt to be uncongenial to the small, closed society which formed a hospital staff. Hence, in the medical profession particularly, academic prowess was not enough. It was necessary also to learn to be a good colleague and to be recognized as such.

A Spirit of Scientific Inquiry

She hoped that, in the student's training, account had been taken of the concept of integration, which implied a synoptic view of the preclinical and clinical years. This was easy to state in so many words, but peculiarly difficult when it came to teaching; and in most medical schools only a beginning had been made to the dovetailing of clinical and preclinical studies so as to do away with the usually abrupt transition from one to the other. Self-education was another most important ingredient in the clinical term of undergraduate experience. It should take the student whenever possible to the post-mortem room. However distasteful it might be to witness this form of demonstration on a subject who had been seen in the wards, it was the sole means of reaching the truth, or, at least, the closest approximation to the truth. This form of diagnosis stamped itself upon the student's memory and he had it as part of his background of experience for all time.

Professor Russell advised students who would take their share in the advance of medical science to be ready to challenge the printed word if it did not agree with their own observations. They should be most reluctant to accept dogmatic teaching, however attractive it might seem. This was an era in which the art of medicine was constantly being encroached upon by the advance of scientific knowledge into the wards. They should, above all, observe objectively in every way possible what they found in their patients and maintain a cautious attitude towards all unsubstantiated statements, however plausible; and they should be humble enough to admit uncertainty when every justifiable investi-

(Continued at foot of next column)

To-day's Drugs

In this column we publish from time to time authoritative notes on a selection of drugs in current use.

Delta-Stab Injection (Boots Pure Drug Co. Ltd.).—This preparation consists of prednisolone acetate 25 mg. per ml., put up in a sterile aqueous suspension for intra-articular injection. It is used for its anti-inflammatory effect in various forms of arthritis, particularly rheumatoid. Its efficacy compared with hydrocortisone acetate, given as an intra-articular injection, is difficult to evaluate. Milligram for milligram it is certainly no less effective, but it has not the 4 or 5 to 1 superiority seen with the oral preparations of prednisolone, and dosage by the intra-articular route is therefore much the same as with hydrocortisone acetate. Before injecting these hormones it is essential to be certain that secondary bacterial infection has not been superimposed on an inflamed rheumatoid joint.

N.H.S. basic price: 5 ml., 30s.

Epidexa (Thomas Kerfoot and Co. Ltd.).—This is a mixture of a chlorocresol with a quaternary ammonium salt intended for use as an antimycotic and bactericide. It is available as a liquid, a cream, or a powder. Although reports of clinical trials of this particular preparation do not seem to have appeared, one may well expect that it will possess antiseptic properties *in vitro* and presumably in clinical use. It is intended by the makers chiefly for fungus infections of the skin but also for bacterial infection.

In recent years many antiseptic preparations have been put forward for the treatment of ringworm infections of the skin. Their number and variety are some indication of their relative inefficiency in spite of their being most efficient when tested *in vitro*. This seems to indicate that fungicide preparations fail not because they do not kill the fungus but because they fail to penetrate, or because they are in some way inactivated on or in the skin. For this reason many dermatologists have little faith remaining in the production and trial of fresh fungicides, and it often seems that Whitfield's ointment has yet to be surpassed.

With these reservations one may comment that epidexa is well formulated. Dichlorocresol is known to have a definite, though not excessive, potentiality of sensitizing the skin, and for this reason should be used circumspectly. It might thus be unwise to apply to the apparently normal skin for a long period as prophylaxis against athlete's foot, since the risk of sensitization increases with long duration of contact.

N.H.S. basic price: liquid, 2 oz., 7s. 7d.; cream, 25 g., 8s. 6d.; powder, 25 g., 5s. 5d.

(Continued from preceding column)

gation had proved fruitless. It was worth devoting as much thought as possible to novel methods of tackling clinical problems. Medical students had been known to make interesting and substantial additions to medical knowledge by this very technique of devising new methods of interpreting abnormalities seen in their patients.

The dean, Dr. KATHARINE LLOYD-WILLIAMS, described the school's continuous growth since its foundation in a private house in Hunter Street in 1874. It was now one of the four largest medical schools in London. In its 84 years of history it had been the first to do many things, and it might well be the first of the teaching hospitals to go in for a completely new modern hospital designed and equipped for medicine to-day. This had been a "pipe dream" for some years, but on the new 15-acre site at Lawn Road, Hampstead, there was the chance to plan a new teaching hospital and school, the first of its kind in the country to be designed specifically for the purpose. There was the same determination to make a success of this as had been shown many years ago by the founders, and the future could be looked forward to with confidence.

Correspondence

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

R.M.B.F. Christmas Gifts Appeal

SIR,—Every autumn an appeal is made to members of the medical profession for contributions to the Christmas Gifts Fund organized by the Royal Medical Benevolent Fund.

To receive a gift at Christmastime is a joy to everyone, but particularly to those who are lonely or in need. To none is a gift more welcome than to those who have fallen on hard times. Our beneficiaries include colleagues who have met with misfortune, and widows and children who are often in desperate need when their breadwinner has been taken before he was able to make provision for them. A gift at Christmas will enable them to enjoy some of the traditional good cheer of the season.

I ask your readers once again to give generously. Contributions marked "Christmas Gifts" should be sent to the Secretary, Royal Medical Benevolent Fund, 1, Balliol House, Manor Fields, Putney, London, S.W.15.—I am, etc.,

HENRY TIDY,
President,
Royal Medical Benevolent Fund.

Premonition of Death

SIR,—The mystery of premonition of death, of which Dr. Arnold B. Cowan gives such a good example (*Journal*, September 27, p. 797), has interested me since I first came across it in 1949. At the time I was working in a large Arab refugee camp in Jordan. Amongst my many patients was a youth of 16, whom I knew well, who was suffering from pulmonary tuberculosis. We were able to confirm radiologically that the condition was not far advanced and clinically his condition did not give cause for undue anxiety, though facilities for treatment were unfortunately very limited. There were two noteworthy features about this boy—firstly, he was simple-minded and was regarded in fact as something of a joke by his friends and relations; secondly, he was a very devout Moslem. His father, a sheikh, had formerly been a man of some wealth, but the son had always eschewed material possessions and all he had earned had been given away to the poor.

Some weeks later, when he seemed physically no worse, rising very early in the morning he walked from end to end of the huge camp (in which dwelt some 17,000 people) bidding farewell to all he met and blessing them. He then walked about five miles (8 km.) to Jericho, where he had relatives, and repeated his action. Returning to his tent at the camp, where his father sat cross-legged upon the ground, he kissed him and invoked the blessing of Allah upon him; he then lay down with his head in his father's lap and died instantly. Later the boy came to be revered as something of a saint or *welee*.

I hope the Gradgrinds will not try to rationalize these things. Let us recognize that there are still imponderables behind both the jargon and the stupendous achievements of present-day medicine.—I am, etc.,

Southborough, Kent.

A. CAMERON.

SIR,—As a doctor's wife I am a regular reader of the *Journal*, and was very impressed by Dr. Arnold B. Cowan's letter on premonition of death (*Journal*, September 27, p. 797), because a similar thing happened to my own mother. She was dying of bronchitis and summoned the family round her because she would die that night. I did my best to dispel this idea and said I would see her the next morning. She replied, "You won't. I shall die soon after midnight to-night." She was perfectly lucid, said good-bye to all of

us, and asked numerous questions regarding outstanding matters. She died at 12.40 a.m. that night. It is conceivable that one might know one was going to die, but how do such people know when?—I am, etc.,

Gravesend, Kent.

MADLINE ALLEN.

Rational Use of Drugs

SIR,—On September 6 (p. 632) you publicized a preparation called "codelprone" in your "authoritative notes" on "To-day's Drugs." Your comment did not in fact go beyond the manufacturer's advertised claims for this mixture of prednisolone, meprobamate, and aluminium hydroxide. Where is the "up-to-date, informed, and expert commentary" (*Journal*, May 3) that we were promised? This is surely just the sort of mixture that should be condemned, a mixture of a drug of proved usefulness, the dose of which is critical, with a drug (meprobamate) which, though widely used, has still to find its place in therapeutics. The trouble with all such mixed tablets is, as has often been pointed out, that the dose of one constituent cannot be altered without also altering that of the others. If there is need for more "spasmolytic action" a larger dose of prednisolone must necessarily be given.

I write as one who is trying to teach the rational use of drugs to medical students and who had hoped that your series "To-day's Drugs" was going to be an innovation that could be recommended to them as a source of critical opinion. My hopes have been largely dashed, although I do not wish to imply that all your reports have been as uncritical as this one. On a number of previous occasions you have cautiously commented in an unfavourable way on polypharmaceutical preparations which are considerably less objectionable than codelprone.

To avoid misunderstanding I would say that I have collaborated in the past and am collaborating now with drug firms in the testing of new drugs, and I recognize the valuable part drug firms play in promoting effective therapy.

If your notes were to become really authoritative, criticism, or lack of mention, would prevent bad preparations from achieving the success which is a tribute to advertising skill rather than to therapeutic efficacy, while favourable comment might lead to your columns being quoted in the advertisements instead of the advertisements being quoted in your columns.—I am, etc.,

London, W.C.1.

D. R. LAURENCE.

Contradictory Statements

SIR,—I should like to draw attention to the following quotations. In the *British Medical Journal* of June 14 an advertisement facing p. 1414 states, "promptly and safely effective, Diamox makes predictable diuresis a matter of routine." (Their italics.) The *British National Formulary* 1957 (alternative edition) at p. 95 states: "Acetazolamide (Diamox) has proved to be of little value as a diuretic, since its effects are both unpredictable and relatively feeble."—I am, etc.,

Wellington, New Zealand.

R. G. PARK.

Myocardial Disease of Obscure Aetiology

SIR,—Your brief report of Dr. W. W. Bridgen's paper on "Myocardial Disease of Obscure Aetiology" delivered at the Annual Meeting of the B.M.A. in Birmingham, and Professor W. Melville Arnott's comments on the incidence in the Union of South Africa (*Journal*, July 26, p. 234), prompt us to record our experience in Durban. As a preliminary to a full study of the obscure myocardiopathies, we have analysed the case histories of 100 consecutive African patients admitted with congestive cardiac failure to one medical unit, as well as the results of post-mortem examinations of 225 consecutive cases dying from congestive failure. In both series the cause was undetermined in approximately 19%, the frequency of this group being

second only to those cases with rheumatic heart disease and subacute bacterial endocarditis taken together (see table).

	Clinical Material (%)	Necropsy Material (%)
Rheumatic heart disease and subacute bacterial endocarditis	30	27.4
Hypertensive heart disease	18	8.4
Tuberculous pericarditis and constrictive pericarditis	11	12.0
Syphilitic aortitis	8	12.0
Degenerative heart disease	4	4.0
Cor pulmonale	3	15.1
Miscellaneous	7	2.6
Unknown aetiology	19	18.5

Professor Arnott, whom we have consulted, would like to add that his comment regarding the probable incidence of these cases (50%) refers to Africa as a whole, particularly tropical Africa, and not to the Union alone.—We are, etc.,

E. B. ADAMS.

J. WAINWRIGHT.

Durban, South Africa.

Convulsions Complicating Anuria

SIR,—Mr. T. F. Redman and Dr. F. M. Parsons (*Journal*, September 13, p. 669) have drawn attention to the super-vention of epileptiform fits on the 17th day of an anuric episode and seek an explanation for its occurrence. One pertinent fact emerges. On the 12th day the patient had administered to her 100 g. of "zeo-carb. 225/Na." On that day she showed a negative balance of water amounting to 370 ml., but thereafter presumably water retention occurred in daily amounts of up to 1,300 ml. for the next four days, when convulsions supervened. Accompanying this retention was a marked fall in the plasma concentration of potassium and of sodium (the latter commencing to rise, however, on the 14th day, reaching approximately normal levels on the 17th). The blood pressure rose steeply on the 17th day—the day that fits supervened.

The exhibition of salt by Dieckmann¹ in the form of intravenous normal saline in a patient in early anuria produced comparable effects, since subsequent to its administration oedema, hypertension, and fits developed. This clinical experience has a counterpart in Hamburger's experimental work,² in which by varying the concentration of the extracellular fluid convulsions were precipitated. Seventeen days of anuria may plausibly have heightened the irritability of the cerebral cells. In this connexion it may be worth considering Goldblatt's recent suggestion³ that under certain circumstances a disturbance of the fluid and electrolyte balance, by some mechanism not yet understood, produces hypertension. In the case described by Mr. Redman and Dr. Parsons the rise in blood pressure was sufficiently marked to be regarded as possibly productive of hypertensive encephalopathy, which Byrom⁴ has demonstrated can result from the accompanying cerebral vascular spasm.—I am, etc.,

JOHN SOPHIAN.

Worthing.

Lichen Planus of the Mouth

SIR,—We were interested in Dr. W. W. Gunther's letter (*Journal*, August 2, p. 327) following our paper on "Lichen Planus of the Mouth" (*Journal*, April 26, p. 983), drawing attention to psoriasis involving the buccal mucous membrane. One of the cases we reported also had cutaneous psoriasis and Dr. Gunther wondered whether the mouth lesions in this case were psoriasis. In point of fact this patient did at one time have numerous cutaneous papules of lichen planus in addition to her long-standing typical psoriasis, and the buccal mucous membrane showed the white dots and streaks so typical of lichen planus.

Since our report another of the patients has developed an epithelioma. This case had previously had cutaneous lichen planus, but for 10 years the condition had been confined to the mouth. The epithelioma occurred on the side of the tongue at a site where there was a persistent patch of lichen planus. We have also recently seen another case, not included in the reported series, presenting with an epithelioma on the inner aspect of the cheek, in whom typical lichen planus streaks and spots were present, up to the edge of the neoplasm and also on the opposite cheek and on the lower lip. Neither case had been taking arsenic. We have therefore seen an epithelioma develop in association with lichen planus of the mouth in four patients.—We are, etc.,

Road Safety

SIR,—Your correspondent Mr. J. K. Stuart Bell (*Journal*, August 23, p. 512) called attention to the many years' delay in legislation regarding tuberculosis. This is now being stamped out.

I would like to point out another flagrant instance of apathy—that regarding road accidents. These are still increasing and are now the main hazard to life in young men. For instance, in the age group 15–25 there are about 10 times as many deaths from road accidents as from all forms of tuberculosis. And yet one of the main causes of these deaths—drinking in drivers and pedestrians—has been known for years and can be dealt with by legislation. From a local survey of fatal road accidents, already reported in your columns,¹ and since reinforced by similar reviews by the Road Research Laboratory,² half the deaths on the road from late accidents, and 10% of all road deaths, are associated with drinking. A speed limit was legalized years ago, and we now need an alcohol limit—a sort of Plimsoll safety-line of alcohol in the system. This will be increasingly necessary as newer and faster roads are built, if we are to avoid the alarming death rates abroad (double ours) in countries where such roads are in being.—I am, etc.,

N. I. SPRIGGS.

Leicester.

- 2 *Road Research*, 1957, 1958, p. 38. H.M.S.O., London.

SIR,—The fitting of splash flaps to all road vehicles is a safety measure which has become urgent owing to the higher speed of modern traffic. Stones thrown up by the rear wheels of fast-moving traffic can shatter windcreens and lamps, and damage the paintwork of following vehicles, which are also plastered with mud. Windcreens shattered in this way may be the reason for some unexplained fatal road accidents.

The flaps, fitted behind the front wheels, protect the undersurface of the car from much mud, and those fitted behind the rear wheels provide greater safety, and a cleaner trip, for the cars following behind. Such flaps are compulsory in Sweden for all vehicles, and in Norway for vans and lorries, I understand. The flaps are made in attractive designs carrying the car emblem or name, and some incorporate reflectors on the rear wheel flaps. Should we not follow Sweden's example and have them as a compulsory fitting for road vehicles?—I am, etc.,

Denham, Bucks

J. MYLES BICKERTON.

Contraception by Inhibition of Ovulation

SIR,—May I reply to some of the points in the letters by Dr. L. M. Franklin (*Journal*, September 20, p. 743) and Dr. G. R. Venning (*Journal*, September 27, p. 796)? I do not wish to do any more than to draw attention to the possibility that substances such as "enavid" may cause foetal abnormalities. It is common experience that substances and methods which have been in use for many years and which have initially been reported on favourably may eventually be condemned as dangerous. Deep x-ra-

therapy had become well established before Murphy¹ drew attention to the danger to the foetus in pregnant women. It is only very recently that the possible hazards of much smaller doses of irradiation have been appreciated. When studies of new drugs are carried out, there is a tendency to concentrate on the effect on the adult recipient, whilst the possibility of foetal damage may receive little attention. Indeed, resources and opportunities are seldom available to enable lesser abnormalities of the central nervous system such as might result from a disturbance of hormonal balance during pregnancy to be detected. This is particularly so in "underdeveloped countries."

Dr. Venning's contention that the taking of tablets would be discontinued with the onset of pregnancy is hardly valid. The women in the trial were taking 20 tablets during each menstrual cycle, beginning on the 5th day. If a woman were to become pregnant, she would not know this until the end of the cycle at the earliest, in practice often later. There is therefore a considerable risk that the contraceptive tablets would be taken during the critical organo-genetic period of foetal development. Dr. Venning also argues that "natural" substances such as progesterone are less likely to be harmful than "poisons" such as aminopterin. Such a distinction appears a trifle old-fashioned, since it is now known that substances such as aminopterin exert their effect by causing an imbalance of the normal metabolites. Moreover, Millen and Woollam² have shown "natural" substances such as vitamin A and cortisone can be markedly teratogenic in excess, whilst Duraiswami³ has shown a similar action in the case of insulin.

Dr. Franklin is, of course, correct in stating that there is a need to be able to control the size of the family in underdeveloped countries, as also in the more developed countries. There are, however, many neo-Malthusians who over-emphasize this aspect of the difficulties of backward countries and neglect the importance of economic factors.—I am, etc.,

London, S.W.17.

Why Are Medical Journals So Dull?

SIR.—I have thought a good deal about Dr. Richard Asher's brilliant article on the subject of medical journals (*Journal*, August 23, p. 502) and have now come to the conclusion that the proportion of its substance capable of undergoing full-scale scientific analysis without refutation is unlikely to be high enough to be of statistical significance; he would probably prefer me to say that a good deal of it is piffle.

A letter cannot, of course, be expected to cover the whole train of reasoning which has led me to this regrettable conclusion, but you may have room for one or two points. First, all journals such as yours must contain a proportion of scientific matter: this, to be of any value to scientists, must be expressed with the greatest possible precision. Hence the necessity for the scientist to write "sucrose" rather than "sugar" when he means sucrose, and "gustation" rather than the obvious alternative suggested by Dr. Asher, "taste," which has, in my dictionary, ten meanings as a noun alone. Again, Dr. Asher has brilliantly exhibited the art of making a statement which has no meaning in such a way that it sounds witty, wise, and incontrovertible. I refer of course to the remark that "ten men cannot write an article any more than ten men can drive a motor-car." It is surely at least equally true to say that one man can no more write an article than he can play a string quartet.

I do agree, however, with the general idea that too many comparatively useless articles are written, especially in specialist journals, and venture to suggest a very simple solution to this problem. If publications are to be considered when medical appointments especially as consultants are made, or when merit awards are allotted, it should

be the duty of the assessors to read the publications and to be prepared to bar a man as readily for inflicting dozens of turgid and unreadable papers on his professional colleagues as (and this seems to be the usual policy at present) for being modest enough to publish nothing except accounts of isolated peculiar or interesting incidents, until his experience really justifies it. This would immediately kill the idea that publication is a tedious hurdle that every doctor must surmount, like dissecting a dogfish.

In the matter of presentation, Dr. Asher is a past master of clinical description, and one of the few medical men writing to-day who can provide his readers with the maximum interest and entertainment which can be extracted from his subject; but a really fancy presentation, such as he used so successfully in his "A Woman with the Stiff Man Syndrome" (*Journal*, February 1, p. 265), is necessary only when the substance of the article is of no importance, just as a really fancy label is most useful to a wine merchant in helping him to sell poor stuff.

Briefly, Sir, my feeling in this matter is that certain types of scientific articles are, by their very nature, bound to be dull to anyone not specially versed in the branches of science under discussion; but they are, some of them, very good, and their authors considerably summarize them at the end, and you quite rightly give them pride of place in the *Journal*, reserving space later on for comment of all kinds, and for "General Articles and News," to which Dr. Asher has made such a characteristically outstanding contribution. Piffle it may be, but it was beautifully written.—I am, etc.,

Colchester.

J. N. FELL.

SIR.—I read Dr. Richard Asher's article "Why Are Medical Journals So Dull?" (*Journal*, August 23, p. 502) with great interest. In it he quite rightly places the blame for the low standard of articles fairly and squarely on the shoulders of the contributors, but I would suggest that at least part of the fault lies with the journals themselves. Dr. Asher correctly states that articles of a standard which would be rejected by the lay press are often tolerated. The real remedy lies in the hands of the editorial staff, who must bear the ultimate responsibility for the appearance and content of any journal. The situation would be greatly improved if they raised their standards, even at the risk of cutting a swathe through the copious crop of journals medical science sponsors. Indeed, in these days when there is scant leisure for reading, both a diminished frequency of publication and a decrease in the number of periodicals would surely be appreciated.

These remarks are not meant to imply that journals should publish only articles with exceptional literary merit, but that those which do appear should be informative and well written. To-day few articles are considered complete without statistics. As these are not always informative, let alone true to the facts which they are supposed to represent, they could in many cases be disposed of with beneficial results. As Mark Twain wrote: "There are three kinds of lies: lies, damned lies, and statistics." Finally, there is more scope for articles which stimulate ideas on the practical problems which occur in everyday medicine, and they are after all what most readers have to face.—I am, etc.,

Oxted, Surrey.

PAUL K. BUXTON.

Medical Education

SIR.—Your account of the conference of the Association for the Study of Medical Education (*Journal*, October 4, p. 851) prompts two comments. Professor G. A. G. Mitchell's remarks about failure rates might well be combined with Dr. J. R. Ellis's upon the Swedish approach: if we examine students after a period suitable to the more able, we shall have a high failure rate; if we allow a period of instruction appropriate to the less able, the brighter students will be encouraged in indolence.

Of multiple-choice questionnaires, the virtues are obvious and the vices too little regarded. As Sir George Pickering

so pertinently remarked, the form of examinations may determine the students' attitude to their studies. The short answer suggests a premium on factual knowledge, even where in fact the question is designed to test mental abilities. Further, the objectivity of marking suggests a spurious accuracy in assessment which no one claims for the essay question—spurious because it is very hard to be sure that in fact the skills needed to answer such questions are accurately related to the qualities sought in an industrious medical student. We have in this department a growing body of parallel tests upon students by essay question and multiple-choice questionnaire, which we hope in time to analyse; quite notable discrepancies arise at times, which, in combination with our knowledge of our students, suggest that our questionnaires, at any rate, are no panacea to the problems of examination.—I am, etc.,

Department of Physiology,
Manchester University.

J. N. MILLS.

SIR.—It is probably unfair to judge the value of the first conference of the Association for the Study of Medical Education on the necessarily short report in the *Journal* (October 4, p. 851). Even so, there seems reason to infer that the participants were all living in a Cloud-cuckoo-land. Thus, Sir George Pickering is reported as intimating that "medical faculties were interested not in training the student's mind but rather in his familiarity with the subject and its practical handling." And further on, "While it was nonsense to suppose that the subject-matter of an arts course was inherently more suitable for sharpening the wits than that of a science course, it was true that science faculties, including medicine, were smothering their students with technological detail." Reflection shows that, the more diagnostically and therapeutically efficient medicine becomes, the less it remains a "learned" profession. This is academically sad, but—let it not be forgotten—the State pays the piper of medical education and the State wants competent doctors, not reflective minds capable of "collecting facts, verifying them, arranging them, drawing conclusions, and testing... conclusions." Let us be honest with ourselves and ask how many persons on the *Medical Register* would be of greater value to themselves or to the community if they did possess these methodological powers. Indeed, Dr. J. N. Morris's surgeon, called on to deal with a crushed foot, was no better at the job because he was "surprised to find that in many factories there was a kind of collusion between management and labour to ignore safety measures." Sir Russell Brain's antithesis of "safe doctors" and "good doctors" is too vague to be significant: a good doctor must be a safe doctor because the doctor's job is an essentially practical one.

Dr. J. Z. Bowers, dean of the Medical School of Wisconsin, seems to have played an outstanding part in the only reform possible in these busy days: "the preparation of students for medical school had been broadened, the attitude being that science requirements should be held to a minimum... and that students should be encouraged to diversify their educational process." Here would appear to be a possibility of enabling the doctor to be an educated member of the community, not *qua* medical practitioner, but as a rounded human being.—I am, etc.,

London, W.1.

A. PINEY.

SIR.—By omitting half of one of the statements I made at the recent conference of the Association for the Study of Medical Education (*Journal*, October 4, p. 853) and removing my remarks from their context your report gives a wrong impression. My point was simply that if students are to be taught in the best clinical tradition, by example and experience, about certain aspects of social medicine this will need to be done in people's homes and in the community as well as in the teaching hospital. Such aspects have to do with the education of individuals and families—on smoking, for example, with the earlier detection of disease, the familial

repercussions of chronic disease, the continuing care of the chronic sick and the functions of multiple social services, the prevention of admission to hospital, etc. These things are important; and for them to be dealt with on a reality basis will mean extending our teaching outside the hospital. The principle of this is accepted by most medical schools and notably by the Universities of Edinburgh and Manchester.—I am, etc.,

London, E.1.

J. N. MORRIS.

Posture and Blood Pressure in Pregnancy

SIR.—I was very interested to read the letter from Drs. P. R. Boucher and Margaret J. Turpin (*Journal*, September 13, p. 693). During the last month I have been treating two pregnant women who had some increase in blood pressure warranting bed rest. Both had only a moderate fall in blood pressure during this time, and it was only after much deliberation that I allowed them up. In both, the following day, there was a considerable fall to normal levels when the blood pressure was recorded in the sitting position. Both these patients, however, had had rauwolfia, and I assumed that the postural factor had been potentiated by this treatment. I wonder if, in view of the possible toxæmia, the reported case had had hypotensive therapy.

Certainly the effect cannot be explained by pressure of the gravid uterus on the great vessels in the lying position, since although the effect is immediate it is maintained, and pressure on both vessels would be more effective in obstructing the flow in the vena cava and give rise to oedema of the legs instead of the relief obtained. Is it possible that the effect could be explained in terms of vasomotor instability causing postural hypotension in individuals with a tendency to this even before they have to cope with the increased circulating volume of pregnancy?

Like Drs. Boucher and Turpin, I am somewhat at a loss to know which figure to regard as the significant one.—I am, etc.,

Harrow-on-the-Hill,
Middlesex.

K. D. PHILLIPS.

Phenylketonuria

SIR.—I think your annotation on the treatment of phenylketonuria (*Journal*, September 20, p. 736) is a trifle pessimistic. There is still a lot to be learnt about the correct management of patients with this disease. It already seems likely that even with an early start some patients do not improve very much on intelligence and others at the same age do. This is not unlike the situation in cretinism, for, even if thyroid extract given in satisfactory dosage is started early, excellent physical results may be achieved without necessarily raising the mental age high enough for ordinary schooling. (Yet one of the late Dr. F. A. Cockayne's cretins won a scholarship in her "teens"!)

Unless a trial is made with a phenylalanine-low diet, it is at present difficult to tell what the response will be. At any rate in young subjects this seems the proper course, although, recently starting treatment late in a girl of nearly 7 years, we think we have pushed her up into the educationally subnormal level. You state: "It seems unfortunately to be the case that by the time phenylpyruvic amentia is established a low-phenylalanine diet is likely to raise a child's mental rating only from idiot to imbecile level, hardly a very gratifying achievement." A child seen since our last paper was completed refutes this. A boy aged 9 months had been attending the Hospital for Sick Children for eczema, and was referred to me for backwardness. My colleague, Mr. Stephen Coates, using the Griffiths scale, made his G.Q. intelligence level only 30 with a wide scatter (that is, almost an idiot). The child was in hospital for six weeks coming under control, and since then has been at home continuously. Six months after discharge his G.Q. was 55 and now at the age of nearly 2½ years it has reached 64, with some indication of levelling out at this point. He will be able to go to an E.S.N. school.

Even if the intelligence level is not satisfactorily raised, the affected children on a phenylalanine-low diet become less restless, more manageable, eczema (if present) improves, and fits (if present) may cease. Thus, when we have proposed stopping the diet to some patients they have begged to be allowed to continue. I feel that if such discouragement as your annotation expresses had been applied to the treatment of cretinism when thyroid extract was first introduced the effect might have been to deny certain cretins a relatively normal life. Ought we not to go on trying a little longer with the phenylketonurics? There is even a faint indication from American sources that tolerance to phenylalanine is acquired and that in some instances perhaps the diet may be discarded when the child reaches the "teenage."—I am, etc.,

Depressive States

SIR,—Dr. Robert Thompson (*Journal*, August 23, p. 510) asks "what can one give" to depressive cases if E.C.T. is withheld? The answer is the amphetamine group, the dose being dependent upon the patient and the preparation. Amphetamine sulphate is about one half as effective as desoxyephedrine or methylamphetamine.^{1,2}

In a comparison of the two treatments in recurring attacks of depression in the same patients, I found³ that, in 20 cases who were treated in 58 attacks, improvement occurred in different attacks with either E.C.T. or methylamphetamine in 14 cases; with E.C.T. but not with methylamphetamine in one case and with the reverse in three cases. Two cases showed no benefit from either treatment. One case treated in each of nine attacks showed improvement with E.C.T. in five attacks and with methylamphetamine in four.⁴ Subsequently he kept the preparation with him, warding off the attacks as they came. Comparison of mild cases treated by myself with E.C.T., 30 cases, or methylamphetamine, 42 cases, gave similar improvement rates of about 80% with each treatment,⁵ the oral methylamphetamine being used in doses of from 1.25 to 60 mg. daily, the larger quantities being divided into three doses before 1 p.m.⁶ Monro and Conitzer⁷ treating depressives in a mental hospital and not exceeding one half of my maximum dosage of methylamphetamine, found 34.5% improvement in 34 cases, but 78.1% in 200 cases with E.C.T. No marked improvements, and double the rate of slight improvements as with E.C.T., were obtained with this low dosage of methylamphetamine and with mental hospital patients.

A summary of the literature showed that of 1,616 cases, of all types of depression, marked improvement occurred in 63.9% with E.C.T. and in 33% with methylamphetamine.⁴ No improvement was seen in 8.7% treated with E.C.T. and in 23.4% with methylamphetamine. Somewhat similar results were found in involutional, manic, and anxiety depression, but reactive depression gave 53.3% marked improvement with methylamphetamine, and only 34.7% with E.C.T.

Although Dr. Gerald Garmany (*Journal*, August 9, p. 341) and Dr. Robert Thompson feel that no types but only degrees of depression exist, I have treated, with improvement, a patient whose constant level of depression was improved with ethisterone, but whose sudden attacks of more severe type were abolished by amphetamine. This one patient shows two types of depression relieved by different methods. In view of the distressing amnesia and other risks associated with E.C.T., I would like to suggest strongly again that, except in severe or suicidal cases, amphetamine should be tried initially, as marked improvement may be obtained with this treatment without resorting to the more inconvenient and serious electric convulsive therapy.—I am, etc.,

Clevedon, Somerset.

Iatrogenic Disease in Childhood

SIR,—I was pleased to read the report of Dr. A. White Franklin's address "Iatrogenic Disease in Childhood" (*Journal*, August 30, p. 559) because it draws attention to some undesirable features of our present medical practice. The child who undergoes a tonsillectomy or circumcision which might well have been omitted, or the child subjected to repeated painful procedures for some mild self-limiting disease, does not quickly forget. But the worst procedure of all was never mentioned—that is, the injection of radioactive materials into the body. What gives us the impression that "there's no real harm in it" when at the same time luminous watches and the shoe-fitting fluoroscopes are under suspicion as potential dangers? Is it not believed that there is no threshold for some of the harmful effects of ionizing radiations?—I am, etc.,

J. VACCARO.

Psychiatric Illness Among Asian Students

SIR,—Like Dr. M. N. Pai (*Journal*, September 13, p. 689), we have seen a number of Asian students with mental illness in the department of psychiatry of Manchester University. I am surprised he does not mention obsessional neurosis. The illness often takes the form of paralysing doubt which stifles any form of original thinking and brings the patient's work to a standstill. It occurs in men of basically insecure character—anankastic in Schneider's classification¹—and its development is favoured by the cultural, social, and sexual problems posed by Western society. The change from their own community, with its rules of endogamy and fixed social-religious order, to an open society with freer relationships between the sexes seems to be responsible. Many have distinct feelings of inferiority and hostility towards English people. A satisfactory doctor-patient relationship in psychotherapy is thereby prejudiced, and a notoriously intractable illness is rendered even more difficult to treat.—I am, etc.,

Manchester, 13.

Buzzers for Bed-wetters

SIR,—I wish to support the plea of Dr. D. Saklatvala (*Journal*, September 13, p. 690) for more humane means of treating bed-wetting. Since the great proportion of cases are psychoneurotic in origin, more investigation into the treatment of the underlying mental condition should be made. Waking the child up with buzzers will further exacerbate any emotional difficulties, since the child will be less able to cope with them through lack of sleep, and may lay the foundations for further hysterical or other phenomena.

Dr. Saklatvala's letter also gives a clue to the aberration responsible; the child has an aversion to water. This will give him a feeling of being short of something vitally necessary for life; his body will store up water during the day; and, when his subconscious control is relaxed in sleep, water will flood out of the tissues and be excreted into the bladder. The fears of the daytime will lead to an undue relaxation at night owing to exhaustion, and bed-wetting will result. This is exacerbated and perpetuated by starving the child of fluids at night.

I have never been disappointed in the general improvement in health and cure of this trouble after telling the parents to load the child with pints of fluid at all times during the day. It is difficult to persuade the parents to co-operate, but it can be done.—I am, etc.,

Reading.

G. H. GILFORD.

SIR,—I hasten to reassure Dr. P. Saklatvala (*Journal*, September 13, p. 690) that he is mistaken in assuming that "subtle unkindness" is implied in the management of nocturnal enuresis by a buzzer technique. Rather, orthodox

Obituary

D. N. NABARRO, M.D., F.R.C.P.

Dr. David Nabarro, consulting pathologist, to the Hospital for Sick Children, Great Ormond Street, London, died at his home in London on October 3. He was 84 years of age.

David Nunes Nabarro was born in London on February 27, 1874, and was educated at Owen's School in the City. He entered University College, London, with an Andrews scholarship, and from there went on to University College Hospital to receive his clinical training. He qualified M.R.C.S., L.R.C.P. in 1897, having previously taken the London B.Sc. in 1893 at the age of 19. He then obtained the London M.B. in 1898, having gained the Fuller exhibition in pathological anatomy and pathology, and proceeded to the M.D. in the following year, winning a gold medal for his thesis and the Clothworkers' Company's exhibition. Elected a Member of the Royal College of Physicians of London in 1901, the year in which he took the D.P.H. of the English Royal Colleges, he became a Fellow of the College in 1917. After holding the appointments of demonstrator of physiology and histology at University College and house-physician at University College Hospital, a period as a ship surgeon followed. He then returned to London and was assistant professor of pathology and lecturer in bacteriology at University College from 1899 to 1910. In 1900 he was elected a Fellow of the College, and at the time of his death was senior Fellow jointly with Professor M. W. Travers. In 1901–2 he was pathologist to the Evelina Hospital for Sick Children. Appointed a member of the Royal Society's commission on sleeping sickness in Uganda in 1903, he was the joint author, with Sir David Bruce, of the first, fourth, and fifth reports. With Sir David Bruce and Dr. Aldo Castellani he discovered the cause and mode of transmission of the disease. In 1907 he translated and edited Laveran and Mesnil's book, *Trypanosomes and Trypanosomiasis*. He was awarded scientific grants by the British Medical Association in 1905 and 1906 to help him conduct an "investigation of butter and butter substitutes for the presence or absence of the *B. tuberculosis*."

After a brief period as pathologist to the West Riding Asylum, Wakefield, Dr. Nabarro returned to London in 1912 and was appointed clinical pathologist to the Hospital for Sick Children, subsequently becoming director of the pathological department and medical officer in charge of the venereal diseases department. He retired in 1939. During his many years at the hospital he conducted an investigation of Sonne dysentery, following his work at Wakefield; he initiated the first children's venereal diseases clinic in 1917; and he started the biochemistry department in 1923. Other work at the hospital included the preparation of measles serum and its utilization, and the treatment of infantile general paralysis of the insane. For some 20 years from 1904 he was scientific assistant in pathology in the University of London.

He wrote many articles for the medical and scientific journals. Before he qualified in medicine he contributed an article to this *Journal*, jointly with Dr. (later, Sir) Leonard Hill, on the exchange of blood gases in brain and muscle in

management based upon fluid restriction, the exhibition of drugs which have side-effects, and arbitrary lifting at times when there is no conscious or unconscious desire to micturate seems not only "unkind" but calculated to perpetuate the disability by conditioning.

It is apparently not generally realized that the buzzer method of management does not train the child to awaken in response to impulses centrally received from the bladder but the diametric opposite—namely, to sleep continent and undisturbed throughout the night. Further, no fluid restrictions are placed upon the child either during or after treatment. Mowrer and Mowrer,¹ in reviewing a large series of enuretics treated by a "buzzer-like" method, stated that "personality changes when they occurred have universally been in a favourable direction." I am not aware of any published refutations of this observation. Finally, I wonder whether Dr. Saklatvala still persists with his plea for "more patience and less drama" when dealing with enuretics in the age group of 14–21 years.—I am, etc.,

Miners' Nystagmus

SIR,—I was interested in your leading article (*Journal*, September 20, p. 732) because in America, where lighting in mines is good and the central helmet lamp is universally used, the general opinion in 1948 was that no problem existed. As you say of this country, "miners' nystagmus has certainly decreased since the introduction of better illumination in mines."

Regarding a few other points: (1) That sufferers from the disease are less emotionally stable than those without, is surely to be expected. Bad lighting increases anxiety and stress, and the unstable show the symptoms first. (2) In the years 1930–3 the importance of working was paramount: none could afford sickness. They were driven by want. The number affected therefore decreased. (3) In the last world war men became exhausted, safety precautions were sometimes neglected and overlooked, and danger suspected in the dark is worse than danger seen. Money was abundant and work not imperative. The numbers therefore increased. (4) Every man has his breaking point and even a little stress endured for a lifetime may ultimately produce symptoms. It is worth considering that where a defect is socially acceptable and widely known there is apt to be hysterical contagion.—I am, etc.,

M. E. M. HERFORD.

Farnham Royal.

Mind the Zip

SIR,—A boy of 8 was brought to the casualty department with his foreskin caught in the zip fastener of his trousers. An attempt to release the foreskin by moving the slide of the zip only resulted in jamming the zip more tightly into the zip. Efforts to dismantle the zip were unsuccessful until it was found that, by cutting it across with scissors just below the place where it emerged from the slide, the slide could be removed quite easily, releasing the imprisoned foreskin.—I am, etc.,

D. L. HADLEY.

Portsmouth.

POINTS FROM LETTERS

Thoracic Outlet

Dr. M. B. LEITCH (Carlisle, Lanarkshire) writes: The term "Thoracic Outlet Compression Syndrome" used in the article by Professor C. G. Roh and Mr. A. Standeven (*Journal*, September 20, p. 709) is surely a misnomer. Is not the "outlet" of the thorax generally considered to be at the lower end: the upper end is the inlet. This may seem a trivial point, but it is one which leads to confusion when a patient is sent for x-ray examination of the thoracic "outlet."

states of rest and activity. At the age of 80 he produced a book entitled *Congenital Syphilis*, which ranks as a classic. He was a founder-member and a past-president of the Medical Society for the Study of Venereal Diseases; a past-president of the Association of Clinical Pathologists and the London Jewish Hospital Medical Society; an honorary member of the British Paediatric Association; and a corresponding member of the Société de Pathologie Exotique of Paris. He was also the senior member of the Pathological Society of Great Britain and Ireland. A member of the British Medical Association for nearly 60 years, he served as a vice-president of the Section of Pathology and Bacteriology when the Association held its Annual Meeting at Manchester in 1929. His hobbies were gardening and philately, in which he was an acknowledged expert on the stamps of the Falkland Dependencies. He married Miss Florence Nora Webster in 1914 and had one son and one daughter.

We are indebted to Mr. T. TWISTINGTON HIGGINS for the following appreciation: The death of David Nabarro removes from Great Ormond Street a familiar and universally beloved figure, and from British paediatrics a pioneer whose name will long be held in honoured memory. To his many friends his passing, even at a ripe old age, brings a deep sense of personal loss, for he was a most lovable character whose sprightly companionship endured. For me his friendship has been a treasured privilege for wellnigh half a century. Nabarro came to the Hospital for Sick Children in 1912 to concentrate on child pathology, which then included the growing science of bacteriology and was soon to incorporate biochemistry. His credentials were brilliant, his experience extensive, varied, and picturesque. The highest professional appointments were clearly within his scope, yet the potentialities of paediatric pathology lured him and at Great Ormond Street he found his *métier*. In accommodation which was far from palatial and on a salary which was certainly not princely, he built up a department unrivalled in its day and a reputation which will not fade.

Nabarro was extremely accurate in all his work; any report franked "D.N." was utterly reliable. Tireless in his devotion, the little white-coated figure, bristling with the armamentarium of his specialty and bustling around usually at the double, became a familiar feature of the wards; and the well-ordered "lab" in the bowels of the ancient building was the Mecca to which all problems could be taken with the certainty of a warm welcome and wise informed guidance. Colleagues trusted him implicitly, children loved him instinctively. In his gentle and wonderfully skilful hands even the dreaded needle lost its terrors. How much is owed in this respect alone to the standards of technique set by Nabarro! An early ploy was the institution of the clinic for syphilitic children which he ran himself. He did his own serology, and the weekly "Wassermann night" was an event which tended to disrupt the residents' evening meal—especially if things went wrong. The increasing lateness of the hour of his departure for home was a measure of the rapid expansion of the clinic's clientele. Congenital syphilis became for Nabarro an absorbing interest by no means confined to its clinical and serological fascination, but also in its sociological and humanitarian bearing. Many a mother tasted the milk of his human kindness. His book, based on a wealth of experience, now happily unrepeatable, will remain a gold-mine of reference.

But David Nabarro was no one-track man. His interests were many, his mind cultured. Widely travelled, an accomplished linguist and littérateur, and a lover of classical music, he was a delightful companion on a country walk or as host at his own table. No one could be a more stimulating and loyal friend. His home life was entirely happy, and he and his wife were rewarded deservedly in the achievements of their children. All who knew him best will share the sincerest sympathy for them at this time. Few men carry with them to the Great Beyond a richer harvest of the things that matter than David Nunes Nabarro.

B. E. S. writes: David Nabarro's death severs one of the last links with the great masters of Great Ormond Street in the early part of this century. During the years he worked at the hospital he saw many generations of young doctors pass through their training and a number graduate to the staff and become his colleagues. He was beloved by all, because his warm character, enthusiasm, and understanding eventually attracted everyone, even those who at first thought him rather an odd little figure as he scurried down the underground passages of the old hospital, for all the world like the White Rabbit in *Alice in Wonderland*. But Nab was always ready to help and advise young housemen and other members of the staff with wisdom, based on long experience, yet great enough to have visions of the future. The hospital will always be grateful to his energy and perspicacity, which gave birth to the pathological department under his guidance as its first director. Apart from routine work he had many interests. Research into the spread and prevention of dysentery, the supply of pure milk, and many other activities occupied his time, but he became best known to the outside world through his studies of congenital syphilis. This culminated in his *magnum opus*, which, like that of Verdi, appeared towards the end of his life. For years he had run a clinic dealing with this disease and was in charge of a ward tucked away so far from the rest of the hospital that the loneliness of the night nurses presented quite a problem. As a young man he was a member of the commission which went to Uganda to study trypanosomiasis, and it is probably true that he never received the recognition due to him for the discoveries made at that time. But he was modest, retiring, and not one to fight for his own rights, although always ready to champion those of others. He was a good example of a little man with a great heart. His old hospital and the pathological world will undoubtedly miss that familiar figure, and his many friends will always have their pleasant memories and smilingly venerate his name.

MARIE C. STOPES, D.Sc., Ph.D.

Marie Carmichael Stopes, D.Sc., Ph.D., noted for her pioneer work as an advocate of contraceptive practices in married life, died on October 2, aged 78. Marie Stopes's early books, published immediately after the first world war, discussed contraceptive techniques and the physical aspects of marriage with a candour unknown in those days, and her views and manner of expressing them were the cause of strong protest. Her books achieved an enormous circulation among ordinary people, to whose needs they appealed and for whom they were largely written. She started birth-control clinics in London, Leeds, and Aberdeen, and others inspired by her work also founded clinics. These eventually became united under the Family Planning Association.

Marie Stopes was by training a botanist. She gained the gold medal in junior and senior botany at University College, London, and took her B.Sc. and later her D.Sc. She graduated Ph.D. at Munich. In 1904 she became the first woman to be appointed to the scientific staff of Manchester University. In 1907 she went to Japan and during a year and a half at Tokyo University explored the country for fossils. She returned to Manchester as a lecturer in fossil botany. She was a fellow and sometime lecturer in palaeobotany at University College, London.

We are indebted to Mr. ALECK BOURNE for the following appreciation:

Dr. Marie Stopes had lived for more than 30 years before she devoted her energies to the propagation of knowledge of the control of conception. Though she was not a member of the medical profession she has contributed indirectly to the medical problems of pregnancy and labour complicated by certain associated diseases. At the University of London she graduated as a Doctor of Science with first-

class honours and a gold medal. Her chief interests during her earlier years were the study of the fossils of plants, which gained her election to the Geological and Linnean Societies and a reputation far beyond this country. Dr. Stopes worked first in London, then in Munich, where she took the Ph.D., and in Berlin, Japan, and Manchester, where she was appointed to a lectureship in palaeobotany, on which, by her scientific papers, she became a recognized authority. The unfortunate experience of her first marriage, annulled on account of its physical failure, turned her attention to the problems of marriage and thus to the prevention of contraception by the use of an obturator by the woman. Though other contraceptive methods had been practised for many years, her missionary zeal in publicizing her technique excited the massive opposition of orthodoxy, partly on religious grounds and perhaps more by her defiance of popular disapproval of public discussion of intimate sexual details. But Marie Stopes became a passionate pioneer and therefore a rebel against the established prejudices of the time.

Unlike the reformer in the fable by R. L. S. who "preached under the tree at noonday and was buried at dusk," she escaped the usual fate of a pioneer and pursued her mission with the courage that flourishes on antagonism. In 1918 she published her first book, *Married Love*, which dealt more with the difficulties of some marriages than with contraception, and later in the same year a forthright appeal for "birth control" in *Wise Parenthood*. She exposed the strain caused by the unwanted child, a yet further addition to a family already worried by economic difficulties, which could be avoided by the voluntary spacing of the children, whereby each birth would be welcomed. *Married Love* commanded an instant and enormous success because it was an entirely new presentation of some of the problems of difficult marriages and written in simple unscientific language which ordinary people could understand. In 1921 Dr. Stopes and her second husband devoted their own resources and the royalties accruing from her books to opening the "Mothers' Clinic for Constructive Birth-Control" in North London. This was the first clinic of its kind to be established in this country and probably the world. Other clinics rapidly followed, until now there is no large town without its consultative centre. Following her example other independent enthusiasts set up their own clinics which were united under the "Family Planning Association," but Dr. Stopes was a dominating personality who could not accept co-operation with other organizations in which she played no part. Nevertheless the association, inspired by her work, has developed into a national institution which now gives advice and practical help not only to women who desire to limit their families but also to those who are distressed by infertility. Slowly but with increasing conviction the whole world is coming to realize that, unless the growth of its population, now increasing at an alarming geometrical rate, can be controlled, it will, within measurable time, outstrip available food supplies, and by its national pressures, especially in Asia and Africa, ultimately lead to wars of expansion in relatively empty countries.

Dr. Stopes, far beyond her original mission, has led the way to a hoped-for solution of these world problems by focusing attention on the control of excessive births and, indirectly, stimulating research on the techniques of contraception. Though not strictly a disciple of Malthus, for she was concerned with the individual woman and family, her emphasis on the necessary control of conception may, and probably will, make it possible in future years to limit the population of the world to an optimum figure.

CHARLES M. FRIER, M.B., C.M.

Dr. Charles Frier, a Fellow of the British Medical Association, and well known at Headquarters as a representative at the Annual Representative Meeting over a very long period, died at his home at Grantham on September 24. He was 87 years of age.

Charles Matthew Frier was born on January 15, 1871, and was educated at Edinburgh University, where he graduated M.B., C.M. in 1892. After graduation he held the appointments of assistant house-surgeon at the Coventry and Warwickshire Hospital, house-surgeon at the Royal Surrey County Hospital, Guildford, and resident medical and surgical officer at Jaffray Hospital, a branch of the Birmingham General Hospital. A period as a ship surgeon followed before, in 1896, he settled in general practice at Grantham, where he remained for the rest of his life. For many years he was also surgeon to the Grantham and District Hospital. In the affairs of the British Medical Association Dr. Frier had an outstanding record. A member for fifty-nine years, he was first elected the representative of his Division at the Annual Representative Meeting in 1913, and from that year until 1953 was returned in a similar capacity on thirty-six occasions. He became the first president of the Lincolnshire Branch when it was formed in 1932, and previously he had been chairman and honorary secretary of the Kesteven Division. Earlier this year he was admitted to the newly established Roll of Fellows of the B.M.A. in recognition of his long service to the Association. He had also been a member of the Conference of Local Medical and Panel Committees for many years since its inauguration. He served on the Kesteven Executive Council for some time, and was honorary secretary of the Lincoln (Kesteven) Local Medical Committee until 1954. Dr. Frier was a popular member of the medical fraternity in Grantham and district, and in course of time came to be regarded as the friend of all and as one from whom guidance and help was to be had for the asking. He will be very much missed by his colleagues, his friends, and his former patients.

K. V. TRUBSHAW, M.B., F.R.C.S.Ed.

Mr. K. V. Trubshaw, for many years honorary surgeon to Chester Royal Infirmary, died on September 15, at Dolgellau, Merionethshire, where he had been living in retirement. He was 81 years of age.

Kenneth Vincent Trubshaw was born on December 22, 1876, the son of Dr. Alfred Trubshaw, and was educated at Epsom College. Receiving his clinical training at Guy's Hospital, he graduated M.B., B.S. from London University in 1901. He was elected F.R.C.S.Ed. in 1918. After graduation he held the appointments of house-physician to Sir Frederick Taylor and clinical assistant and house-surgeon to Sir Arbuthnot Lane at Guy's Hospital. Following a period as a ship surgeon, he joined his father in 1904 in general practice at Mold, Flintshire, where he remained until 1919. During the first world war he could not be released for military service, and conducted three men's practices single-handed. During this time he was in charge of Leeswood Hall military orthopaedic hospital, where he came into close contact with the late Sir Robert Jones and Dame Agnes Hunt. From 1919 to 1930 he was honorary surgeon on the staff of Chester Royal Infirmary. After leaving Chester he went to live at Dolgellau, and was appointed consultant surgeon to the local hospital, which received the benefit of his skilled service almost daily until 1939, when he was succeeded by Lieutenant-Colonel H. Bodley Scott, who outlived him by only five days.

R. W. E. and H. D. O. write: In the passing of Mr. K. V. Trubshaw the profession has lost a specialist who possessed an all-round knowledge of every branch of medicine—a rarity in this age of "watertight compartments." His experience in general practice served him well later as a surgeon. He was never in a hurry and his approach to a patient was always calm and modest, and so he gained the complete confidence of all concerned. His extreme care and consideration of every surgical problem gave him a clear concept of treatment and a high efficiency as an operator. He possessed a boundless energy. A keen athlete and sportsman, he had distinguished himself as a cricketer and Rugby player in his earlier years and continued to play tennis with vigour to the age of 65. When not engaged with

his professional work, he enjoyed occupying himself in his workshop and garden. A skilled mechanic, his handling of all sorts of tools and instruments was exceptionally dexterous. He was a very loyal colleague and maintained the highest traditions of the medical profession. He is survived by his wife and three daughters, who nursed him with loving and tender care during his last illness, and to them we extend our sympathy.

H. BODLEY SCOTT, O.B.E., F.R.C.S.Ed.

Lieutenant-Colonel H. Bodley Scott, formerly professor of surgery in the University of Rangoon, died at his home at Dolgellau, Merionethshire, on September 20. He was 75 years of age.

Herbert Bodley Scott was born on December 14, 1882. He received his medical training at St. Bartholomew's Hospital, and qualified M.R.C.S., L.R.C.P. in 1904. He was elected F.R.C.S.Ed. in 1923. After qualification he held the appointment of assistant house-surgeon at Salisbury Infirmary. In 1907 he entered the Indian Medical Service, in which he served for over 30 years, retiring with the rank of lieutenant-colonel in 1939. He was appointed O.B.E. in 1921 for services rendered during the operations in Waziristan. He is survived by his only daughter, to whom our sympathy is extended. Mrs. Bodley Scott died in 1956, and his only son was killed in 1940 while on active service in the second world war.

R. W. E. and H. D. O. write: Lieutenant-Colonel H. Bodley Scott from the start of his career took an active interest in surgery, and his success in this field led eventually to his appointment to the chair of surgery in Rangoon University, where he was held in high esteem both by his colleagues and by his students. He served throughout the first world war with an Indian cavalry regiment in Egypt and Mesopotamia. After his retirement from the I.M.S. he went to live at Dolgellau, and was appointed consultant surgeon on the staff of the local hospital, succeeding Mr. K. V. Trubshaw, who died only five days before he did. At the hospital he willingly gave his services and proved himself to be a first-class surgeon. Somewhat reserved and most discreet, he was courteous in his dealings with patients and staff. His military career had made him a man of action and few words, and to the end he led a busy life, keeping himself fully occupied in various pursuits around his country home.

W. H. LASLETT, M.C., M.B., Ch.B.

Dr. W. H. Laslett, who was in general practice at Farnworth, near Bolton, for over 40 years, died at his home there on September 6 after a long illness. He was 69 years of age.

William Henry Laslett was born on January 30, 1889, the son of Dr. T. G. Laslett, and was educated at Hutton School and at the Victoria University of Manchester, where he graduated M.B., Ch.B. in 1911. After graduation he held the appointment of house-surgeon at Rochdale Infirmary and St. Mary's Hospital, Manchester, before joining his father in general practice at Farnworth. After the outbreak of the first world war in 1914 he volunteered for service and was drafted to the South Staffordshire Regiment, and was mentioned in dispatches while in Gallipoli. Later, when a captain in the R.A.M.C. attached to the Royal West Surrey Regiment in France, he was awarded the Military Cross in 1918. At the end of the war he rejoined his father in practice. The extra work during the last severe influenza epidemic in all probability aggravated his illness. He was a very reserved man, hating publicity. He was a vice-president of the local amateur dramatic society and was also interested in chess, photography, and sport. Our sympathies go out to his widow and two daughters, and to his son, who is carrying on the practice.—J. F. S.

Sir BENNETT HANCE, K.C.M.G., K.C.I.E., O.B.E. M.D., F.R.C.S.Ed

H. H. E. writes: I would like to add a few words to the excellent obituary of Sir Bennett Hance which appeared in the *Journal* of September 20 (p. 745). Before the first world war, at Guy's Hospital, he was a popular, colourful personality, very much the leader in his "firm." We met again after the war on the North-West Frontier of India, where he was a civil surgeon and I was still on the military side. We collaborated in all the surgery there, and he was a stimulating person to work with, full of ideas and anxious to try new treatments. In addition to being civil surgeon he was superintendent of the local jail. At midnight in the middle of the hot weather he rang up and asked me to go with him to the jail, where rumour stated that irregular practices were being carried out. We found nothing, but the fact that the superintendent could visit the jail at that time of night certainly shook the staff and kept them on their toes. "J. B." (as he was called) told us once that when working in Vienna on one of his study leaves he had been psycho-analysed by Freud. I wonder if that experience had anything to do with his poise and zest? His innumerable kindnesses to young officers and others, both British and Indian, will never be known by other than the recipients—none of them could do anything to repay his kindness—but I am sure all retain happy memories of a delightful personality.

Medico-Legal

TRAUMA AND SARCOMA

On July 4 William Nunn, aged 49, a cowman, died in the Ipswich and East Suffolk Hospital from a metastasizing fibrosarcoma of his right femur. Four years previously he had been violently kicked by a cow just above his right knee, and at the inquest into his death, held by the Ipswich coroner, medical evidence was offered as to the relevance of this accident to the development of the sarcoma.

Kicked by a Cow

On a morning in October, 1954, Nunn was assisting the head cowman at Capel Hall Farm, Trimley St. Martin, where a herd of 65 cows was being tuberculin-tested in the milking parlour. Nunn walked up to the left side of one of the last animals to be tested, in order to remove a chain from a post near the cow's hind legs and attach it to another post. As he was fastening the chain the cow lashed out and gave him a very violent kick just above his right knee-cap so that he was knocked against the wall. He hobbled about until lunch-time, but left work then and did not return for some days. When he came back, the head cowman said Nunn showed him a "terrific bruise" just above his knee. Subsequently Nunn complained to him of pain in his knee after heavy work and in the second year sometimes of pain in the groin; occasionally his knee swelled up. Nunn's wife said they called in the doctor the day the accident occurred, but, despite treatment with a lotion, the knee remained always uncomfortable. Because of this and a recent increasing swelling around the knee he was sent in January, 1957, to an orthopaedic surgeon at the Ipswich and East Suffolk Hospital. There was then a swelling involving the lower part of the shaft of the right femur. On biopsy sarcoma was diagnosed and the leg was amputated through the upper part of the femur. Pathological examination of the femur showed a spherical tumour at its lower end 5 in. (12.7 cm.) in diameter, with the appearances of a fibrosarcoma. There were pathological fractures in the bone, but the exact site of origin of the tumour could not be determined.

Nunn made a good recovery from his operation, but by October secondary deposits were apparent in his chest. In February, 1958, a lump appeared in his right groin. He

was seen by the radiotherapist, but, as there were no symptoms, he was not given x-ray treatment. By June a large secondary deposit in the right lung was pressing on the mediastinum and he had palliative radiotherapy. He died on July 4.

Medical Opinion

At the inquest the orthopaedic surgeon, the radiotherapist, and the pathologist concerned in the case all gave their views on the possible relationship of the kick to the development of the fibrosarcoma. The surgeon said it was a fairly uncommon tumour. He had not seen many similar cases, but the lower end of the femur was the commoner site for the tumour. He knew of one recent case where injury and infection had preceded the growth, but it was impossible to say definitely whether the kick had caused Nunn's growth; equally it was impossible to deny that it might have done so. However, his own view was that it was more than a coincidence that the tumour had developed at the site of the kick. It had been a severe blow, and so far as could be seen the tumour had arisen at the exact site.

The radiotherapist said that, while medical opinion held generally that a causal connexion between trauma and tumour development was strongly improbable, it could not be excluded in a particular case. The pathologist thought most of the evidence was against such an association. There did occur, however, occasional cases in which a sarcoma appeared a few months or years after an injury to the bone at the particular site. This might be a chance association, but there were cases—though rare—in which the relation to injury appeared well established.

A verdict of accidental death was recorded.

Vital Statistics

Poliomyelitis Vaccine

By October 3 last 17.5 million doses of poliomyelitis vaccine had been distributed in Great Britain since the programme started in 1956. Of these, 5.7m. were British, and 11.8m. Salk-type. Up to the end of August 5.8m. children and adults in priority groups had received two doses of vaccine, and the number of doses then held in stock by local authorities was 3.2m. The Ministry of Health is recommending parents to avoid delay by accepting whatever vaccine is available locally.

Scotland in Second Quarter

The birth rate in Scotland during the second quarter of 1958 was 19.9 per 1,000 of the population, and was 0.4 above the rate for the preceding second quarter. The infant mortality rate was 27 per 1,000 registered live births, which was the same as in the corresponding quarter of 1957. The neonatal mortality rate was 19 per 1,000 live births, and was 1 below the rate for the preceding second quarter. The crude death rate was 11.8 per 1,000 of the population; this was 0.6 higher than in the second quarter of 1957 and 0.4 above the average of the corresponding quarters of the five previous years.

The mortality from bronchitis and pneumonia was high, with death rates of 34 and 37 per 100,000 of the population, respectively, compared with the average rate for the five previous years of 30 in each case. The number of deaths from tuberculosis was 118 for the respiratory system and 16 for other forms. Compared with the preceding second quarter these deaths were 20 fewer for respiratory tuberculosis and 1 more for other forms of tuberculosis. The 43 deaths attributed to the principal epidemic diseases included 36 from influenza, 6 from meningococcal infections, and 1 from measles. Deaths from violence numbered 667. Of these, 137 were due to road transport accidents. These deaths were 27 and 11, respectively, more than in the corresponding quarter of 1957.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the years 1949-57 are shown thus -----, the figures for 1958 thus ————. Except for the curves showing notifications in 1958, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Week Ending September 27

The largest fluctuations in the notifications of infectious diseases in England and Wales during the week ending September 27 were increases of 151 for measles, from 1,470 to 1,621, 109 for scarlet fever, from 434 to 543, 23 for dysentery, from 410 to 433, and decreases of 47 for whooping-cough, from 718 to 671, 22 for food-poisoning, from 369 to 347, and 21 for acute pneumonia, from 175 to 154.

The largest rise in the incidence of measles was 39 in Gloucestershire, from 38 to 77. A small rise in the incidence of scarlet fever was recorded throughout the country; the only large rise was 42 in Lancashire, from 53 to 95. The only fluctuation of note in the local trends of whooping-cough was a fall of 25 in Sussex, from 40 to 15. Two cases of diphtheria were notified, being the same number as in the preceding week.

The notifications of acute poliomyelitis numbered 95, and these were 6 more for paralytic and 10 more for non-paralytic cases than in the preceding week. The largest returns were Yorkshire West Riding 16 (Leeds C.B. 4, Rothwell U.D. 3, Bradford C.B. 2), Lancashire 14 (Manchester C.B. 6, Preston C.B. 2), London 10 (Bethnal Green 2, Stepney 2), and Devonshire 6 (Plymouth C.B. 6).

The largest centres of dysentery were Yorkshire West Riding 84 (Leeds C.B. 26, Barnsley C.B. 16), Lancashire 65 (Liverpool C.B. 16, Kirkby U.D. 13), London 64 (Islington 12, Deptford 10), and Warwickshire 34 (Coventry C.B. 20, Birmingham C.B. 12).

Fewer in Mental Hospitals

The number of patients in mental hospitals in England and Wales again fell in 1957, according to the Annual Report to the Board of Control (H.M.S.O., 9d.). There were 2,518 fewer than twelve months before, and at 146,962 the total was the lowest since 1949. But the rate of admission continues to increase. Last year admissions numbered 88,943 (45% readmissions), compared with 83,994 in 1956 and 55,856 in 1950. While voluntary admissions increased, admissions under certificate were fewer. In 1956, 78% of the admissions to designated mental hospitals were voluntary and 20% were under certificate. During 1957, voluntary admissions increased to 83%, and certified cases fell to 16%. Of the 82,778 patients discharged, 19,643 were listed as recovered, 54,054 were relieved, and 8,822 showed no improvement.

The number of student nurses in mental hospitals (excluding mental deficiency hospitals) continued to increase during the year, but a serious shortage of nursing staff remained. Whole-time staff numbered 20,903 and part-time staff 7,176 at the end of September, 1957, as compared with 20,358 and 6,937 a year earlier.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending September 20 (No. 38) and corresponding week 1957.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the whole of England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

† Includes primary and influenza pneumonia.
‡ Includes puerperal pyrexia.

Medical News

Insurance for Private G.P. Treatment.—The Fellowship for Freedom in Medicine has persuaded the British United Provident Association to launch an insurance scheme to help cover the cost of private treatment by general practitioners. Details of the scheme, which will come into operation on January 1, are due to be announced next month. While there already exist several excellent schemes for providing cover against the costs of treatment in a hospital or nursing-home and of specialist advice and investigation—such as those of B.U.P.A. itself, the London Association for Hospital Services (Hospital Service Plan), and the Western Provident Association—this is the first insurance scheme to offer cover in Britain against the cost of private treatment by a general practitioner. The new cover will be an option restricted to those already insured under B.U.P.A.'s standard scheme (for private beds, specialist fees, etc.), whereby for an additional rate a subscriber may obtain cover for himself and his dependants for attendance by a private general practitioner and for minor operations; as yet, the cost of drugs is not able to be included. The basic annual rates for a single subscriber (with additional rates for dependants) are on two scales: Scale A is £2 10s., allowing a payment of 12s. 6d. towards the G.P.'s fee; Scale B £4 15s., allowing a payment of 20s. Further information may be obtained from the B.U.P.A. offices at Provident House, 24-27, Essex Street, London, W.C.2, early in November. In the Channel Islands the Western Provident Association has a special scheme which includes insurance cover for private practitioners' fees, and it appears that this company is now thinking of following B.U.P.A.'s lead and offering a scheme applicable to Britain.

Restrictive Practices.—On October 6, at its first hearing, the Restrictive Practices Court began the examination of an agreement between all members of the Chemists' Federation. The main restriction before the Court was one whose principal purpose, according to the Federation, is to restrict the sale to the public of proprietary medicines to retail chemists and pharmacists. This, the Federation submitted, is not contrary to the public interest. The hearing arose from a reference by the registrar of restrictive trading agreements, under section 20 of the Restrictive Trade Practices Act, 1956 (*The Times*, October 7).

Middlesex Hospital.—Details of the new Middlesex Hospital Medical School were given by the dean, Professor B. W. WINDEYER, at the school's annual dinner at the Savoy Hotel on October 3. He announced that the school council had decided to name the residential college after Lord Astor and to call the large lecture theatre the Edward Lewis theatre. The latter is included in the first phase, now under construction. The dean said it would accommodate 180 and would be available for undergraduate meetings; it would have a fully equipped stage. The second-phase building was planned to give maximum flexibility for changes that might be necessary in the light of changing demands of teaching and research. It would complete the premedical and preclinical departments, and would also provide an improvement in school amenities and accommodation for the student health service. The third stage would be the residential college for 150 students.

King's College Hospital.—The annual dinner of past and present students of King's College Hospital was held at the Savoy Hotel on October 4. Dr. SYDNEY THOMSON presided over a large gathering. Dr. K. E. D. DAUNCEY proposed the toast of the Medical School and paid a tribute to the work of the dean, Dr. V. F. HALL, who gave a good report on the school. Sir CECIL WAKELEY proposed the toast of the chairman and Dr. THOMSON replied. On October 1 new medical and surgical units were inaugurated at the school. Dr. CLIFFORD HOYLE has been appointed part-time director of the medical unit, and Mr. HAROLD EDWARDS part-time director of the surgical unit.

Accidents to B.M.A. Members.—Details of the special accident insurance scheme available to B.M.A. members are given at p. 11 of the advertisements. The scheme was first announced at this year's Representative Meeting, and was welcomed in this *Journal* as "a new and most valuable practical benefit of membership of the B.M.A." (*Journal*, July 19, p. 150).

Symposium on Response to Injury.—Immediately following the Fourth International Congress of Biochemistry (*Journal*, September 20, p. 738), an international symposium on the biochemical response to injury was held under Dr. D. P. CUTHBERTSON's chairmanship at Semmering, in Austria, from September 7 to 12. It was attended by 24 research workers from nine countries, and the proceedings are to be published by Blackwell Scientific Publications Ltd. The symposium was organized by the Council for International Organizations of Medical Sciences with assistance from the Wellcome Trust and the International Union of Biochemistry.

New Medical Films.—Films recently released by pharmaceutical houses include "Simplified Urine Analysis," sponsored by Messrs. Ames Company (London) and introduced at its first showing on October 2 at the Royal Society of Medicine by Sir CECIL WAKELEY; "Management of Twins in Pregnancy and Labour" and "Routine Use of Ergometrine in the Third Stage of Labour," produced by the Wellcome Foundation's film unit and introduced at their first showing on October 8 by Professor W. C. W. NIXON; and "Prostatectomy under 'Fluothane,'" released by Imperial Chemical Industries Ltd. All these films are 16 mm. with colour and sound. Further details may be obtained from the sponsoring firms.

General Nursing Council.—Among those appointed by the Minister of Health to the General Nursing Council for England and Wales for the next five years are the following: Mr. P. H. CONSTABLE, secretary and house governor, St. George's Hospital, London; Dr. ALEXANDER WALK, physician superintendent, Cane Hill Hospital, Coulsdon; Dr. JOHN DOUGLAS, M.O.H. of Bradford; and Mr. BASIL HUME, formerly senior surgeon, St. Bartholomew's Hospital, London.

International Scientific Unions.—The Royal Society's delegation to the eighth general assembly of the International Council of Scientific Unions in Washington, October 2-6, was led by Sir RUDOLPH PETERS and included Professor A. V. HILL. The council is concerned with plans for the International Geophysical Year, future Antarctic research, and space research.

Polar Medal.—Colonel R. A. SMART, R.A.M.C., leader and medical officer of the Royal Society Antarctic Expedition for the International Geophysical Year, has been awarded a polar medal.

COMING EVENTS

Nurses and Midwives Conference.—Annual conference and the London Nursing Exhibition, October 13-17 at the Seymour Hall, London.

Annual Service for Doctors, Nurses, and Allied Professions.—Sunday, October 19, at 3 p.m. at Trinity Presbyterian Church, Unthank Road, Norwich. The preacher will be the LORD BISHOP OF NORWICH.

Leeds University, Faculty of Medicine.—The BISHOP OF BRADFORD will give the inaugural lecture at 3 p.m. on October 20. His subject will be "The Wholeness of Man."

Abortion Law Reform Association.—Public meeting, 7.15 p.m. on October 22 at Caxton Hall, Westminster, on "Our New Bill." Details from the secretary, 18, Wyatt Park Road, London, S.W.2.

27th General Hospital.—Annual reunion dinner at the Eccleston Hotel, London, S.W.1, October 25, at 7.15 p.m. Tickets (25s. inclusive) may be obtained from Mr. G. PUDNEY, 161, Silverleigh Road, Thornton Heath, Surrey.

Recent Advances in Cancer.—Week-end symposium for junior consultants, S.H.M.O.s, and senior registrars, October 25 and 26 at the Royal Marsden Hospital. Further details from the department of clinical studies, Royal Marsden Hospital, Fulham Road, London, S.W.3.

Faculty of Radiologists.—Provincial meeting in Sheffield on October 25. Details from Captain T. W. BARNARD, "Broom Cross," Tree Root Walk, Sheffield, 10.

Thomas Vicary Lecture.—Sir JOHN MCNEE will lecture on October 30 at 5 p.m. at the Royal College of Surgeons of England on "Barber-Surgeons in Great Britain and Ireland."

Association of Anaesthetists of Great Britain and Ireland.—Annual meeting, October 30 to November 1 in Southport. Further details from the honorary secretary, 47, Lincoln's Inn Fields, London, W.C.2.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lecture: marked ●. Application should be made first to the institution concerned.

Monday, October 13

BRISTOL YOUNG DOCTORS GROUP.—At Board Room, Bristol Royal Infirmary, 8 p.m., discussion: G.P. Trainee Scheme.
EDINBURGH UNIVERSITY.—At Anatomy Lecture Theatre, University New Buildings, 5 p.m., Inaugural Lecture by Professor W. L. M. Perry: Pharmacology and Practice of Medicine.
● INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—At Queen Charlotte's Hospital, 4.30 p.m., guest lecture by Professor Chassard Moir: Some Thoughts on the Technique of Caesarean Section.
LONDON UNIVERSITY.—At Physiology Lecture Theatre, St. Bartholomew's Hospital Medical College, 5.30 p.m., special university lecture in physiology by Professor W. F. Hamilton, Ph.D. (Georgia): Measurements of the Cardiac Output.
● ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Mr. F. B. Cockett: Post-thrombotic Syndrome of the Leg; 6.30 p.m., Mr. Clive Butler: Carcinoma of the Colon.
ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—5 p.m., Bengué Memorial Award Lecture by Dr. B. G. B. Lucas: Artificial Aids in the Control of the Circulation (illustrated).

Tuesday, October 14

HEATHERWOOD ORTHOPAEDIC HOSPITAL.—2.30 p.m., Professor G. Perkins: Radiodiagnosis of Bone Diseases.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. H. O'Meara: Sweat Production and Anomalies.
● INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—(1) At Hammersmith Hospital, 2 p.m., guest lecture by Colonel P. H. Addison: Legal Hazards in Obstetrics and Gynaecology. (2) At Hammersmith Hospital, 3 p.m., guest lecture by Professor C. V. Harrison: Obstetric Anuria.
LONDON UNIVERSITY.—At Physiology Lecture Theatre, St. Bartholomew's Hospital Medical College, 5.30 p.m., special university lecture in physiology by Professor W. F. Hamilton, Ph.D. (Georgia): Regulation of the Cardiac Output.
MANCHESTER MEDICAL SOCIETY.—(1) At Large Anatomy Theatre, Medical School, Manchester University, 4 for 4.30 p.m., University Lecture on the History of Medicine by Professor W. I. C. Morris: John and William Hunter, and their Polemics. (2) SECTION OF SURGERY.—At Staff House, Manchester University, 7.45 for 8 p.m., Presidential Address by Mr. H. T. Cox: Dumping Syndrome.
● ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Mr. H. C. Edwards: Disorders of the Jejunum-Ileum; 6.30 p.m., Mr. W. P. Cleland: Surgical Treatment of Acquired Valvular Disease of the Heart.
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Institute Disease in Pregnancy.
WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Dr. T. Rowland Hill: neurological demonstration.

Wednesday, October 15

BRITISH ASSOCIATION OF SPORT AND MEDICINE.—At Charing Cross Hospital Medical School, 5.30 p.m., Mr. Frank Law and Mr. M. J. Roper-Hall: Vision in Sport.
COLLEGE OF GENERAL PRACTITIONERS: NORTHERN HOME COUNTIES FACULTY.—At Lecture Theatre, St. Bartholomew's Hospital Medical College, 9 p.m., second annual Pfizer Lecture by Dr. E. F. Scowen: Some Difficulties in Prescribing.
EUGENICS SOCIETY.—At Royal Society, Burlington House, W., 5.30 p.m., Dr. Christopher Tietze: Human Fertility—Statistical Considerations.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. H. Haber: Histology of Normal Skin.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. A. B. Paterson: Development and Detection of Tuberculin Sensitivity.
INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Mr. A. H. Harkness: Non-gonococcal Urethritis.
LIVERPOOL UNIVERSITY: FACULTY OF MEDICINE.—At Large Lecture Theatre, New Medical School, Ashton Street, 5.15 p.m., Professor I. F. S. Mackay (Jamaica): Measurement of Arterial and Venous Valvular Incompetence.
LONDON UNIVERSITY.—At Physiology Lecture Theatre, St. Bartholomew's Hospital Medical College, 5.30 p.m., special university lecture in physiology by Professor W. F. Hamilton, Ph.D. (Georgia): Experimental Congestive Failure of the Circulation.
MANCHESTER MEDICAL SOCIETY.—At New Union Buildings, Oxford Road, 8.15 to 11 p.m., reception for Fellows and friends.
● MIDLAND MEDICAL SOCIETY.—At Birmingham Medical Institute, 7 for 7.30 p.m., annual dinner, 8.45 p.m., Address by Dr. T. F. Fox (Editor, *The Lancet*): Rewards and Follies.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., guest lecture by Dr. D. J. Bell: Carbohydrate Metabolism.
ROYAL COLLEGE OF SURGEONS OF EDINBURGH.—3.30 p.m., Mr. C. P. Wilson: Diverticula of the Pharynx.

● ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Mr. Sol. M. Cohen: Place of Sympathectomy procedures; 6.30 p.m., Mr. John Charnley: Fractures of the Femur.
WILKESDEN GENERAL HOSPITAL MEDICAL SOCIETY.—At Department of Physical Medicine, 8.45 p.m., Professor C. G. Rob: Arterial Reconstruction and its Effect on General Medicine.

Thursday, October 16

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At Beveridge Hall, Senate House, 5.30 p.m., Sir Edward Salisbury, F.R.S.: Influence of Botany on Health and Disease.
HONYMAN GILLESPIE LECTURES.—At Anatomy Theatre, University New Buildings, Teviot Place, Edinburgh, 5 p.m., Dr. D. V. Hubble: Auto-immunizing Thyroiditis.
HYPNOTHERAPY GROUP.—At Royal Society of Medicine, 8 p.m., Dr. Lindsay Neustatter: Homosexuality.
LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.—At Royal Free Hospital School of Medicine, 8 p.m., Dr. Jean Mackintosh: Future of Medical Women in the Public Health Service.
NORTH-WESTERN THORACIC SOCIETY.—At Clinical Science Buildings, Manchester, 5 p.m., Presidential Address by Dr. Robert Coope: Sundry and Manifest Changes.
ROYAL ANTHROPOLOGICAL INSTITUTE, 21, Bedford Square, London, W.C., 5.30 p.m., Dr. H. Lehmann: Abnormal Haemoglobins.
● ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Mr. H. R. T. Wolfe: Testicular Tumours; 6.30 p.m., Mr. Ashton Miller: Diverticula of the Bladder.
ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.—7.30 p.m., 1st Manson Oration by Sir Philip Manson-Bahr: The March of Tropical Medicine During the Last Fifty Years.

Friday, October 17

BRITISH INSTITUTE OF RADIOLOGY: Radiobiology Meeting, 2 to 4 p.m., papers by Dr. J. R. Munson, Miss T. Alper, Dr. N. E. Gillies, Dr. S. R. Pele, and Dr. W. B. Looney (U.S.A.): 4.15 to 5.30 p.m., papers by Dame Janet Vaughan and Dr. Maureen Owen and Mr. D. M. Taylor.
EDINBURGH UNIVERSITY.—At Anatomy Lecture Theatre, University New Buildings, 5 p.m., Inaugural Lecture by Professor J. I. P. James: Evolution of Orthopaedic Surgery.
● INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. G. B. Mitchell-Hogg: clinical demonstration.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. E. H. Hudson: clinical demonstration.
INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—3.30 p.m., clinical discussion for general practitioners by Mr. N. Asherson: Deafness.
KENT AND CANTERBURY HOSPITAL.—8 p.m., clinical meeting.
LEICESTER CHRISTIAN MEDICAL ASSOCIATION.—At Leicester Royal Infirmary, 8.45 p.m., Mr. S. G. Browne (Congo Belge): Sunshine and Shadow in the African Equatorial Forest.
MANCHESTER MEDICAL SOCIETY: SECTION OF ANAESTHETICS.—At Clinical Sciences Building, York Place, 4.30 for 5 p.m., joint meeting with North of England Society of Obstetricians and Gynaecologists. Dr. A. Mackenzie, Dr. E. G. Rees Jones, Dr. H. E. Pooler, Dr. Trevor Johnson, Mr. O. Vaughan Jones, and Professor T. N. A. Jellicote: Anaesthesia in Obstetrics.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—10 a.m., guest lecture by Professor G. Hadfield: Hormonal Control of Normal Mammary Glands.
● ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Mr. G. C. Knight: Cervical Disk Lesions; 6.30 p.m., Mr. Ralph Shacknan: Non-tuberculous Urinary Infections.
ROYAL MEDICO-CHIRURGICAL SOCIETY OF GLASGOW.—At Royal Faculty of Physicians and Surgeons of Glasgow, 8.30 p.m., joint meeting with Medico-Chirurgical Society of Edinburgh, discussion: Relative Importance of the Scientific and the Clinical in Medical Training. Openers, Professor M. Woodruff, Mr. Robert Mailer, and Dr. J. D. S. Cameron.

Saturday, October 18

BIOCHEMICAL SOCIETY.—At Chemistry Lecture Theatre, Royal College of Science, 2 p.m., 376th meeting.
SOUTH-EAST METROPOLITAN REGIONAL TUBERCULOSIS SOCIETY.—At Preston Hall Chest Hospital, Maidstone, 10.30 for 11 a.m., Mr. R. H. F. Brain: Oesophageal Disease and the Lung; Dr. G. R. W. N. Luntz: Diabetes and Tuberculosis; Dr. E. R. Jones and Dr. A. Golciewski: Demonstration of Pulmonary Function Tests; 2.30 p.m., annual general meeting.

Sunday, October 19

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—10.15 a.m. to 12.30 p.m., seminar, Mr. A. Radcliffe: Common E.N.T. Conditions.
MANCHESTER UNIVERSITY: FACULTY OF MEDICINE AND NORTH-WEST ENGLAND FACULTY: COLLEGE OF GENERAL PRACTITIONERS.—At Theatre 1, Clinical Sciences Building, York Place, 11 a.m., demonstration by Dr. J. F. Wilkinson: Blood Disorders.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Emson.—On September 7, 1958, at the University Hospital, Saskatoon, Canada, to Mary, (formerly Lewis) and Dr. Harry E. Emson, a daughter—Susan.

DEATHS

Howlett.—On September 16, 1958, at his home, Wimbledon, London, S.W., Michael Joseph Howlett, M.B., B.Ch.
Jones.—On September 19, 1958, the result of a road accident, Pauline Miriam Jones, M.B., B.Chir., of 16, Elmleigh Road, Weston-super-Mare, Somerset.
Keeling.—On September 20, 1958, at 12, Clevedon Road, Tilehurst, Reading, Berks, George Sydney Keeling, M.D., formerly of Attleborough, Norfolk, aged 85.
Oltway.—On September 19, 1958, at Londonderry, Alexander Loftus Oltway, M.B., B.Ch., D.P.H., Lieutenant-Colonel, R.A.M.C. (retired).
Rae.—On September 17, 1958, at Fownhope, Bromsrove, Worcs, Arthur Joseph Rae, M.R.C.S., I.R.C.P., aged 79.
Richard.—On September 15, 1958, in London, Kurt Simon Richard, M.R.C.S., I.R.C.P., of Welwyn Garden City, Herts.
Timms.—On September 15, 1958, at the Royal Falmouth Hospital, Hastings, Charles Gordon Timms, O.B.E., M.C., I.R.C.P.S.E.d., L.R.F.P.S.
Trubshaw.—On September 15, 1958, at Cusfaw, Llanfyllid, Dolgellau, Merioneth, Kenneth Vincent Trubshaw, M.B., F.R.C.S.E.d., aged 81.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Maternal Virus Infections and Congenital Heart Disease

Q.—What is the present view on the relationship between the incidence of congenital heart disease and maternal virus infections during pregnancy?

A.—It is generally accepted that there is a direct association between rubella and congenital cardiac malformations. In two British series^{1,2} the number of children with congenital heart disease was 3 in 11 when the mother contracted rubella in the first month of pregnancy, and 1 in 18 for the next two months of pregnancy. The cardiac malformations that occur particularly are patent ductus arteriosus (often with pulmonary stenosis) and ventricular septal defect. Rubella, however, probably accounts for only about 2% of all cases of congenital heart disease. No other maternal virus diseases have been definitely shown to be responsible for congenital cardiac malformations.

"Nivembin" for Amoebiasis

Q.—What is the value of nivembin (chloroquine sulphate and di-iodohydroxyquinoline) in the treatment of amoebiasis?

A.—Chloroquine is a good drug for the treatment of hepatic amoebiasis, a condition which occurs in acute form in association with amoebic dysentery and, in more chronic form, associated with abscess formation after an interval which may be prolonged, following an alimentary amoebic infection. In the latter case, however, an intensive course of chloroquine or emetine would be required probably together with aspiration of pus from the liver. Nivembin would not be a satisfactory drug for the treatment of such cases.

Di-iodohydroxyquinoline is of moderate usefulness in the treatment of patients passing cysts as the result of a sub-acute or chronic infection with *Entamoeba histolytica*. The relapse rate following such treatment is higher than that which follows the use of some other amoebicides. It therefore follows that nivembin has but limited application, for its di-iodohydroxyquinoline fraction is of very little value in acute amoebic dysentery in which the liver may be acutely infected and therefore apt to be benefited by the chloroquine constituent of the compound. On the other hand, in patients suffering primarily from amoebic abscess of the liver more chloroquine is required than can properly be given in the form of nivembin. The compound is another example of a blunderbuss remedy which aims to do two things, neither of which it does adequately.

Treatment of Chronic Prostatitis

Q.—What is the treatment for chronic prostatitis when no organisms have been isolated and the patient has had no chemotherapy?

A.—Treatment depends largely on the type of chronic prostatitis which is present. If it is a catarrhal chronic prostatitis, with a diffusely enlarged and uniformly boggy gland in which the prostatic secretion contains only a moderate number of pus cells, it is essential to prevent pelvic congestion and overaction of the prostate gland. Prostatic massage at fortnightly intervals combined with one of the long-acting sulphonamide drugs should clear up the chronic catarrh. Should massage be unsuccessful short-wave

diathermy or rectal diathermy may succeed. If the purulent type of prostatitis is present, in which the gland is irregular with alternating areas of induration and boggy, there will be numerous pus cells in the prostatic secretion. Prostatic massage at weekly intervals will drain the acini of pus, and the number of pus cells in the secretion will indicate the efficacy of the treatment. The seminal vesicles must be included in the massage, as they are invariably involved in the infection. Any organisms which may be cultured from the secretion must be typed for sensitivity and the appropriate antibiotics prescribed. If this type remains resistant to massage, diathermy may be tried, failing which a minimal perurethral resection to open up occluded prostatic ducts has proved successful in very resistant cases. It would be advisable to make sure that prostatic calculi are not maintaining infection. A radiograph of the pelvis would exclude calculi, while a urethral stricture, which may also initiate and maintain prostatic infection, should be excluded by urethrogram. If the infection has been present for some time and has become "burnt out," scar tissue replacing the inflammatory process, the sclerotic type of chronic prostatitis results. The gland is small and hard, the prostatic urethra is narrowed, and the bladder neck obstructed. In these cases a perurethral resection is indicated.

Life of the Tapeworm

Q.—What is the duration of life of a tapeworm if no treatment is given or if successive treatments fail?

A.—Tapeworms in general have long lives, and instances have been known in which untreated worms have lived for 15 to 16 years. No evidence is available on whether a worm's life is shortened by repeated treatment which fails to expel it from the host, but there is no reason to suppose that it is.

Fantus Test

Q.—What is the Fantus test for estimating urinary chloride excretion?

A.—Fantus's test is performed as follows. Using a dropping pipette, place 10 drops of approximately neutral urine and 1 drop of 20% potassium chromate in a test-tube. Wash the pipette out thoroughly with distilled water. Take into the pipette 2.9% silver nitrate and add dropwise to the urine while shaking. Count the number of drops needed to change the colour to brick red. This number expresses in grammes the content of sodium chloride per litre of urine. Physiological variations in urinary pH are not important, but strongly alkaline urine due to, e.g., cystitis should be approximately neutralized with acetic acid before use.

Undulant Fever

Q.—What is the treatment for undulant fever?

A.—Brucellosis or undulant fever has been successfully treated by sulphonamides, streptomycin, the tetracyclines, chloramphenicol, erythromycin, and novobiocin, but relapses are apt to follow treatment. Whereas extracellular brucella organisms are readily destroyed by antibiotics, intracellular organisms develop a satisfactory *modus vivendi*, finding a suitable medium for multiplication and protection against lethal phagocytosis and against antibiotics. This successful intracellular parasitism accounts for persistence and relapses of the infection despite treatment. Increased therapeutic success depends upon the future development of chemotherapeutic agents which penetrate the host cell easily and without injury or by some method of dislodging organisms from their intracellular position.

Initially, tetracycline should be given in doses of 2 g. daily for two weeks. Relapses, as they occur, may be controlled by further courses or by giving streptomycin in daily intramuscular doses of 2 g. together with tetracycline.

Alternatively, novobiocin may be used in daily oral doses of 2 g. for two weeks. In view of the numerous antibiotics now available for ringing the changes, it is often overlooked that brucellosis is a self-limiting disease and that most patients are free from the infection within a few months. Some continue to have symptoms during convalescence and need firm reassurance rather than further chemotherapy, unless a recurrence of fever heralds a relapse. This should be treated along the lines outlined above.

Occult Blood in Urine

Q.—What are the relative merits of a chemical test for the presence of occult blood in the urine, such as the "occultest" tablets made by Ames and Co., and routine microscopic examination of deposit as a screening check on each urine specimen?

A.—The tests for blood in urine were compared by Caplan and Discombe.¹ They record that the o-tolidine test, such as used in occultest tablets, will detect 5×10^4 cells per ml., equivalent to 0.15 mg. haemoglobin per 100 ml. urine; this figure has been confirmed by other workers. Routine microscopic examination of a centrifuged deposit will detect between 10^3 and 10^4 cells per ml. according to the details of the technique: if 12.5 ml. urine is centrifuged, 12 ml. removed, the cells resuspended in the residual 0.5 ml. and examined in a Fuchs-Rosenthal chamber, red blood cells will be detected when not more than 1,000 per ml. are present. If a drop of the deposit is placed between ordinary slide and coverglass the limiting frequency will be ten times greater—i.e., about 10,000 per ml.

NOTES AND COMMENTS

Treatment for Roundworms.—Dr. L. G. GOODWIN (Wellcome Laboratories of Tropical Medicine, London, N.W.1) writes: I raised the point on toxæmia and fluid balance ("Notes and Comments," August 16, p. 462) because too little attention has been given to this aspect of treatment. In territories such as the west coast of Ceylon, where roundworm infection is heavy, it is not at all uncommon for children to be admitted to hospital with "toxæmia" and convulsions caused by *Ascaris* without the classical signs of intestinal obstruction. Attention to fluid balance and a dose of piperazine (which narcotizes the worms and does not stimulate them) is often sufficient to bring about recovery. I recently saw two cases treated in this way by Dr. Stanley de Silva at the Lady Ridgeway Hospital in Colombo. The patients are usually pitiable, ill-nourished children who are very poor surgical risks. Sappenfield, Swartzwelder, and Miller¹ reported the successful use of piperazine given by intestinal tube in cases of partial intestinal obstruction caused by roundworms. Roundworms produce an evil-smelling secretion which can be smelt in the breath of heavily infected persons. Rashes and other sensitization phenomena are not uncommon in infected people in the tropics; many laboratory workers who handle the worms for any length of time become allergic to constituents of *Ascaris*. It is likely that some (though not all) cases of tropical eosinophilia are associated with *Ascaris* infection. It seems to me that *Ascaris* toxæmia requires more study, and it would be of value to have the views of physicians working in areas of heavy roundworm endemicity.

REFERENCE

- ¹ Sappenfield, R. W., Swartzwelder, C., and Miller, J. H., *Amer. J. trop. Med. Hyg.*, 1957, 6, 383.

OUR EXPERT replies: Dr. Goodwin is shifting his ground and raising issues which bear little relation to the original question ("Any Questions?" July 26, p. 260) or to his first comments on the answer given to that question. He then stated: "Small children are sometimes admitted to hospitals in the tropics with toxæmia, vomiting, and convulsions caused by massive *Ascaris* infections. These patients are often severely dehydrated. . . ." He now implies that attention to fluid balance is not uncommonly necessary even in the absence of vomiting or massive infections. Unless some degree of intestinal obstruction is present, however, it is very rare for children suffering only from ascariasis to be dehydrated. At all large hospitals in areas in which the infection is endemic many thousands of children will be encountered in whom a heavy *Ascaris* infection is present yet in whom no dehydration or manifest signs of toxæmia are found, and the vast majority can be

treated without more attention to fluid balance than is given to patients in general. Indeed, Dr. Goodwin indicates that factors other than ascariasis are probably playing some part in the production of the children's condition, for he mentions their pitiable, ill-nourished state. He also states that they constitute poor surgical risks. This implies that surgery has to be considered in such cases, and this implication accords ill with the contention that dehydration is the result of a non-massive infection in the absence of some degree of intestinal obstruction. The causal relationship between convulsions and toxæmia resulting from ascariasis which Dr. Goodwin assumes is doubted by very many workers in this field. Larval forms of the worm may occasionally reach the brain during their migratory phase, and consequently give rise to an epileptiform attack, but toxæmia produced by worms resident in the intestine cannot be accepted as a proved cause of convulsions. The cause of a convulsion may require detailed elucidation, and it is quite unjustifiable to implicate an *Ascaris* infection merely because such an infection happens to be present.

Brucella Abortus in Milk.—Dr. H. R. E. WALLIS (Bath) writes: Dr. J. M. Ross ("Notes and Comments," September 20, p. 754) clarifies the position from the point of view of the medical officer of health, but I should like to contest his statement that "the evidence suggests that most current cases of undulant fever are not due to ingestion of infected milk but to contact with infected material from occupational or other circumstances." This may be true in America, where many cases occur in people who handle meat, where better care is taken of milk than in this country, and where most of the published work appears. Reports in this country are few and far between, but during the past 20 years two milk-borne epidemics have been reported.^{1,2} Barrett and Rickards³ recorded 25 cases, of which 11 had no direct contact with infection, and in the other 14 milk may have been responsible. Davies⁴ reported 11 cases, of which seven were considered to be due to drinking raw milk, and in my own series⁵ of 10 cases in children there was only one who might have derived his infection from direct contact. Lastly, Dalrymple-Champneys,⁶ in his masterly review, considered 907 patients and found that only 123 had been specially exposed to direct contact with infected material, and in only 34 of these did he consider that was the probable mode of infection. This may seem an unimportant point, but it does serve to emphasize that raw milk is not safe even if it has a nice label saying "Tuberculin-tested" and a gold top to the bottle.

Correction.—Professor L. F. LARIONOV (Institute of Experimental Pathology and Therapy of Cancer, Moscow) writes to say that the four patients he described as being active and well after 9–10 years of maintenance chemotherapy (*Journal*, July 19, p. 160) were suffering from Hodgkin's disease, not leukaemia as stated in our report.

Collected Articles from the "British Medical Journal"

The following books are available through booksellers or from the Publishing Manager, B.M.A. House. Prices, which include postage, are now the same for both inland and overseas.

EFFECT OF SMALL DOSES OF ALCOHOL ON A SKILL RESEMBLING DRIVING

BY

G. C. DREW, M.A.*

W. P. COLQUHOUN, M.A., Ph.D.†

AND

HAZEL A. LONG, B.Sc.†

Department of Psychology, University of Bristol

Since the drinking of alcohol in one form or another is so common a characteristic of the social life of man in a variety of cultures, it would seem important that as much as possible should be known both of its physiological effects and of its effects on behaviour. In fact, at the present time, very little precise information is available, in spite of an extensive literature on the subject. This literature has been reviewed, more or less comprehensively, periodically since the early part of this century (Fisk, 1917; Darrow, 1929; Emerson, 1933; M.R.C. Alcohol Investigation Committee, 1938; Jellinek and McFarland, 1940; Drew, 1950).

The most striking feature to emerge from any such review is the marked lack of agreement between authors, amounting in many instances to direct contradiction of one another. This is especially true of the effects of smaller doses. Perhaps not surprisingly, doses of intoxicating strength have generally resulted in deterioration in efficiency in almost all aspects of behaviour tested. For doses below this level, however, the picture is not clear.

Some authors have reported deterioration in performance however small the dose, some have failed to find any effects, while several have shown actual improvements following doses of the order of one single whisky.

In part these discrepant findings reflect the unreliability of many of the results in this field, but in part they arise from the complexity of the effects of alcohol.

For moderate and intoxicating levels it has been established that the effect of alcohol is related to its concentration in the blood, and that the blood alcohol concentration obtained from a given ingested dose depends both on the body weight of the recipient and on the rate at which the alcohol is absorbed into the blood (Winton and Bayliss, 1948). The rate of absorption, in turn, has been found to be dependent on the amount, type, and the dilution of alcohol, the contents of the stomach, and the drinking habits of the individual (Goldberg, 1951).

Previous reports further suggest that, apart from a slowly developed tolerance to alcohol from repeated exposure to it over a number of years, known as habituation, there is also a more rapid adaptation to each dose consumed, so that it has a greater effect when the blood alcohol level is rising than when it is falling (Mellanby, 1919; Miles, 1924; Goldberg, 1951; Eggleston, 1955).

*Now at University College, London.

†Working with Medical Research Council grants.

The nature of the task used is also important. Goldberg (1943) has shown that some tasks are more readily impaired by a given dose than are others. Familiar tasks, too, deteriorate less than ones that are unfamiliar (Jellinek and McFarland, 1940). The method of measuring change in performance is often of great importance. The additional stimulation provided by a new task frequently enables the subject to compensate, for a short time, for conditions which have produced an overall reduction in his efficiency. For this reason, short interpolated tests may fail altogether to measure this deterioration and may show normal or even above normal efficiency (Drew, 1942). Reasonably long-lasting tests seem necessary unless the deficiency is a gross one. Welford (1951) has stressed the importance, for the analysis of skilled behaviour, of measuring different aspects of performance, since relatively gross measures may obscure changes in the way in which different actions are integrated in the final performance.

The wide individual variations in performance in response to alcohol remaining when the above factors are taken into account have been attributed to temperamental differences, and especially to those differences related to extraversion-introversion.

Differences along this dimension have been noted in other contexts. Extraverts have been shown to be relatively less concerned with accuracy of performance (Himmelweit, 1946), to deteriorate more rapidly during continuous work (Broadbent, 1956; Eysenck, 1957a), and to be less consistent in performance (Venables, 1956). It has, furthermore, often been noticed, when giving depressant drugs to psychiatric patients, that a given dose has a greater effect on patients with hysterical disorders than on anxiety and depressive patients. A theory postulating a greater amount of cortical control for introverts and a greater susceptibility of extraverts to depressant drugs due to the reduction of cortical control was first put forward by McDougall (1929) and has recently been extended by Eysenck (1957b). Experimental confirmation of the greater susceptibility of extraverts to the depressant action of amylobarbitone sodium has been published by Shagass (1954, 1956).

The aims of this experiment were to investigate the effect of small doses of alcohol on a complex skill, resembling driving; to relate any changes found to the level of blood alcohol; to see whether individual differences in response to alcohol could be explained in terms

spondence of the rise and fall through time of blood alcohol and tracking error is shown in Fig. 3. In this figure, tracking error scores are expressed as the mean score for each driving period. Blood alcohol concentrations have therefore been expressed in the same way. The rise and fall of urine alcohol, expressed similarly, have been included. The

FIG. 3.—Rise and fall of blood alcohol, error score, and urine alcohol with time after drinking. (Urine alcohol levels reduced by one-fifth.) Each point is mean of 40 subjects.

figure for urine alcohol has been reduced by one-fifth (in view of the ratio of 1.252:1) to enable it to be presented on the same scale. Although only the largest dose has been plotted, the data for the other doses follow the same pattern.

It can be seen that urine alcohol reaches a maximum about 20 minutes later than blood alcohol. The error curve looks as though its peak would occur somewhere between the two. The calculation of lag correlations confirms this. Maximum correlations are obtained when error scores are correlated with blood values some 10 minutes earlier, and with urine values some 10 minutes later. From this it would appear that maximum error slightly lags in time behind the maximum blood alcohol and slightly precedes maximum urine alcohol.

Product-moment correlation of the rise and fall of blood alcohol and the rise and fall of error is positive and significant. The mean correlation of the four paired values, calculated separately for each individual, is $r = +0.271$, with p lying between 0.01 and 0.02. The size of this correlation, though significant, seems small. It will be seen from Fig. 3 that there is a time lag between the two variables with an inverted relationship in periods 2-3. This, and the clustering of points in the second, third, and fourth driving periods, probably have reduced the size of the correlation. When blood alcohol values at five-minute intervals, obtained by interpolation from the individual curves, are correlated with the five-minute error scores, allowing a much smaller lag than the 20-minute scores, the correlation rises to $r = +0.89$. Because the test ends before blood alcohol has dropped very markedly, it is not possible from these scores to say whether error scores recover more quickly than blood alcohol levels, though inspection of Fig. 3 shows that the slope of error scores in the last half hour is steeper than for blood alcohol. The frequency of kerb-bumping rises steeply to a maximum, for each dose, with blood alcohol, and falls almost equally steeply after the maximum has been passed.

In an attempt to interpret the increased error with increased blood alcohol, records were sampled for mean position on the road surface, amount of swing about this position, and consistency of behaviour on corners. Significant differences were found. Without alcohol, subjects tended to drive on the left-hand side of the road, to remain

on that side for relatively long periods—that is, with relatively little “wobble”—and rapidly to correct swings to the right by moving back to the left once more. The effect of alcohol appears to be to produce a shift of the mean driving line from the left towards the crown of the road ($p < 0.01$). With increasing dosage there is an increasing swing or “wobble” about this new, more central position ($p < 0.01$), together with a tendency to tolerate swings to the right but rapidly to correct swings to the left ($p < 0.01$). There was, furthermore, greater variability in the positioning of the car in negotiating a corner ($p < 0.01$).

Effect of Alcohol on Speed

In this experiment there were no clear-cut group effects on speed of driving. Mean driving speeds are insignificantly different for all doses. Variability in speed around a mean shows a tendency to rise and fall through time with blood alcohol rise and fall, but this again is not significant. It is possible that the large effect of practice on speed is camouflaging any alcohol effect for the group. Changes in speed of driving after alcohol were found to be closely related to personality characteristics. These are discussed below.

Effect of Alcohol on Steering-wheel Movement

Like error, steering-wheel movement increases progressively as blood alcohol increases. The regression of amount of change of steering-wheel movement on blood alcohol is shown in Fig. 4. This regression is linear and is highly significant ($p < 0.001$). There is also a decrease in the consistency of steering-wheel movement after alcohol ($p < 0.01$). The decrease in consistency appears to be due to a greater variability in the timing of responses to a corner.

FIG. 4.—Regression of steering-wheel movement on blood alcohol level. Each point is mean of 80 paired values.

As might be expected, the amount of steering-wheel movement is related to the amount of tracking error made. The relationship is U-shaped, such that there is an optimum amount of movement for controlling the car, both less and more movement resulting in increased error. Following alcohol there is an increasing tendency to make either too little or too much movement in negotiating a particular corner, though the predominant effect is to make too much.

B. Individual Differences in Response to Alcohol

Although the latin square design used makes comparison of the performances of individuals difficult, certain features nevertheless emerge. There is undoubtedly a considerable range of individual variation in response to alcohol. This is summarized in Table II, which gives the number of subjects changing their score after alcohol by varying

TABLE II.—Number of Subjects Showing Different Percentage Change in Scores After Alcohol (Dose 4)

Measure	Percentage Change of Score													
	Decrease							Increase						
	-50	-40	-30	-20	-10	+10	+20	+30	+40	+50	+60	+70		
Error	1	0	2	2	5	10	12	4	2	2	—	—		
Steering-wheel movement	—	—	—	3	5	12	13	3	3	—	—	—		
Time	—	—	4	5	11	13	5	2	—	—	—	—	1	

amounts. The changes are expressed as percentage change from their own no-alcohol score. Tracking error shows a wide scatter. Though the distribution is fairly heavily skewed towards increased error after alcohol, 10 of the 40 subjects show reduced error, one as much as 50% reduction. This subject, however, showed also one of the largest reductions in speed, and achieved a high degree of accuracy by driving extremely slowly. Time scores, on the other hand, are distributed fairly normally around the “no change” position.

An attempt has been made to relate these individual differences in response to alcohol to various personal characteristics. No relationship was found between response to alcohol and differences in initial level of skill, previous driving experience, age, sex, or drinking habits. The subjects varied widely in their initial level of skill and in previous driving experience, so the lack of relationship between these variables and alcohol effect may be stated with some confidence. The range of drinking habits, however, was small, so that the comparison was between the few individuals who drank once or twice a week and those who drank very

shown in the effect of alcohol on speed of driving. The extraverts showed very little change of speed after alcohol, but the introverts changed considerably. The nearer the introvert end of the scale they were, the more speed changed. They subdivided, however, into two distinct groups, one of which speeded up very considerably, and the other slowed down. It has not so far been possible to relate this to any personal characteristics. Fig. 6 shows the regression of change of speed on extraversion-introversion as measured by the Bernreuter Neurotic Inventory. This regression is linear and is significant at the 5% level. Comparing those scoring more than 50 on the Bernreuter with those scoring less than this in terms of whether they change speed by more or less than 8 units gives a χ^2 significant at better than 0.01. It would appear that personality characteristics—at least those of the extravert-introvert dimension—are related to the effects of alcohol.

DISCUSSION

It is now generally agreed that a relationship exists between the concentration of alcohol in the blood and the appearance of clinical signs of intoxication. The definition of intoxication based on clinical evidence is, however, a variable one.

Liljestrand (1940) gives evidence of a considerable variation in diagnoses made by different clinicians on people who all had blood alcohol concentrations between 100 and 150 mg. per 100 ml. Moreover, the range of blood alcohol concentrations at which people are judged intoxicated is very wide. Goldberg (1951) has shown that the level at which 50% of people are judged clinically to be intoxicated varies with the legal definition in different countries. In America it has been defined by the National Safety Council as 150 mg. per 100 ml., in Sweden it is 100-120 mg. per 100 ml., and in Denmark and Norway 80 mg. per 100 ml.

The level of alcohol in the blood at which people are diagnosed clinically to be intoxicated, besides being variable, tends to be high in comparison with the concentrations used here. This is not surprising, since an estimate of impaired behaviour is made in the absence of any criterion of normal behaviour for that individual, so that the impairment must be obvious before it is detected, and since it is known that people can compensate for their reduced efficiency over the short periods of time during which they are examined. It does not follow, however, that, because no impairment is found in clinical tests, more complex skills, like driving, will also be unaffected.

The present study shows that performance begins to deteriorate with very low blood alcohol concentrations, certainly of the order of 20-30 mg. per 100 ml., and that the deterioration is progressive and linearly related to blood alcohol level. There is, in this study, no evidence of a threshold effect.

The impairment of performance was shown most clearly in the operation of the controls. As the aim of the task was primarily to track, it is perhaps not surprising that in attempting to retain a level of accuracy the operation of the steering-wheel should be most affected. Efficiency in using the steering-wheel is indicated by the amount of tracking error which results. With practice the amount of steering-wheel movement made goes down without a reduction in the accuracy of tracking, whereas after alcohol tracking error increases despite an increase in steering-wheel movement. This suggests that timing of the steering-wheel movements required to negotiate a corner supports this view. The importance of timing of control movements in a

FIG. 5.—Comparison of the tracking error of extraverts and introverts under no alcohol and dose 4 conditions. Extraverts $n=7$; introverts $n=9$.

rarely. The range was therefore too small to draw conclusions on the lack of relationship.

Scores obtained, for 35 subjects, on the extraversion scale of the Maudsley Personality Inventory were well distributed. The mean was 10.24 (sigma 4.53) as compared with the standard norm of 10.94 (sigma 4.74). Performance scores were compared for a group of subjects scoring high in extraversion and a group scoring low. Fig. 5 shows the mean differences in tracking performance between the resulting seven extraverts and nine introverts. The extravert group made more error ($p < 0.05$), were less consistent in car positioning ($p < 0.05$), and showed a bigger increase in error during each period of driving ($p < 0.01$). The effect of alcohol on error was greater for the extravert group ($p < 0.05$), the extraverts having an average increase of 23% and the introverts of 6%.

FIG. 6.—Regression of change of speed after alcohol on extravert-introvert score. Each point plotted is mean of five subjects.

complex skill has been stressed previously by Bartlett (1943), and adverse conditions such as fatigue have been shown to have a marked effect on timing (Drew, 1942; Russell Davis, 1948).

The work of Cohen *et al.* (1958) is interesting additional evidence. While the task used in this present study reasonably reflects the tracking aspect of driving, it is almost completely free of hazard and risk-taking. These authors have shown that an amount of alcohol not much larger than the biggest dose used in this experiment produced a significant increase in the hazards in which drivers became involved. From the two studies it is reasonable to assume that not only will drivers become involved in greater hazards with this amount of alcohol but they will be less efficient in dealing with them.

It is suggested, furthermore, that the results reported here show that the level of alcohol in the blood is a good indicator of the extent of impairment of performance. It may be pointed out that the blood alcohol levels reported by Cohen *et al.* (1958) seem surprisingly low. Assuming their drivers to weigh rather more than 11 stone (70 kg.), on average, their two doses correspond fairly closely to the smallest and biggest used here. Their blood samples, however, would appear to have been taken almost two hours after subjects began to drink. If this is so, the blood alcohol levels correspond very closely to those found here. They report a concentration of 4 mg. and 58 mg. per 100 ml. for the two doses. At two hours comparable figures in this experiment were 6 mg. and 62 mg. per 100 ml.

While this in no way affects the conclusions reached by these authors about the effect of such doses on performance, it does affect their discussion about "safe" levels of blood alcohol. At the time of the tests the blood alcohol levels in their drivers would almost certainly be at least 10-20 mg. per 100 ml. higher than those reported. Even so, their experiments, and these, suggest a marked impairment of performance on such tasks with blood alcohol levels of 60 to 80 mg. per 100 ml.

In view of the known difficulty of clinical estimates of impairment in such situations, and of the individual's capacity, if he is capable of realizing that he is under test, to compensate temporarily for loss of efficiency, estimation of blood alcohol level would seem the most direct way of assessing impairment. Estimation of the alcohol excreted in urine and in breath allows a close approximation to blood alcohol. In these experiments, urine alcohol agreed very closely with blood alcohol. Breath analysis, which has enormous administrative advantages over both blood and urine analysis, can, from these results, given a suitable instrument, also give a very close approximation.

It would seem fairly clear, from these results, that the efficiency with which a task like driving is performed is likely to decrease progressively as blood alcohol rises. At some point the loss of efficiency is likely to be large enough to constitute a danger in a practical driving situation. As this experiment has been carried out in a laboratory, necessarily free of the hazards and many of the motivating features of a real-life situation, it is not possible, from these results, to say at what level of blood alcohol the increased risk of accident would become unacceptable. Some evidence on this is available from the experience of the U.S.A., Denmark, Norway, and Sweden, where rather different cut-off levels are used.

Individual differences in response to alcohol appear to be related, at least in part, to personality characteristics, especially those of extraversion-introversion. Eysenck (1953) has collected the evidence for the existence of this dimension of personality and has postulated (Eysenck, 1957a) that extraverts would be more susceptible to the effects of depressant drugs like alcohol. The extraverts in this experiment behaved as a group, and tend to confirm Eysenck's hypothesis. The introverts do not behave as a group. It is of interest that all the scales used agreed on the extravert end but did not agree on the introverts. It is possible that the almost bimodal effect noted on change of speed for introverts

reflects the intrusion of some other personality characteristic not tested in this experiment. The test which showed this bimodal effect most clearly was the Bernreuter, which uses a more "neurotic" criterion of introversion than the Maudsley.

In this experiment extraverts appear not to be bothered by the extra stress imposed by alcohol. They drive at much the same speed as before, make very little additional corrective movements, but make much greater error, are less consistent, and deteriorate more rapidly during 20-minute driving periods. Introverts, on the other hand, appear to be striving to compensate for the alcohol effect, and to be anxious to demonstrate their efficiency. They over-react to the situation, make more corrective movements of the steering-wheel, and change their speed markedly. Some slow right down, presumably in an attempt to achieve accuracy, though they do not necessarily do so, while others appear to be attempting to demonstrate how quickly they can drive, again not always with a proportionate loss of efficiency.

SUMMARY

An experiment has been carried out to investigate the effects of small doses of alcohol on a complex skill.

Four alcohol doses and a placebo dose were used. The peak blood alcohol concentrations from the doses were approximately 20, 40, 60, and 80 mg./100 ml. of blood.

Urine and breath analyses were compared with direct blood analysis. Urine alcohol peaked later and higher than blood, but breath alcohol followed blood alcohol in time. The ratio of urine alcohol to blood alcohol was 1.252:1.

Three kinds of breath-testing apparatus were used. Best results were obtained from the "breathalyser." The others either showed high constant errors or were unreliable. The results from the breathalyser were good enough to warrant its consideration from a practical point of view.

Mean error showed an increase with increase in blood alcohol, amounting to about 16% deterioration with a blood alcohol concentration of some 80 mg./100 ml. Part at least of the increase in error is to be explained by a significant tendency for subjects to move towards the right-hand side of the road after alcohol and also by less consistent positioning. Error scores and control movement scores also showed a variation in time, rising and falling in a way similar to that of blood alcohol.

Mean speed showed no significant change, but marked individual differences in speed after alcohol were found.

Control movements, as measured by steering-wheel movement, showed significant increases and a significant reduction in consistency.

Age, sex, previous driving experience, and previous drinking habits, within the limits available, showed no relation to individual differences in response to alcohol.

Personality ratings, especially those relating to extraversion-introversion, showed a definite relation to behaviour changes. Extraverts did not change either speed or control movements very much, though they were less consistent in control movements, but showed large increases in error. Introverts changed speed considerably, though it is not possible to differentiate between those who slowed down and those who speeded up. Control movements also increased, but were relatively consistent. Error may or may not increase, but the mean error score was significantly less than that for extraverts.

APPENDIX

Average Scores For Various Aspects of the Tracking Task, After Each Alcohol Dose

Performance Variable	Dose 0	Dose 1	Dose 2	Dose 3	Dose 4
Tracking error	227	230	235	246	246
Kerb bumpings	209	255	350	260	359
Inconsistency in tracking	4.82	5.08	5.63	5.78	5.53
Time per lap	403	390	386	393	398
Steering-wheel movement	674	673	690	708	764
Inconsistency in steering-wheel movement	3.61	3.51	3.61	4.03	4.15

We should like to express our thanks to the Medical Research Council, who supported this work; also to the Director and his staff at the Road Research Laboratory of the Department of Scientific and Industrial Research, who provided us with accommodation, subjects, and much of the apparatus, and who were unfailing in their help and advice. We are indebted to Mr. E. B. Parkes, the Director of the S.W. Forensic Science Laboratory, and to Mr. K. Jones, of that laboratory, for their help in the analysis of body fluids carried out by Mrs. A. Myers.

The World Health Organization has published its eighth annual volume of vital statistics of various countries for the year 1955 (699 pp., £3). The number of subjects has been increased in order to make possible a more thorough analysis of the factors influencing public health. In some 700 pages the report includes, in addition to the subjects usually covered, detailed specific death rates, by sex and by age, for the main sites of malignant neoplasms (lungs, digestive organs, breast and genital organs, lymphatic and haematopoietic tissues). It also presents for the first time a type of information previously unobtainable—namely, the distribution of cases of communicable disease by sex and by age. Among some other statistics not previously included are the numbers of health personnel in various countries, hospital establishments, and numbers vaccinated against certain communicable diseases in 1955.

SIMPLE CLINICAL HEARING-TESTS FOR VERY YOUNG OR MENTALLY RETARDED CHILDREN

BY

MARY D. SHERIDAN, M.A., M.D., D.C.H.
 Medical Officer, Ministry of Health

In the course of an inquiry into problems of deaf and partially deaf children in mental deficiency hospitals and occupation centres carried out during 1955, it became apparent that there was need for a series of graded clinical hearing-tests, suitable for routine application by medical officers and psychologists concerned with official ascertainment of handicapped children, which could be repeated at intervals by different examiners and recorded in some standard fashion. Originally, with the intention of obtaining results as precise as possible, some form of instrumental testing was envisaged, and numerous trials were laboriously carried out with drums, whistles, pitch-pipes, tuning-forks, and, in a few cases, with pure-tone audiometers; but it was soon obvious that the difficulties of routine testing of mentally handicapped children with what were, to them, completely meaningless sounds were insurmountable. Since, in any case, the aim was primarily to obtain reliable information concerning the child's capacity to hear with comprehension in everyday situations, it became clear that the tests should be based on his reactions to familiar homely sounds and particularly to "live" speech. It is hoped to give in detail elsewhere the reasons for employing each individual item in the present series.

This paper is intended only to describe the general principles underlying the tests, the materials used, the procedure which was eventually decided upon, and the responses which may be expected. In order to establish comparative developmental standards, it was found necessary to keep checking the performance of mentally handicapped children against that of young normal children attending day nurseries and infant schools, and in the process it was discovered that in these groups, also, the tests could usefully be employed for sorting out children with difficulties of hearing and speech. The tests can be carried out in any quiet room, and the material required is easily obtainable. They are simple enough in content to be readily grasped by young children, but when correctly applied provide clear-cut evidence regarding capacity for auditory discrimination. Since it is essential for adequate assessment to observe how the child responds, the tests should be carried out personally by the medical examiner (or psychologist) or in his presence. They are not intended at this stage for large-scale application by ancillary personnel. Suitable techniques are already available for this purpose (Ewing, 1957).

Categories of Hearing-tests

The hearing-tests for children at present in use fall into two broad categories: (1) those which are designed as preliminary screening devices, first to sort out as quickly and effectively as possible children whose speech and hearing is below the normal for their age and who therefore require further investigation, and then to provide a means of recording results for future reference; and (2) those more precise diagnostic procedures which seek to define more accurately the nature and extent of the speech and hearing disability.

Considerable research has been carried out in Britain on both types of test, notably by the Ewings and their team of workers (Ewing, 1930, 1957; Ewing and Ewing, 1944, 1947), Fry and Kerridge (1939), Dix and Hallpike (1947, 1952), Whetnall (1952, 1956a, 1956b), Fry and Whetnall (1954), Fisch (1955), Dawson *et al.* (1956), and Thomson (1956).

Although I derived much useful information from the published reports then available, few of the tests in use were found to be suited to my purpose owing to the limited intelligence and restricted experience of the children whose needs prompted my own investigations. Statistical evaluation of the tests here described is not possible or desirable. The mental age levels given are approximate, and, although in practice the series provides a considerable amount of information concerning developmental progress, it is not designed for use as an intelligence scale. The terms "pass" and "fail" are not employed. The child is judged to respond or not to respond according to the level of performance which might reasonably be expected at his age. It need hardly be stressed that any child showing deviations from the broad pattern of speech and hearing behaviour appropriate to his chronological age should be referred for expert opinion and full diagnostic testing immediately. Children do not grow out of deafness, but they do most assuredly grow into dumbness if they are not given expert auditory training in the critical early years. The sooner the young child with impaired hearing is provided with a suitable hearing-aid and his parents are given guidance regarding his daily management the better his chance of normal development.

Much research is in progress regarding the auditory behaviour and testing of young babies under 6 months, including neonates (Graham, 1957; Ewing, 1957; Whetnall, 1958; Ballantyne, 1958). These procedures demand much training and experience. Since their application to mentally handicapped children has not yet been investigated, it is not proposed to discuss them here. The present tests are intended for use with children with mental ages between 6 months and 7 years. To date (March, 1958) they have been personally applied with 192 mentally handicapped children aged 2-16 years, and with 537 normal children between 6 months and 7 years distributed as follows: under 2 years, 107; 2-4 years, 179; 5+ years, 251.

Response to Spoken Language

In order to test whether a child possesses hearing over the range of sound cycles which are essential for speech discrimination, it is necessary to satisfy oneself that he can respond to spoken language. His reaction to other meaningful sounds possessing similar characteristics in pitch, intensity, and duration may provide valuable supporting evidence regarding the child's auditory acuity and his ability to interpret the world of sound in which he lives; but until he has given unmistakable evidence first that he *hears*, later that he can *imitate*, and eventually that he can *correctly use* the individual phonetic units of speech, it is not possible to be certain that his auditory discrimination is normal.

From 6 months onwards the child's own spontaneous vocalizations provide a useful clue to his capacity for hearing and using spoken language. They should therefore be carefully observed and recorded at the time of examination. The mother's description of his speech and hearing habits should be reported separately. Even when accurate pure-tone testing becomes possible a clinical speech test should always be given (Sheridan, 1948). Hearing for pure tones and hearing for speech, although closely related, are not identical. This is particularly true of young children. The pure-tone audiogram provides valuable information regarding the severity of hearing loss, the sound cycles involved, and the possible location of the blockage in the auditory relay system between the meatus and the cerebral cortex, but it cannot show how the individual child interprets what he does hear. Some children with poor auditory discrimina-

tion and gross speech defects show perfectly normal audiograms, while other children showing loss for pure tones function as normally hearing individuals. While it is therefore desirable to apply and compare results of both tests whenever possible, the first essential is to discover the child's ability to hear and use spoken language or, as Fisch (1957) aptly terms it, his capacity for auditory communication.

The tests are grouped in series as follows:

- Baby tests: (a) 6-14 months: Voice and noise-making objects
(b) 15-18 months: " " " "
(c) 19-23 months: Five-toy test
2 years old: Six-toy test and first cube test
3-4 years: Seven-toy test and second cube test
5-7 years: Picture vocabulary tests and third cube test

The materials required are:

Babies.—(a) and (b) soft high-pitched rattle; squares of new tissue paper (e.g., toilet paper); small handbell; china or pottery cup with wide brim; metal spoon. (c) Ball, golf size, plastic type which will not break windows; baby doll 2-3 in. (5-7.5 cm.); motor-car 2 in. (5 cm.); 1-in. (2.5-cm.) wooden cube, different colour from motor-car.

2-4 Years.—Child's spoon, fork, and knife (blunt); baby doll 4-5 in. (10-12.5 cm.); motor-car 3-4 in. (7.5-10 cm.); train or plane 3-4 in. (7.5-10 cm.); ship 3-4 in. (7.5-10 cm.); eight 1-in. (2.5-cm.) wooden cubes, two each of blue, yellow, green, red.

5-7 Years.—Four cards of special pictures; one card decorated with coloured squares; lists of selected words and sentences.

In application three general rules must be observed. (1) The room should be quiet and homely, and the mother or other familiar adult should remain with the child throughout. (2) The tests are based on fundamental psychological and acoustic principles, so that, although it is permissible to vary the spoken "carrier phrases" and in some instances the order of application, the materials used may not be varied and the tests themselves must be applied with strict attention to detail or they will cease to give valid results. (3) The record should state clearly the test used, the distance, the results obtained, and a note regarding the child's own vocalization or speech.

Babies Aged 6-14 Months

Babies over 6 months are comparatively easy to test, those between 9 and 12 months particularly so. At this stage of development the child is eagerly seeking through vision, hearing, and manipulation to explore and find meaning in the world around him. He has already learned to associate certain sounds with human beings and the interesting events they initiate, but his experience is still so incomplete and his ability to discriminate between foreground and background noise so rudimentary that he cannot yet take the significance of any sound within his area of attention for granted, but is impelled to support his uncertain powers of auditory recognition and localization with visual verification. Hence his response to a meaningful sound in his environment is to turn immediately to look for the person or object originating it. This localizing reaction probably plays a necessary part in the child's stereoscopic and stereophonic learning, and thus in the building up of his concepts of space and possibly of time. Whatever the reason, the response is so constant at this age that it is almost automatic and can usefully be pressed into service in testing.

It is necessary to remember that the infant's world is very small and only gradually expands. Although he has vague impressions of an outer space, his span of selective visual and auditory attention is at first fragmentary in time, and in space no larger than the circle bounded by his mother's arms. His sphere of continual awareness later widens to cot and play-pen size, and only at about 18 to 20 months reaches full room size. For this reason soft, varied, meaningful sounds close to the infant are much more likely to evoke a response than loud featureless sounds further away. The examiner (E) should stand well to the side of

the child (C), but outside his immediate range of vision. To ensure the most consistent results the sound stimulus should be given on a level with the ear. Sounds below this horizontal plane seem to be less easy to hear, and above it less easy still. Sounds immediately behind or above the head, particularly when they are in the middle line, appear to be difficult to distinguish and, before 3 or 4 years, impossible to locate. Ewing (1957) has recorded similar findings.

Babies of 6 and 7 months are usually very outgoing and friendly, but after this the near approach of strangers is apt to be unwelcome and acceptance must be won. The examiner should not make boisterous frontal overtures to the child, but should allow himself to be seen moving about at a respectful distance and heard conversing with the mother. The child's reactions to the mother's voice are instructive, particularly when she is addressing herself directly to him.

E should first ask by what name the child is known at home. C may sit on his mother's knee facing outwards, or in his cot or pram within touching distance of her. C's position must not be closer than 4 ft. (120 cm.) to any wall. In all the tests it is essential that E does not stand where his movements or his shadow are visible to C. Similarly, reflections in a shiny surface, light touches, vibrations, currents of air, and even perfumed cosmetics may provide unsuspected clues to an observant child who has learned, of necessity, to make use of them. If an assistant is available E should sit in front of C observing his reactions while the assistant applies the stimuli under his direction. If E is alone he must wait until C's attention is visually attracted straight ahead (but not too deeply engaged) before he begins the test.

The sounds are given at distances from 1½ ft. (45 cm.) (at 6 months) to 3 ft. (90 cm.) (at 9 months upwards) in

The child's attention is immediately drawn by the sound of the spoon stroked round brim of cup. (Aged 8 months.)

the following order—voice, rattle, spoon against cup, tissue paper, handbell. The speech sounds are delivered at quiet conversational level. They consist of the low-frequency vowel OO, repeated two to four times (for example, "Oo-oo John; Oo-oo"), and the high-pitched consonant sounds "tit-tit-tit," "ps-ps-ps," "pth-pth-pth," repeated rapidly three to six times. The remaining sounds are given for one to two seconds. The rattle is shaken softly, the tissue paper is rustled quietly, the handbell is tinkled very gently, and the spoon is merely stroked round the inside brim of the cup (see photographs), unless for any reason a sharp tapping sound is needed, when the spoon can be struck briskly against the side.

With normal children of 9 months upwards the first application of the stimulus usually provokes instant turning, often with a delighted smile (E should respond to the smile), and when the same sound is repeated immediately afterwards on the other side of his head C will promptly locate it in the new position. Younger babies may be slower to react. If the first stimulus evokes no response E should wait for two seconds and then repeat it. E should then wait a further two seconds, as C may still turn slowly and deliberately although the sound has ceased. This delayed response is apt to occur also in retarded older children. It is as if there is a definite time-lag between the reception of the sound in the primary auditory area, its recognition in the audio-psycho area, and the initiation of the motor impulse. Probably for a similar reason a baby who has not responded to the single application of a sound on one side of his head will often locate it promptly and correctly when it is repeated immediately afterwards on the opposite side; but I prefer to apply a double (or occasionally treble) stimulus to one ear, since absence or delay in response provides additional information. If no response is elicited to the second (or third) repetition of the sound the stimulus should then be changed or the child will become bored and withdraw from the situation.

I have been interested to note that the cup and spoon and rattle seem to evoke the most consistent responses in young babies, perhaps because these sounds carry a concrete "near-by" meaning—that is, food and manipulative play; while the paper and handbell appear to be more interesting to the older babies whose sphere of memory and attention is expanding. After response to the handbell has been evoked it should be presented to the child, since his use of it as a plaything provides further useful information regarding his ability to comprehend its function and his willingness to make and enjoy sound (Gesell, 1925).

If the child shows a clear-cut response to any three out of these five sounds there is good reason for the assumption that he possesses enough hearing to learn to speak, but it must be remembered that the tests are not fine enough to distinguish partial deafness, particularly high-tone loss, with any degree of certainty. If the child does not respond in the expected fashion to these sounds on both sides, the tests should be reapplied as soon as possible within the following month. If the result of this second test is still uncertain expert opinion should be sought without further delay.

Speech.—From about 4 months onwards the child laughs aloud and vocalizes freely, particularly when his mother talks to him, at first in single sounds such as "ba, ka, goo," etc., and later from 7 or 8 months in a tuneful repetitive babble of the "dad-dad, bab-bab, mam-mam" variety. By 10-12 months most normal babies show by their behaviour that they understand several words used in familiar context, and their mothers may report that they can say one or two words, but these are rarely intelligible to outsiders. At 14 months many children have acquired two to six recognizable words, but others, equally intelligent, have not. By this time babbling has progressed to a more complicated jabbering, which possesses all the cadences of ordinary speech without its phonetic discipline. This the child practises with great enthusiasm when alone

(Sheridan, 1945). Any report of decrease in vocalization from the babbling stage onwards, or the most tentative suggestion on the mother's part that the child's cry is unusually monotonous, or that he seems inattentive to sound, should be treated with the utmost respect.

15–23 Months

Children within this age group are often very difficult to test and the examination calls for much patience and experience. In fact, if the response to the first test is uncertain and if there is any reason to doubt that the child's hearing is normal, it would be wise not to delay until a second test can be carried out, but to refer him immediately for diagnostic investigation. At this age the child is usually very active in crawling or running about, and, since to restrain him would defeat the possibility of reasonable assessment, it is often necessary to follow him round the floor. By this time he usually possesses enough auditory experience to recognize and interpret the sounds used in the baby tests described above without needing to verify them visually. He may concede one brief glance, but frequently does not offer the slightest sign that he has heard. At the same time he may not yet be sufficiently advanced to be able to co-operate in the simplest form of toy test described below. In these circumstances the child's own spontaneous vocalizations may provide the most useful indication of his ability to hear speech. Indeed, E's imitations of C's own vocalized sounds may be the best way of provoking him to stop, listen, and turn to look.

The child between 15 and 18 months should first be addressed by name and invited to join E in play. If he does not respond to these spoken overtures the baby tests at 3-6 ft. (90-180 cm.) may be tried, E remembering that it will be necessary to vary them frequently, as the immediate repetition of a sound which has just evoked response on one side will seldom, at this age, arouse equal interest on the other. The rustling of the paper wrapping of a packet of sweets followed by the spoken invitation "Come and get one," and the presentation of the bell accompanied by the definite instruction "You ring it; ring it with the other hand," are useful extensions of the baby tests at this age. Commands are more likely to produce results than mere friendly suggestions.

With children over 18 months a beginning may be made with the simplest form of toy test—that is, “the five-toy test.” The objects used are *cup*, *ball*, *miniature motor-car*, *plastic baby doll*, and *toy brick*—that is, coloured inch (2.5 cm.) cube which should be a different colour from the motor-car. C is placed sitting or standing by a small table with E facing him at 2–3 ft. (60–90 cm.)—that is, conversational distance. E presents the objects slowly in the following order, saying, “Here is a *cup*” (the responsive child will delightedly echo “*tup*”). “Here is a *ball*—and a motor-car.” Then presenting the doll E says, “What’s this ?”, waits for C to say “*dolly*” or “*baby*,” and thereafter uses C’s own word. If C does not speak E says, “A *dolly*—and here is a *brick*” (the word “*brick*” is acoustically essential and must not be altered). Then, holding out his hand flat (*not* suggestively cupped), E says in this order, “Give me the *ball*, please. Thank you. Give me the *brick*, please . . . the *car* . . . the *dolly*—Good.” If the child does this correctly E hands the *cup* to the mother and says, “Now I am going over there and you’re going to give the things to Mummy when I tell you,” and retreating to 6 ft. (1.8 m.) says, “Give Mummy the *ball*,” then, slowly retreating to 10 ft. (3 m.), “Give Mummy the *brick* . . . the *car* . . . the *dolly*”; then, finally, “Put the things in the *cup* and bring them to me.” Many normal children of this age find it difficult to maintain rapport at 10 ft. (3 m.). If E feels that he has dropped out of C’s world at 10 ft. (3 m.), he should return to 6 ft. (1.8 m.), noting this in the case

If the child does not give the correct toy when requested, E should wait a moment without speaking, as another

delayed response may be operating. C may even lift the incorrect toy, then put it down and hand the correct one. If C gives an incorrect toy E should put it down gently and repeat, "The ball, please." If C still hands the incorrect toy E puts it down again saying, "No, I want the ball, please." If the child persists in giving the incorrect toy or goes on handing the other toys without waiting for the command, E accepts them; then, giving the cup to the mother, holds out the toys to C, saying, "Give these to Mummy." While C is doing this E retreats to 6 ft. (1.8 m.), saying, "Good; now put the things in the cup and bring them to me." While C's attention is momentarily engaged in filling the cup the vocalized sounds "ps-ps" or "tit-tit," the high-pitched rattle, or the rustle of paper usually provoke the turning response.

Speech.—By 18 months most children have acquired 6 to 12 recognizable words. The child continues to jabber to himself while he is playing or in his cot, but as his vocabulary grows this jabbering begins to include an increasing number of distinguishable words. By 2 years the hearing child can verbally communicate his toilet needs, ask to be taken for a walk, and demand what he wants at table. He is usually putting two or three words together to form simple sentences. His understanding of spoken language, which is related to familiar objects, activities, and emotional states in his daily life, continues to improve rapidly and is far in advance of his ability to use speech. At this age he is physically restless and vocally demanding, incessantly provoking his mother to give verbal reply to his loudly expressed claims on her attention. After 20 months persistent tendency to tug at his mother's garments and point silently with his finger when he wants anything is very significant and should be carefully followed up.

2 Years

The testing of children of this age group is easier again, and the six-toy test is applicable. C is invited to a small table with E sitting facing him as before. The toys are briskly presented in this order: Here's a cup—what's this? (spoon) and this (ball, car, doll), and here is a brick. "Give me the *ball*, please, the *brick*, the *car*, the *doll*; thank you. . . . Look, I'll put the *spoon* in the cup. Now you put the other things in when I tell you." E retreats to 6 ft. (1.8 m.) and, hiding his mouth lightly with a card so that the child is unable to see his lips, continues, "Put the *ball* in the cup. Put the *brick* in the cup, the *car*, the *doll*. Good. . . . Now, when I say so, you take them out again." E retreats to 10 ft. (3 m.) and says, "Take out the *spoon*, the *brick*, the *doll*, the *car*. What's left in the cup?" This is an advanced language concept. The outgoing child usually picks out the ball promptly, saying delightedly, "Ball." The reserved child leans forward and looks into the cup without speaking. The dull child looks at E uncomprehendingly. To reassure him E says, "Take out the ball." A quiet conversational voice is used throughout. I seldom use whispered speech for children under 4 or 5 years, and only then for special reasons and with previous notice. Whispered speech is an unnatural form of communication for young children who are accustomed to hearing voiced speech at "mother-distance"—that is, at high decibel intensity. It not only tends to confuse them, but sometimes provokes anxiety and even tears, thus jeopardizing rapport or destroying it irretrievably.

In order to make sure that the child has no high-tone loss, however, it is desirable to test his hearing for voiceless consonants. The following simple test, the first cube test, can be used from about 2½ years onwards. E places the cup and six coloured inch (2.5 cm.) cubes before C, saying, "Now we're going to play another game. See these bricks. When I say, 'In, in, in,' I want you to put a brick in the cup. It will get quieter and quieter, like this (demonstrating). You try." E gradually drops out the vowel and sounds only the consonant—"In, in, n, n, n. Good. Now I'm going over there, and when I say, 'Lift, lift,' I want you

OCT. 25, 1958

to lift a brick out of the cup and put it on the table. It will get quieter and quieter like this" (demonstrating). E moves to 10 ft. (3 m.) from C's right ear. "Ready? Lift, lift, if, if, -f, -th (th voiceless as in 'thin'). Good." E then repeats the test for the left ear. C should not be allowed to lip-read. The sounds must be delivered at irregular intervals in order to prevent automatic performance. In practice this will be found exceedingly simple, as it is possible to monitor the child's movements visually to a split second. If C lifts the brick before the signal, E says, in playful admonishment, "I didn't say anything. Put it back. Listen." The children greatly enjoy this game, and it is a very sensitive test.

Speech.—If C's own speech has not been completely demonstrated by this time it may be necessary to engage him in some simple conversation, or, if he is capable of it, he may be asked to point to and name objects or pictures. The following simple "doll" vocabulary list provides a useful rapid test for most of the common vowels and consonants. *Doll, shoe, nose, frock, arm, feet, hair, hand, mouth, eyes, teeth.* Although at this age the normal child's phonetic usage still shows numerous infantile substitutions, his speech is adequate for most domestic occasions. Self-talk during play still continues and will probably do so until about 3½ years. Although not yet capable of sustained conversation the child can now put words together to form more complicated sentences, and is beginning to engage in spontaneous verbal interchange with other children of his own age, as well as with adults. Any child whose speech development during the first three years does not progress in this way, but remains arrested at the jabbering stage, should be referred for expert examination whether or not he appears to hear normally. He may be generally retarded or he may be a case of developmental aphasia, but he may also be suffering from high-tone deafness, so that, although he can fully appreciate the cadences and vowel sounds of ordinary speech, he cannot discriminate, and therefore cannot imitate the difficult high-frequency consonants. Denied the ability to communicate, he may express his frustration in violent temper tantrums, or in despair take refuge in silence or social withdrawal. This type of deafness is likely to be permanent. These children, unhelped, run a real risk of being wrongly diagnosed as maladjusted, psychotic, or mentally defective (Sheridan, 1944; Minski, 1957).

3 and 4 Years

The seven-toy test is easily applicable from 3 years onwards and can be used until the child is able to cope with the more comprehensive picture vocabulary test. It has shown itself capable of holding the interest of mentally handicapped children up to 16 years and, if necessary, of normal children up to 7 or 8 years. The seven objects are a child's *spoon, fork, and knife, doll, car, train* (or plane), and *ship*. A slightly larger doll and car at this age are advisable as they are easier to handle (and harder to put in the mouth), but the smaller ones can still be used. Sitting opposite C at the table, E places the toys before him from C's right to left, in the following order—car, train, fork, spoon, knife, doll, ship. E asks C to name the objects as they are placed. If C says "engine" or "boat," E replies, "Yes, a train" or "ship." If C does not speak E says the name clearly, asking the child to repeat it before he passes to the next object, checking him again at the end of the line. If C speaks readily but shows momentary confusion between knife and fork, E should go back to these at the end of the line. If the child still shows the slightest doubt it is wise to discard the test rather than modify it and to give the six-toy test instead. If C knows all the objects, E says, "Show me" (or if C is sufficiently advanced, "point to") "the *spoon, the doll, the fork, the car, the knife, the train, the ship, the spoon, the car, the ship*." It is essential that the words should be called in this order. E then retreats to 10 ft. (3 m.) and, covering his mouth, repeats the list in the same order.

(It will be obvious to those experienced in psychological testing of children that this simple performance provides E with a good deal more information than C's ability to discriminate the phonetic units which compose the seven words involved: for instance, his use of his right and left hands, his interest, speed, manipulative skill, and his actions which demonstrate "definition by use.")

In order to test the hearing for high frequencies E may repeat the test in a whisper at 10 ft. (3 m.), having first warned C what to expect. A more sensitive test is the following—that is, the second cube test. E places on the table before C the cup containing eight coloured inch (2.5 cm.) cubes with the instruction: “Whenever I say a little sound, oo, sh, t, anything—I want you to take out a brick and put it on the table, like this” (demonstrating): “Oo—ee. . . . Now you go on: sh, t, s, p, f, th. Good. Now I’m going over there,” etc. Each ear is tested separately at 10 ft. (3 m.) as before. This is not only a more sensitive test than the “In, lift” one, but it is also more difficult, particularly for retarded children, because it includes the two plosives *t* and *p* as well as the continuants *sh*, *s*, *f*, and *th*, thus involving appreciation of duration as well as of pitch. If the child does not respond to the first delivery of *t* or *p* E should repeat the sound once. If response is still absent E should proceed to the next continuant, adding a further *th* at the end to compensate, so that the child is unaware of his lack of success. The case record should be noted accordingly. It will be obvious that the “placing” of these consonants by the speaker is important. In order to keep the sounds at their highest pitch, the short vowel “i” should be imagined as preceding each consonant—for example, (i)sh, (i)p, (i)th. It is essential to avoid “per” and “ter.”

Speech.—The child of 3 years is capable of sustained conversation. His speech is usually completely intelligible, although it still shows a number of infantile substitutions and omissions, the majority of which gradually disappear before 5 years. About 3½ years self-talk during play tends to merge into a sort of running commentary of passing events, interspersed with questions, more or less vaguely addressed to the adults and children in his vicinity, to which he expects his hearers to pay at least intermittent attention. About 4 years comments become less frequent but more pertinent, while his questions become more persistent, so that he is incessantly asking, "How? When? Why?" Any deviation from this broad developmental pattern occurring in children of 3 and 4 years is likely to be of serious significance and requires urgent investigation.

5-7 Years

It is usually quicker and more convenient to use a picture vocabulary test at this stage. Those who have tried to design similar tests in the past will know that their preparation involves considerable labour. The words used must be monosyllables, preferably nouns capable of pictorial illustration, and within the experience and language capacity of very young children. M. Reed kindly provided me with a set of the admirable pictures he designed for use in the audiology unit, Gray's Inn Road (Whetnall, 1952), but they proved too difficult for the mentally handicapped children. It was therefore necessary to compile new sets of words and pictures. Six lists of 12 words were prepared. Four of these lists contain an assortment of vowels and consonants in common use. The fifth list contains pairs of words which have similar vowels but different consonants, and the sixth list is composed of words in which the high-pitched vowels *ee* and *i* are combined with high-frequency consonants. Pictures to illustrate three of the lists (given below) were prepared by a children's artist. They were then carefully arranged on the page to prevent guessing from juxtaposition.

The clinical value of spoken vocabulary tests is high. Some children are able and willing to cover the distal ear and repeat a list of words spoken at 10 ft. (3 m.) into the proximal ear, without further aid. If an assistant is available to sit by the child and check his responses, this test,

combined with the third cube test described below, provides a very convenient and rapid method of screening the everyday hearing of normal 5-year-old school entrants. It is noteworthy, however, that even the most intelligent of the 5-year-olds appear to enjoy the test and give a better performance when the pictures are presented, as if, like the babies, they still feel the need to reinforce their hearing of words by visual verification when they are isolated from context.

Since it is the speech sounds in the highest frequency ranges which usually provide the greatest difficulty, the quickest way to discover if the child has any impairment of hearing is to present the sheet representing the sixth list and ask him to point to the pictures. At first the whole 12 pictures in this set were used, but later six (seat, feet, ship, fish, pig, chick) with a two-word check were found to be sufficient. In any case of doubt the longer lists should be given. As before, E starts by sitting opposite C at 3 ft. (90 cm.) asking him to identify the pictures in turn. If C says "chair" or "bird," E replies, "yes, a seat"; or "chick." If C stumbles over any word he should be taken back at the end to this picture. If he still shows any hesitation, the vocabulary test should be discarded and the toy test presented instead. If C identifies all the pictures correctly, E retires to 10 ft. (3 m.) and, with his mouth hidden as before, delivers the list in the order given below.

In order to check discrimination for high-frequency consonants, a *third* variation of the *cube test* was evolved. C is given the cup containing eight cubes as before, two each of green, red, yellow, and blue. Beside the cup on the table is placed a card measuring approximately 8 by 12 in. (20 by 25 cm.) decorated with 12 brightly coloured squares, three each of the same four colours. C is told to stand sideways with one ear towards E and to cover the distal ear firmly with the palm of his hand, placing the fingers in the nape of the neck. He is then instructed to take out a brick as before and "put it on its own colour." This procedure not only adds to the interest of the test, it also acts as a visual distraction. Children of this age are quick to interpret any raising of the eyebrows or least movement of the head which E makes in delivering the sounds. If C shows the slightest lack of comprehension or confidence, the coloured card should be removed and the easier second cube test given instead. A fair indication of the child's probable school-room hearing for continuous speech, allowing for the quieter conditions of the examination, may be obtained by asking him to repeat a few of the sentences below, delivered in a quiet voice with mouth hidden at twice the distance of his seat from the teacher's desk.

Speech.—The spoken language of the normal 5-year-old is fluent and correct. A number of children, particularly boys, still show minor consonant substitutions, principally confusions of *th* and *f*, which are usually the last phonetic units to be differentiated, but occasionally of *s* and *t*, or of the *r*, *l*, *w*, *y* group. These minor immaturities of speech normally clear up before the age of 7 years. If they persist, audiometric assessment and speech therapy become imperative.

Specimen Vocabulary Lists

PICTURE TESTS

General: Shoe, horse, cart, seat, cup, frock, cat, bike, face, chick, fish, ship.
Vowels: House, coat, pin, book, cart, boy, horse, cat, pen, bike, cot, bear.
High Frequencies: Tree, chick, feet, leaf, fish, key, ship, teeth, pig, seat, dish, wheel.

SENTENCES

The father caught a bus. The baby slept in a cot.
The girl ate all the sweets. The boy has three big sisters.
The postman rang the bell. The driver stopped the train.
The teacher made a picture book. The wind blew away the nurse's cap.
The kitten climbed the Christmas tree. The new dog liked to sleep in chairs.

Summary

A series of simple clinical auditory screening tests which have been found useful in the preliminary assessment of the everyday hearing of very young or mentally handicapped children is described. The material required (common household objects—toys and pictures) is listed. A brief summary of normal speech development during the preschool years is given.

The work described in this report would not have been possible without the generous help of many colleagues and friends in hospitals, public health departments, and schools. It is impossible to name them all individually, but I wish particularly to acknowledge my debt to the consultants and members of the staff of the Cell Barnes Hospital, Great Ormond Street Hospital for Sick Children, and the audiology unit of the Royal National Throat, Nose and Ear Hospital who allowed me to work in the wards or observe in clinics; also to the Medical Officer of Health of London, Manchester, Cardiff, and Cornwall County Councils, who granted me facilities to try out the tests in day nurseries, occupation centres, and infant schools. Mr. M. R. Sheridan made helpful suggestions.

Arrangements are being made for distribution of the material described in this paper through the agency of the National Foundation for Educational Research, 79, Wimpole Street, W.1.

The results of successive surveys of smoking habits show that a person's replies are fairly consistent with each other. This is one of the conclusions reported in *Research Papers No. 2* on "The Reliability of Statements about Smoking Habits," by G. F. Todd and J. T. Laws, issued by the Tobacco Manufacturers' Standing Committee. Successive inquiries showed that replies given in the course of interviews during 1946-9 overstated the amount smoked by about 11%, and in the years 1952-7 understated it by about 13%. A possible explanation for this given is that the earlier figures, although intended to refer to packeted cigarettes, referred also to hand-rolled cigarettes owing to ambiguity in the questions. After 1950 the report states that the figures suggest that informants had an inherent tendency to understate their consumption slightly. "On the other hand, since in most tables in the papers informants are classified into broad groups consisting of non-smokers of cigarettes and of smokers of 0-4, 5-14, 15-24, and 25 or more cigarettes a day, the percentage of smokers, particularly in view of the proportion smoking 10 or 20 cigarettes a day, likely to be classified wrongly even with a 15% error is negligible. For instance, if those who said they smoked 20 cigarettes a day in fact smoked 23 cigarettes day, they would still be placed in the same consumption category." An analysis of other figures showed, according to the report, that the number of cigarettes stated to have been smoked on the day before an interview can reasonably be recorded as the number likely to be normally smoked at that time.

PRESENT PLACE IN OBSTETRICS FOR FOETAL PHONOCARDIOGRAPHY AND ELECTROCARDIOGRAPHY WITH THE NEWER TECHNIQUES OF FOETAL ELECTROENCEPHALOGRAPHY AND MOVEMENT-RECORDING

BY

C. N. SMYTH, M.A., B.M., B.Sc., M.I.E.E.

AND

JENNIFER L. FARROW, B.Sc.

Obstetric Unit, University College Hospital Medical
School, London

Foetal heart rate, rhythm, and waveform can be studied by phonocardiography and electrocardiography from the maternal abdominal surface. The present value of these instrumental observations in relation to foetal welfare and clinical obstetric practice is reviewed and the basic design features of the instruments employed for the survey are given.

The subject is divided into: (1) conditions determining the choice between the two methods of foetal heart recording; (2) recording techniques and description of the quantities measured; (3) principal applications; (4) details of apparatus; (5) examples of typical recordings and their interpretation; (6) other instrumental observations on the foetus; and (7) discussion of foetal distress and its treatment.

Choice of Method

Phonocardiography is the most suitable method for recording heart rate and rhythm and for estimating the systolic and diastolic time intervals. It is always practicable when the heart is audible with a stethoscope; it is impossible when the heart is inaudible to an experienced obstetrician or midwife listening in a quiet room. In some instances an active heart can be recorded when it has not been heard with certainty because of acoustic masking by uterine souffles, maternal heart sounds, or other foetal heart beats in a multiple pregnancy. In certain cases of severe foetal distress the heart sounds may be so uncharacteristic that they are not recognized as such, and then phonocardiography is helpful.

Electrocardiography has its field of usefulness when the heart cannot be heard. The technique is also possible, of course, in other cases, but it is then less convenient than using the phonocardiograph. Electrocardiography is possible in all patients from 16 weeks' gestation to term, with a few exceptions between 30 and 34 weeks, when some foetuses are totally covered with vernix caseosa, an electrical insulator (Wimmer, 1954).

Recording Techniques and Quantities Measured

Phonocardiography

The microphone must be firmly applied at the point on the abdomen where the heart can best be heard; it may need to be repositioned if the foetus moves.

Phonocardiography is not unduly disturbed by extraneous noises, but is very severely affected by the mother's speech or movement and by intestinal disturbances. While the recording is in progress, therefore, the patient is asked to lie still and quiet.

In our particular studies we have used devices which register the intensity of the first and second heart sounds and their time relationships, and we have paid little attention to the acoustic quality of the sounds—that is, to the

waveform. Many murmurs which are heard from the foetus disappear with the circulatory changes that occur at birth. The presence of high frequencies in the sounds depends not only on their production in the heart but also on the foetal position and the volume of surrounding maternal tissue and liquor amnii. Consequently, muffled sounds are not necessarily indicative of reduced cardiac output. Attempts to relate cardiac performance to sound levels must take account of relative movements between foetus and microphone, even for short-time changes in a particular patient. This we assumed to be too difficult, and limited our studies principally to time relationships. The measurement of systolic and diastolic times is of sufficient clinical value to justify phonocardiography in the labour ward, even if the more elaborate problems of sound analysis are omitted.

FIG. 1.—Foetal electrocardiograph in use.

Electrocardiography (Figs. 1 and 2)

The electrodes are formed by the two feet of a small metal box containing the pre-amplifier. These should rest firmly on the linea alba—for vertex presentations, one just above or below the umbilicus, and the other just above the pubic-hair line. A metal belt for the indifferent electrode is placed around the patient's waist between fundus and heart. Good contact is made under the belt and under the electrodes with "Cambridge" electrode jelly. The bladder should be empty. Other electrode positions are satisfactory but more influenced by maternal heart and muscle potentials.

Interference can be prevented when it arises from extraneous sources, but the recordings are disturbed by movements of the patient and by potential changes arising in organs other than the foetal heart. For this reason records of P and T waves are difficult to distinguish with certainty, but the QRS complex can be recorded faithfully in amplitude and duration. Maternal heart waveforms are usually also registered, but, since a maternal heart beat only occasionally coincides with a foetal one, the record is little impaired.

When clinical requirements necessitate a full foetal E.C.G. with P and T waves (for example, in cases of severe foetal distress or before caesarean section in a suspected cardiac abnormality), then intrauterine electrodes should be passed through the cervical canal, preferably after rupturing the membranes, and their positions, if necessary, ascertained by radiography.

Applications

The principal uses of phonocardiography are: (1) to monitor the foetal heart in a sleeping or overanxious patient; (2) to check regularity of rhythm, and rate after version (success or failure), after surgical induction of labour, during oxytocin therapy, during the induction of anaesthesia, and during forceps application and traction; and (3) diagnosis of foetal distress.

With the aid of phonocardiography the effects of administering oxygen, taking pressure off the presenting part, relaxing the uterus, pressing upon the placental site, and inducing regular uterine contractions with oxytocin (to improve the foetal circulation) can be followed speedily. Measurement of the systolic and diastolic times by recording both heart

sounds enables a failing myocardium, or pulmonary stenosis, to be distinguished from impeded venous return, for the former lengthens the systolic time and the latter the diastolic time (Palmrich, 1951, 1952a, 1953).

Pressing the presenting part into the pelvis in patients with placenta praevia will slow the heart by lengthening

was delivered by caesarean section about an hour later. Unfortunately it was too severely injured by "intra-partum asphyxial changes" to survive for more than an hour. Occasional cases such as this illustrate that electrical diagnostic measures need to be backed up by quick decisions and prompt surgical service.

Foetal Distress in Pregnancy.—In one case irregularities of the foetal heart were recorded three weeks before the expected date of delivery. Braxton Hicks contractions and manual pressure on the abdominal surface produced marked slowing of the foetal heart. The QRS complex and the systolic times were normal, but the long diastolic times showed some impediment to foetal venous return. The effect was intermittent. The patient was advised to avoid tight clothes or pressure on the abdomen, and a frequent watch was kept on the heart until labour began at term. On delivery the cord was found to be twisted around the leg and compressed each time the knee was flexed.

Slowing of Heart Rate During Contractions.—In an example in early labour the heart was slowed by an increase in diastolic time only, demonstrating impaired venous return (Fig. 6).

Fig. 6.—Slowing of heart during uterine contractions due to increase in diastolic time; impaired foetal venous return.

Electrocardiography

Forceps Delivery.—Fig. 7 shows changes in the foetal heart rate during forceps extraction. Such recordings can be used at the time to warn the surgeon of the effects on the foetus of the application of the forceps and traction.

Fig. 7.—Electrocardiogram during forceps delivery. Note slowing of heart rate.

Diagnosis of Twins.—This was a suspected case of hydatidiform mole (18 weeks' gestation). The E.C.G. (Fig. 8A), however, gave a clear recording for twins, which were, in fact, aborted a week later.

Threatened Abortion.—Difficulty had been found in hearing the foetal heart with a stethoscope at 20 weeks' gestation. The E.C.G. (Fig. 8B) confirmed foetal life; the heart rate is within the normal range.

Moribund Foetus.—We have had cases in which the foetal heart was heard feebly until 15 minutes before delivery and then the foetus was born with slight signs of maceration.

Fig. 9 is an example of a foetal E.C.G. taken three days after the heart was last heard. On delivery by caesarean section one hour after the recording, the foetus was severely macerated, but the heart tissue was still normal. Clearly, the E.C.G. must not be accepted as evidence of foetal viability if the heart cannot be heard when, by reason of the length of gestation, it should be audible with a stethoscope. It is only fair to point out, however, that all cases in which this phenomenon has been observed have had a very abnormal heart rate—that is, above 300 beats per minute. The case recorded in Fig. 9

had at one time a rate of 700 beats per minute, and this was slowed to 350 before the section by administering digoxin to the mother. Another patient had a rate of 300 beats per minute. Presumably, in such extreme cases the heart is maintained in fibrillation nourished by blood circulated by the action of the uterine contractions on the placental-heart flow. The heart muscle fibrillates, with a high-speed circus movement, and has no substantial effect on the circulation. There is a state of morbid hypotension leading to peripheral maceration. N. J. Brown (1957, personal communication) states that in macerated foetuses he has occasionally found live blood cells in the heart and placenta when other organs were in an advanced state of decomposition.

After Termination of Pregnancy by Hysterotomy.—In two cases the entire conceptus was put into normal saline immediately after removal and the E.C.G. recorded until the foetus died. One was allowed to cool, while the other was oxygenated and maintained at constant temperature. Both cooling and oxygen lack reduced the heart rates.

Fig. 8.—Electrocardiograms (electrodes on maternal abdomen) demonstrate foetal life. (A) Twin pregnancy in case of suspected hydatidiform mole, 18 weeks' gestation. (B) Case of threatened abortion at 20 weeks' gestation.

Fig. 9.—Foetal electrocardiogram three days after heart became inaudible and one hour before delivery of a severely macerated foetus.

Other Instrumental Observations on the Foetus

Recording of Foetal Movement

During the recordings of uterine contractions by abdominal tocodynamometry the slowly changing curve of uterine action is often disturbed by kicks and bodily foetal

movements causing sharp changes of pressure. Whether the foetus is attempting reflexly to remove the tocodynamometer, to jerk its way to a different presentation, or just exhibiting *joie-de-vivre*, is not clear, but the frequency of movements varies from perhaps 30 in half an hour to none at all. Some foetuses respond to finger pressure or flicks on the abdominal surface by kicking or moving, while others appear oblivious.

These findings have not been related to the condition of the baby at birth, but various theories concerning the possible loss of consciousness of the foetus during labour have been advanced; principally anoxia, analgesics, or compressive forces are blamed. Here we draw attention to the possible value of this investigation as a means of anticipating neonatal asphyxia, or

Fig. 10.—Recording of contractions showing foetal movements superimposed.

the need for additional care in searching for an unexpected onset of foetal distress.

Fig. 10 is an example of a tracing of uterine action during labour, which shows how readily foetal movements are recorded.

Foetal Electroencephalography

During foetal electrocardiography employing abdominal electrodes various potential variations are recorded in addition to those expected to arise from the heart. These are due to activity in the maternal bladder and other visceral organs, to arterial pulsation synchronous with the maternal heart and, it is thought, to the foetal brain. With vaginal electrodes there is an increase in the non-cardiac waveforms, and the recordings in some respects are not unlike electroencephalograms.

To investigate this, a portable two-channel Ediswan recorder (having a time-constant of 1 second) was borrowed. A few recordings were done, of which Fig. 11 is an example,

Fig. 11.—Presumed foetal electroencephalogram taken with intra-vaginal electrodes.

using pure silver, chlorided vaginal electrodes placed in the fornices. These recordings have been variously interpreted by experts in this country and France as 100% artifacts, doubtful, and undoubted evidence of gross anoxia. The subject has received more attention from Bernstein and Borkowski (1955, 1956).

Until the interpretation of the electroencephalogram of the newborn is well documented in relation to anoxia, head moulding, maturity, foetal movements *in utero*, and other factors, work on the foetus must be limited to improvements in technique and the collection of data for research analysis.

Foetal Distress

Clinical opinion holds that if an irregular heart improves with oxygen therapy prompt delivery is desirable, even necessary, because this is a sign of impaired oxygen transfer following placental separation or damage, and is unlikely to be relieved by relaxing pressure on the cord or placenta. This is a good working rule, but pressure on the cord or placenta can slow the heart, and, so long as the systolic time and the duration of the QRS complex remain normal, relaxation of uterine tone or repositioning of the foetus may relieve the distress; if the distress is severe, as in the case illustrated in Fig. 5, there is little time for these manoeuvres. If, however, the distress is slight and the uterine contractions are less frequent than one every five minutes, a weak oxytocin infusion will start a regular uterine rhythm, reduce the tone, and, by improving placental-foetal circulation, may relieve the foetal distress.

It would appear very probable that the first sign of anoxia is acceleration of the foetal heart, which can be slowed with oxygen; later there may be a dramatic slowing of the heart, and in such cases oxygen therapy will accelerate it. The first sign of impaired circulation caused by compression of the cord or placenta is undoubtedly a slowing of the foetal heart. Infection or pyrexia must also be considered as possible causes of a fast foetal heart. Hence the factors underlying a heart of abnormal rate need instrumental diagnostic tests. Thick meconium is an adverse prognostic sign, and its presence or absence ought to be determined in every case of foetal distress. For cases showing intermittent foetal heart irregularities, with slight distress, at the end of pregnancy, immediate delivery is not necessary. Such conditions, however, may suddenly become worse or better, and frequent monitoring of the heart is desirable, especially when the membranes rupture or labour begins.

Summary

Techniques for foetal phonocardiography, electrocardiography, electroencephalography, and movement-recording are described.

The fields of usefulness of the two methods of cardiology are defined, and the possible value of foetal electroencephalography and movement recording is discussed briefly.

Typical recordings are reproduced and discussed.

Observations on moribund foetuses increase our understanding of one manner of foetal death, and emphasize the danger of regarding the foetal electrocardiogram as conclusive evidence of foetal viability.

The differential diagnosis of foetal myocardial failure from impaired foetal venous return in cases of foetal distress is demonstrated.

Acknowledgments for financial assistance in this work are gratefully rendered to the Board of Governors of University College Hospital, to the Trustees of the Rockefeller Fund of University College Hospital Medical School, and to the Nuffield Foundation, who have supported this work in the years 1950 to 1958. Thanks are also due to Professor W. C. W. Nixon, who organized and encouraged the programme, and to the staff and students of the obstetric unit who have helped with the recordings and called our attention to cases suitable for studying the usefulness and limitations of these recording techniques.

ADULT CHRONIC BRONCHITIS— CONTINUOUS ANTIBIOTIC THERAPY

BY

GORDON EDWARDS, M.B.E., M.B., M.R.C.P.
Consultant Physician, Leeds United Hospitals; Senior Chest
Physician, Leeds Chest Clinic

AND

E. C. FEAR, M.B., Ch.B.
Clinical Research Assistant, Leeds Chest Clinic; Chief
Medical Officer, N.E. Gas Board

The use of the broad-spectrum antibiotic in the treatment of chronic bronchitis has occasioned considerable interest in the recent past (*Lancet*, 1955; *B.M.J.*, 1957). Several trials employing drugs of this kind in the management of chronic or recurrent pulmonary infection have been carried out to determine the results which immediately follow such a prolonged course of treatment (Helm *et al.*, 1954, 1956; May and Oswald, 1956; Moyes and Kershaw, 1957). We have also reported our experience in such a controlled trial employing a double-blind technique using oxytetracycline (Edwards *et al.*, 1957). The antibiotic was used alone, or in combination with other agents, in the domiciliary management of patients with chronic bronchitis, and was given continuously during six winter months in 1955-6. We here describe the further progress of these patients to show the duration of the benefit which followed such a course of treatment, and to determine the frequency with which these courses require to be repeated.

In the original oxytetracycline trial, 66 patients were allotted to various treatment schedules by random selection, and of these 53 completed the six-months course of treatment. In the oxytetracycline series of 29 patients, 21 were improved and 8 showed no improvement. In the control group of 24 patients who completed the course of treatment, 7 were improved and 17 showed no real change. This represents a significant degree of improvement in the oxytetracycline-treated group as compared with the control series. In order to assess the fate of these patients, follow-up studies for a further period of 12 months were carried out on the 29 oxytetracycline-treated patients (Series 1) and 13 selected patients of the 24 controls (Series 2).

Further Follow-up

Series 1

Of the 29 oxytetracycline-treated patients who were to be followed up, those alternately numbered on the Trial Register continued therapy with oxytetracycline with or without a sulphonamide as in the first trial. The other alternate patients were now treated with blank control material exactly similar in appearance to the active substances which they had previously received. Thus the 29 patients were divided into group A and group B. Group A consisted of 14 patients who continued with the antibacterial substances for a total of 18 months' continuous therapy. Group B consisted of 15 patients who, after the initial six months' oxytetracycline treatment, continued under observation as controls on blank material for a further 12 months. When patients relapsed they were removed from the trial so that other antibiotic therapy could be given as required. All the patients followed up were seen monthly for review and assessment in accordance with the method we have described elsewhere.

The results of the assessments at the end of each six-monthly review period are shown in Table I. Each assess-

ment refers to the patient's condition at the end of the review period compared with that obtaining at the start of that period. No patient in group A on continuous therapy was known to have relapsed during any of the observation periods lasting through two winters and one summer from November, 1955, to April, 1957, and some patients even continued to improve during each observation period. In Group B, after six months' active therapy during the first winter followed by dummy control therapy for a further year, 7 patients relapsed during the period April to November, 1956, and another 4 relapsed in the succeeding winter. During the total period of follow-up, three patients were lost to the trial—namely, two who defaulted in the second six months of observation, although both were known to be well, and one who died from so-called "heart failure," no other information being available. These patients were all in group A, and have been shown as "exclusions." Comparison of the patients' conditions at the end of 18 months' observation with their condition at first entry into the trial in November, 1955, shows that all of the 11 remaining in group A on continuous therapy were improved, while there were no known relapses. In group B only 2 out of 15 patients were improved after 18 months' observation, but 11 had relapsed.

Series 2

From the 24 patients in the control group of the original trial who completed the first six months' observation, 13 had previously been selected for continued observation for another purpose. These 13 patients, who comprise Series 2, were treated continuously for a second period of six months from April to November, 1956, with the various agents (excluding oxytetracycline) used in the original investigation. On the anniversary of their entry into the trial, 6 of these patients chosen at random were given in addition oxytetracycline (group C), whilst the other 7 (group D) continued treatment as before. Apart from this change, groups C and D were comparable. These two groups were then observed for a further period of six months from November, 1956, to April, 1957.

Both groups had reacted in a similar fashion by the end of the first 12 months of observation. When the condition of these patients was assessed at the end of the second six-months review period and compared with the condition at the end of the original trial (Table II), 3 of the 6 in group C, and 3 of the 7 in group D, had relapsed, whilst none in either group showed any improvement. When the assessment was made at the end of the third six-months observation period and compared with the condition at the end of the previous review, 4 of the 6 patients in group C now receiving oxytetracycline were improved and 2 showed no real change. In group D, however, 3 patients had again relapsed, whilst the remaining 4 showed no real change. Comparing the situation at the end of this 18 months' observation with the condition at first entry to the trial, the relapse rate in those bronchitics not receiving oxytetracycline is considerably greater than in the treated group. In group C 4 patients were improved, whilst in group D none was improved and 4 were worse.

Time of Relapse

No patient in group A was known to have relapsed, but three patients have been excluded from further follow-up for reasons already stated. Of the 7 patients in group B who relapsed in the period April–November, 1956, one relapsed one month after stopping treatment, 4 after five months in September, and two in October, 1956, in the sixth month of the period. Of the 4 relapses in the next six months two occurred in November and one each in December and January. In group C 3 patients relapsed in the period April to November, 1956—one in August and the other two in October. Similarly, of the 3 relapses in group D, one also took place in August and two in October. Of the 3 further relapses in group D in the succeeding period,

one occurred in December and two in the following January. No patient in group C relapsed in the final six-months observation period while receiving oxytetracycline.

The time relationship of the total relapses in all of the groups is shown in Table III, where the exclusion of three patients from group A has been assumed to be due to relapses. This accounts for a loss or possible relapse rate of about 20%. In group B no relapses occurred whilst the patients were treated with oxytetracycline, but within six months of stopping the antibiotic about half of them had relapsed. Of those who remained under further observation, another 50% relapsed during the last half-yearly review period, making a total relapse rate of about 75% during the whole period of 18 months' observation. Of those patients treated without oxytetracycline (groups C and D), about one-third relapsed during the first six months' observation, whilst about a half relapsed in the second six months' review period. The group C patients were then

treated with oxytetracycline, and the relapse rate was reduced to zero, whilst in group D, whose treatment continued without oxytetracycline, a relapse rate of about 50% was maintained.

Over the whole 18-months period the relapse rate in group A appeared to be nil, although it is possible it may have been in the order of 20%; in group B it was 73%; in group C 83%, and in group D, after 18 months' observation without antibiotic therapy, all patients had suffered one or more severe exacerbations, producing a summated relapse rate of 114%.

Discussion

It has been shown that continuous oxytetracycline therapy throughout the six winter months produces statistically significant improvement in chronic bronchitis during the period of its use (Edwards *et al.*, 1957), and when given continuously for 12 to 18 months the improvement rate apparently

TABLE I.—The Results in Series 1 at End of Each Six-monthly Period as Compared with the Condition at End of Previous Period, and at End of 18 Months' Observation as Compared with the Start

* = Exclusions. T = Treatment with oxytetracycline. C = Treatment excluding oxytetracycline.

increases. Conversely, continuous drug therapy prevents relapse in bronchitis, and the longer the duration of therapy the more effective the preventive measure against relapse appears to be. It would seem that relapse in chronic bronchitis during the summer and autumn months is considerably reduced, if not entirely prevented, by continuous antibiotic therapy. Without such continued treatment about half of the bronchitics during a six-monthly review period may be expected to relapse, and this seems to occur irrespective of whether antibiotics were used continuously in the previous season or not. Once a severe exacerbation occurs, many bronchitics are often appreciably disabled for a long period unless the relapse is intensively treated with antibiotics. These appear to be adequately suppressive in controlling the effects of bronchial infection.

The suppressive action of oxytetracycline is apparently effective only during the period of its administration, and does not seem to prevent or even delay the appearance of relapse following its withdrawal. The relapse rates during six winter months from November to April in patients treated without antibiotics are but little different from those occurring in the months from April to November. However, 80% of all relapses observed in the four treatment groups appeared between September and February. This may well be related to the climatic and atmospheric changes associated with the onset of autumn, particularly in highly industrialized communities.

It would thus seem reasonable to initiate a six-months course of continuous broad-spectrum antibiotic therapy when the first significant relapse occurs. Since most of these relapses occur in the autumn and winter, such a course of treatment may well overcome the relapse itself and also prevent further deterioration during the winter months, when most bronchitics are mainly at risk. Also it may be anticipated that no further continuous antibiotic therapy may be required for about six months after completing this course of treatment. It would therefore seem that only one period of continuous prolonged treatment with oxytetracycline in a dosage of 0.5-1 g. daily for about six months—the actual duration depending on the time of starting the treatment—may be required to prevent incapacitating exacerbations and maintain many bronchitics in effective and useful employment throughout the whole year.

Comment has already been made concerning the expense of prolonged therapy with the tetracycline group of drugs for a period of six months. If a course of antibiotic treatment is started at the time of the first major relapse and continued for six to seven months, as may be required, the total cost to the National Health Service would be about £45-£55, and would be occasioned but once in each year. The arguments already adduced for suggesting that such a course of treatment with a seemingly expensive drug may in fact be an economy when other aspects of national expenditure—such as National Insurance benefit, the cost of a hospital bed, etc.—are considered, now have added significance.

No untoward difficulties or complications occurred in those patients on prolonged antibiotics; toxicity was minimal, significant drug resistance was not observed, and the development of bronchial or intestinal oxytetracycline-resistant coagulase-positive staphylococci and of monilia did not materially differ in any of the treated or control groups.

Summary

The results of an 18-months follow-up of 42 patients with chronic bronchitis, when treated with or without oxytetracycline for periods of varying duration, are presented.

Continuous and prolonged antibiotic therapy for one year or more not only prevents relapse in chronic bronchitis but increases the rate of improvement the longer the therapy is maintained.

Acute exacerbations of chronic bronchitis assume major proportions during the autumn and winter, particularly between September and February, when 80% of relapses tend to occur.

It is suggested that continuous therapy with oxytetracycline for one period of about six months in each year, to include the period of maximum relapse, may prevent exacerbations and maintain most bronchitics in effective and useful employment.

We acknowledge with thanks the considerable clinical assistance in the management and review of these patients we have received from Dr. A. R. Buckley, late senior registrar to the Leeds Chest Clinic. We are also grateful to Dr. G. B. Ludlam, of the Public Health Laboratory Service, and to Dr. H. T. Levi, of St. James's Hospital, Leeds, for the routine laboratory investigations they carried out. We are indebted to Messrs. May and Baker, Ltd., and Messrs. Pfizer, Ltd., for the generous supplies of "sulphatriad" and "terramycin SF" respectively, and the appropriate dummy controls. Part of the expenses involved in this work were defrayed by a grant from a Joint Research Fund administered by the British Tuberculosis Association in conjunction with the Association of Industrial Medical Officers.

CARBON DIOXIDE POISONING

REPORT OF EIGHT CASES, WITH TWO DEATHS

BY

H. I. WILLIAMS, M.B., B.Chir.

Pathologist, Institute for Medical Research,
Branch Laboratory, Penang

Although rarely reported, carbon dioxide poisoning is probably not so infrequent an occurrence. McNally (1937) states that it is one of the most commonly occurring of all gases, and is often the cause of death of persons entering caves, wells, and other low-lying or confined spaces. Smith and Cook (1948), on the other hand, state that death from carbon dioxide poisoning is very rare, and that cases so reported are nearly always due to other gases, such as carbon disulphide.

Deaths due to carbon dioxide poisoning are included in the rubric E894 of the *International Classification of Diseases, Injuries, and Causes of Death*, "Accidental Poisoning by Other Specified Gases and Vapours," and in 1955 17 males and one female died from this cause in England and Wales. These figures include deaths due to gases other than carbon dioxide, and it is not known how many of them were caused by carbon dioxide poisoning.

The following cases are reported to illustrate the occurrence of carbon dioxide poisoning as a hazard in the handling of ships' cargoes.

Early in March, 1956, a liner arrived at Penang with a cargo of onions. The particular hold had been loaded six days previously, and contained 5,000 bags of onions and a quantity of "jaggery" (a crude brown sugar obtained from the sap of palm trees). It was full to within 9 ft. (2.7 m.) of the deck. At about 1 p.m. the ship was boarded by labourers, who removed the hatch covers and opened the hatch. One entered the hold and collapsed as he was standing on the onions. Another went in to help him and also collapsed. Then the ship's doctor was sent for; he went

into the hold, followed by one of the ship's officers, and assisted him to lift the unconscious man who had first entered the hold. As he was doing so the doctor collapsed, and the ship's officer carried the man out. One of the ship's crew then went into the hold to assist, but he collapsed. Another ship's officer then entered with breathing apparatus, and brought out the doctor and the other unconscious men. The four men who had collapsed were then taken to hospital, where it was found that two of them were dead.

Four other labourers who had also entered the hold for short periods developed minor symptoms and were taken to hospital.

Estimates of the length of time that the men were lying in the hold varied considerably, but it seems that the doctor was lying there unconscious for about five minutes, and the others for variable periods up to about 15 minutes.

The first patient was admitted to hospital about an hour and a quarter after he had gone into the hold. On admission he was deeply comatose and having continuous convulsions. Breathing was stertorous, the pupils were non-reactive, the conjunctivae were injected, but there was no cyanosis. The pulse rate was 156 a minute, and the blood pressure 160/100 mm. Hg. He was immediately given continuous oxygen, and an injection of nikethamide was administered and, after about an hour, paraldehyde by injection to control the convulsions.

Spasms passed off after two hours, and the patient recovered consciousness about seven hours after admission. He was able to get up two days later, but complained of giddiness, which passed off after three days. He was discharged eight days after admission. Spectroscopic examination of his blood the day after admission showed no abnormal pigment.

The doctor was admitted about one and a half hours after he entered the hold. He was conscious on admission, but gave a history of loss of consciousness for about half an hour. He complained of headache and aching in the joints. The pulse rate was 100 and the blood pressure 114/80 mm. Hg. The conjunctivae were injected, but there was no cyanosis. He recovered rapidly and was discharged four days later.

The remaining four patients were admitted later in the day. They all stated that when they entered the hold they became giddy, and three of them complained also of pains in the legs and of pain and dryness of the throat. Only one showed any injection of the conjunctivae, and none showed cyanosis. They were all discharged after one or two days.

Post-mortem Examinations.—The bodies of the two men who died were brought to the mortuary and kept in the cold overnight. At the urgent request of the relatives, only an external examination was performed. Neither body had any sign of injury, but both showed marked injection of the conjunctivae, and cyanosis of the finger- and toe-nail beds and of the buccal mucosa. Death was certified as being due to carbon dioxide poisoning.

Analysis

An analysis of the gases present in the hold was carried out by the senior chemist about an hour and a half after the hold had been opened. He obtained an appreciable reaction for carbon dioxide in the hold, particularly beneath the deck; and on examining other holds in the ship, as yet unopened, he obtained a strong reaction. No other poisonous gases were detected. For three months following this accident, the department of chemistry carried out inspection on all ships carrying onions for unloading at Penang. Nineteen ships were inspected, and carbon dioxide was found in significant amounts in one instance, in which it appeared that the onions had come from the same source as those held responsible for the incident.

Later, experiments were carried out, using onions from the ship, and it was found that the atmosphere in a sealed

flask containing $\frac{1}{3}$ v/v of onions contained over 30% carbon dioxide after five days. It was not possible to give an accurate estimate of the quantity of carbon dioxide present in the hold, as a good deal had been dispersed by the time tests were made.

Discussion

The toxic action of carbon dioxide is twofold. By dilution of the air it reduces the oxygen tension, thus acting as a simple asphyxiant, and it also has a chemical action as a respiratory stimulant and narcotic. There is, however, a great deal of difference of opinion over what concentration of carbon dioxide will be fatal. Jacobs (1941) states that 25% of carbon dioxide is required for several hours to produce death, and cites an incident in Brooklyn in 1936 when several workers were asphyxiated in the hold of a ship in which solid carbon dioxide was used as a refrigerant. Owen (1935) gives a concentration of 10% as sufficient, or even 5% if the oxygen tension is lowered, but makes no mention of the time of exposure before death occurs. He describes an incident in which 13 men were poisoned in the hold of a ship which contained bags of grain of various sorts. Elkins (1950) mentions 10% as an intolerable concentration, and states that at higher levels coma and death result. He suggests that carbon dioxide acts primarily as a narcotic at very high concentrations. Peterson *et al.* (1923) give figures similar to those of Elkins.

Anselmo *et al.* (1951) describe an incident in which five persons were overcome with carbon dioxide in a well 4.75 metres deep. Two died, but in these cases carbon dioxide was not the immediate or the only cause of death. Analysis of the air in the well later showed a concentration of 12.5% carbon dioxide and 10.5% oxygen at a level of 1 metre above the surface of the water. In this case it is clear that the decreased oxygen tension would have some effect.

Although it was not possible to give any figure of the concentration of the carbon dioxide present in the hold in the incident described, it seems likely, from the rapidity of onset of unconsciousness and the speed with which death followed in the two cases, that the concentration of carbon dioxide must have been in the region of 25-30%, and this figure is supported by the subsequent experiments. Indeed, it is possible that at the lower levels, only a foot or so above the cargo, the concentration may have been somewhat higher, owing to the density of carbon dioxide in relation to the atmosphere. Elkins (1950) states that in order to reduce the oxygen tension to a fatal degree the vapour content must be about 50%. It is possible that the concentration of carbon dioxide at lower levels may have been of this order.

The symptoms displayed by these men accord well with descriptions given elsewhere. Owens describes symptoms of headache, giddiness, tinnitus, and loss of muscular power. He suggests that carbon dioxide has primarily a narcotic action, and mentions convulsions as being sometimes present. The symptoms described by Smith and Cook (1948) are similar; and the cases described by Anselmo *et al.* (1951) also gave symptoms of mental excitement and later giddiness, weakness, and headache.

The doctor subsequently described his experiences, and said that when he entered the hold he was aware that the atmosphere seemed to make breathing difficult, and that there was a fairly pungent smell. He had no pain or any warning signs, but became unconscious very rapidly.

Summary

An incident is described in which eight persons were poisoned by carbon dioxide. The mode of action of carbon dioxide as a poison, its rate of action, and the symptoms are discussed.

My thanks are due to Dr. R. A. Pallister, senior physician, General Hospital, Penang, for clinical details of the patients; to Mr. S. A. Baron, senior chemist, Penang, for details of the

investigations carried out by the department of chemistry; and to H.M. Coroner, Penang, for permission to see the report on the inquest.

TRIAL OF DEQUALINIUM FOR SKIN INFECTIONS

BY

R. B. COLES, M.B., M.R.C.P.

C. GRUBB, M.B., B.S.

D. MATHURANAYAGAM, M.B., B.S.

AND

D. S. WILKINSON, M.D., M.R.C.P.

From the Skin Departments of the Northampton General Hospital and the Aylesbury and High Wycombe Group Hospitals

Despite the many preparations now available for the treatment of infective skin conditions, none are universally acceptable. The older agents, particularly the heavy metals, will occasionally irritate or cause sensitization, and the dyes—though effective and still widely used—are cosmetically unattractive. Sulphonamides and penicillin, used locally on the skin, are particularly apt to sensitize, and on this account are avoided by dermatologists.

Although the modern polyvalent or "wide-spectrum" antibiotics are very efficient and rarely irritant, their dangerous influence on the adaptable staphylococcus raises new problems. The skin infections may be improved at the price of increasing the cadre of existing staphylococci and of subjecting the patient to a subsequent, and more serious, attack by the resistant strain thus created.

Antibiotics that are not generally used parenterally—such as neomycin, framycetin, tyrothricin—have been preferred for local applications. Even so, resistant strains are already developing to some of these and may well become more prevalent. This potential danger of outrunning the future supply of antibiotics suitable for skin treatment, and to which the staphylococcus remains sensitive, justifies the search for suitable alternatives. There are sufficient grounds, therefore, for assessing any new synthetic bacteriostatic agent which seems likely to fulfil the necessary criteria. Many such synthetic chemicals are widely used by surgeons for the sterilization of wounds, burns, grafts, and other abraded surfaces, but in these instances the problem of epidermal sensitivity is not of great importance and they are not all suitable for use on the skin itself.

The qualities required of such a preparation are: (1) freedom from irritant action, (2) a low rate of sensitization, (3) a wide range of bactericidal or bacterio-

static activity, (4) ease of application and cosmetic acceptability, and (5) cheapness. Monilicidal or fungicidal activity would be an additional advantage.

We have recently carried out a preliminary clinical investigation of a new preparation claimed to have a wide spectrum of activity against pyococcal organisms, *Candida albicans*, and some fungi. This substance, dequalinium (decamethylene bis-(4-aminoquinolalidium) chloride), is marketed by Allen and Hanburys Ltd. as "dequadin."

The wide antibacterial activity of dequalinium *in vitro* was reported by Babbs *et al.* (1956), who found that it inhibited the growth of all of 21 species of pathogenic bacteria tested, including Gram-positive, Gram-negative, penicillin-resistant, and acid-fast bacteria; and some fungi. In a concentration of 100 µg. per ml. at 20° C. it destroyed within one hour 99.99% of organisms in a suspension of *Staphylococcus aureus*. Its activity was not inhibited by serum.

The local antiseptic action was demonstrated by injecting dequalinium solutions intraperitoneally into mice half an hour after lethal doses of bacterial suspensions had been injected into the same site. When streptococci were used, a dose of 0.9 mg. of dequalinium per kg. of body weight protected all mice from death, and when staphylococci were used 4 mg. per kg. was fully effective.

Clinical reports of the use of dequalinium for its local antibacterial action have been published by Trotter (1956) and by Fowler and Jones (1957). The former used dequalinium chloride in gelatin sponge as a bacteriostatic and haemostatic dressing after dental extractions in over 900 patients, and found it effective in counteracting and preventing sepsis and promoting healing. Fowler and Jones used a powder containing dequalinium chloride 0.1% as a wound dressing in veterinary practice. The powder was applied topically to accidental and surgical wounds in over 100 animals and was effective in controlling infections due to the common bacterial contaminants occurring in infected wounds in animals.

Clinical Investigations

We have used dequalinium on 241 patients suffering from various skin conditions. Of these, seven defaulted, and 234 clinical trials were completed on the remaining 234, 20 of whom suffered from two separate conditions or took part in two separate trials. The preparations used were dequalinium cream, containing 0.4% dequalinium chloride, and dequalinium paint (propylene glycol base) containing 0.5% dequalinium chloride. Dequalinium lozenges were used in a few cases.

In order to satisfy ourselves of the absence of toxic or irritant effects on the human skin, we first used these preparations on 12 patients with acute or extensive epidermal damage—eczematous, bullous, and ecchymatous. No adverse effects were encountered after a minimum of two weeks' treatment, and it was therefore considered justifiable to continue with a full trial. The trial was conducted in three parts.

Range of Activity

First, we applied dequalinium to a wide variety of skin diseases in order to determine its range of activity. The results are shown in Table I.

124 trials were carried out, the preparation being used for a period of two weeks in most cases and from four to six weeks in paronychia and *Trichophyton rubrum* infections. Cure, or considerable improvement, resulted in 43

out of 51 trials in staphylococcal skin infections of various sorts, usually within a week. Good results were also obtained in conditions of mixed aetiology in which staphylococcal or monilial infections played an important part. A small number of ringworm lesions were treated, and in 8 out of 13 cases these cleared or improved. It is accepted, of course, that cattle ringworm in particular tends to remit spontaneously. Various conditions not primarily due to infective causes responded indifferently.

Therapeutic Effects

In order to establish that the therapeutic effects obtained were due to the active agent itself and not merely to the

TABLE II.—Comparison of Dequalinium With Inert Base

Diagnosis	More Effective	No. Difference Between Dequalinium and Base	Base More Effective
Infective conditions (e.g., impetigo, folliculitis)	12	3	1

base or to spontaneous resolution, a second series of 36 patients were treated with both substances—that is, base and the base with dequalinium incorporated. Whenever possible, opposite sides were treated at random. Where this was not practicable the preparations were each used consecutively for a minimum period of five to seven days. The active preparation and the base were labelled and dispensed by the pharmacist or ward sister and applied "blind." The results are shown in Table II.

In addition, six cases of "idiopathic" black hairy tongue were treated (see below). There was a significant difference in the activity of the two preparations.

Table II shows that the preparations containing dequalinium, when used in conditions where infection was present, were more effective than the bases alone.

Finally, dequalinium cream or lotion was used in comparison with preparations normally used by us—for example, dyes, neomycin ointments, hydrocortisone, etc. The two preparations were again allocated to sides at random, wherever possible. Where similar lesions could not be treated concurrently, however, the preparations were used consecutively. The results are given in Table III.

Comment

In conditions of pyococcal origin the results were the equivalent of those obtained with antibiotics and dyes, but a particularly gratifying effect was noticed in cases of secondarily infected eczema and infective eczematoid dermatitis around the ears and in the body folds. On the hairy areas, the beard, and scalp the paint was especially useful.

We have not yet had enough experience of the routine treatment of dequalinium in ringworm infections to assess its comparative effect against standard remedies; further trials are proceeding.

A small group of six patients with idiopathic black hairy tongues were treated. They had all had much previous treatment and had suffered from the complaint for more than six months. A variety of organisms and yeasts had been cultured from the mouths. These were probably of secondary significance only. In two cases where dequalinium paint was applied thrice daily, there was no difference between it and the base; in four cases the patients noticed an improvement in the appearance and taste while using dequalinium, but in only two of these did complete clearance take place. The four patients still affected were then given dequalinium lozenges in addition; one of these improved. The condition is subject to curious irregular remissions, and no firm conclusions can yet be drawn.

Bacteriology

As this was primarily a clinical trial bacteriological results are not discussed in any detail. If the clinical efficacy of dequalinium is confirmed, properly controlled bacteriological trials should be conducted separately. There are certain material difficulties inherent in a combined assessment, particularly in skin infections. For instance, the *in vitro* behaviour of the staphylococcus under controlled conditions is frequently different from that *in vivo*; the effective local concentration of a bacteriostatic depends upon tissue exudates and immunological mechanisms, and the problem of superinfection change of staphylococcal type in hospital material must be allowed for. We did not attempt, therefore, to control the results of treatment bacteriologically. But routine swabs were taken from the skin before and during treatment in a number of cases, and it may be of interest to mention the results of these.

From the affected area of skin 65 swabs were taken before treatment. Routine cultures grew no organisms, or commensals only, in 14 cases. A coagulase-positive staphylococcus was grown in 27 cases. In 15 of these the culture was sterile at the end of the first week of treatment, and, in a further 3 cases each, at the end of two and four weeks respectively. In the remaining 6 cases a staphylococcus was

still present. In 10 cases of leg ulcers, various Gram-negative organisms were grown, and these cleared in only four cases. Beta-haemolytic streptococci were cultured in an insufficient number of cases to merit comment.

From these routine bacteriological findings it seems likely that, at any rate so far as the staphylococcus is concerned, the clinical improvement obtained in most cases is reflected in the results of routine cultures from the skin.

Findings

In general we found dequalinium to be non-irritant even when applied to mucous membranes and the skin of infants. However, three cases of allergic sensitization were encountered. One of these was to the base and two to the active ingredient. The latter showed positive patch tests to the active cream and no reaction to the bases applied alone. This figure of 1.2% is low enough to be acceptable in practice, but occasional cases of sensitization will probably arise, as with other antibiotic and antiseptic agents.

Our findings may be listed as follows.

1. *Impetigo*.—Dequalinium is a clean and useful agent in this condition, and it has the great advantage of not creating antibiotic-resistant strains of staphylococci. The paint is particularly valuable in impetigo of hairy areas.

2. *Staphylococcal Neonatal Infection*.—Dequalinium constitutes an effective and most useful application in all forms of neonatal sepsis.

3. *Intertrigo*.—This condition, in which monilial or pyococcal infection is an important factor, responds well to dequalinium. (It was also very effective in a case of monilial balanitis.)

4. *Paronychia*.—Chronic paronychia of pyogenic or monilial origin responded well. (In all cases advice about keeping the fingers dry was given in addition to treatment with dequalinium.)

5. It may be used with safety and success in conditions in which infection is present together with eczematous changes in the skin. It has no specific value in non-infective conditions, but the cream appears to be soothing and is pleasant to use. It may have some value as a prophylactic in such conditions as acute cheilopompholyx, eczematized ringworm of the feet, and eczema of the scalp, all of which are particularly prone to secondary infection.

Summary

A new antibacterial agent, dequalinium, has been used on 241 patients suffering from various skin conditions. In the form both of cream and of paint it was used alone, in comparison with the inert bases, and in comparison against standard routine measures of treatment.

Dequalinium was found to be of considerable value in pyococcal infections of the skin, notably impetigo and neonatal staphylococcal infections. It was also of considerable value in skin conditions in which pyococcal or monilial infection played a predominant part. It also appeared to be of value in tinea infections in a relatively small number of patients.

Non-infective conditions did not respond, but were not made worse.

Dequalinium appeared to be as effective as antibiotic preparations and dyes and is pleasant to use, colourless, and relatively cheap. No irritant or toxic properties were observed, and it can be used on the mucous membranes and on the skins of infants. However, three cases of sensitization occurred, an incidence of 1.2%. In one of these the base was responsible.

We believe dequalinium to be a useful valuable preparation against pyococcal and monilial infections of

the skin, and one that represents a welcome addition to dermatological therapy.

ADDENDUM.—Since writing this paper we have been supplied with a quantity of dequalinium cream containing 0.5% prednisolone. Some 37 cases of atopic eczema, pruritus ani et vulvi, intertrigo, and neurodermatitis have been treated with this preparation. This prednisolone-dequalinium mixture showed a superior effect to the plain dequalinium cream, when used in these states, where itching and reflex rubbing are very pronounced. There were no failures in this short series, nor was any sensitization seen.

We are grateful to Drs. G. R. Boyes and L. L. Banks for their help; to Messrs. Allen and Hanburys Ltd. for supplies of dequadin cream and paint; and to Dr. C. L. Greenbury for his interest and advice.

SIZE OF THE ADRENALS IN JAMAICANS

BY

G. A. STIRLING, M.D.

AND

V. J. KEATING, M.B., F.F.A.R.C.S., D.A.

From University College of the West Indies, Jamaica

Not only does the pattern of disease in Jamaica differ from that encountered in Europe but the response of the Jamaican to shock is poor. Because a difference in endocrine make-up may be concerned, the weight of the adrenal glands in the Jamaican was compared with that of the European.

Variations in total adrenal gland weight may be due to cortex or medulla or both, and for this reason the weight of both components was estimated in 10 glands covering the full range of gland weights. In 20 more glands the cortical thickness was measured.

Materials and Methods

The adrenal glands from 105 (67 male and 38 female) adult Jamaicans of all racial groups were examined. The glands, obtained from routine necropsies, included material from 10 male cases of sudden and usually violent death.

The glands were dissected clean of fat and connective tissue, blotted dry with filter paper, and immediately weighed in grammes to two places of decimals on an analytical balance before fixation in 10% formol-saline solution. Ten of the glands, covering the whole range of weights, were selected and the cortical and medullary masses estimated by a modification of the methods of Swinyard (1940) and Allbrook (1956). Frozen sections were cut at intervals of 2 mm. and the unstained sections projected at eight diameters enlargement on to photographic paper. The photographic enlargements were cut out and the cortical and medullary components weighed separately to give a ratio. From this ratio and the weight of the whole gland the cortical and medullary weights were calculated.

In 20 more glands the thickness of the cortex was measured by means of a micrometer eyepiece. Each gland was divided by three parallel cuts made lengthwise. Frozen sections were cut from three of the surfaces and four different fields measured on each section, giving 12 measurements of cortical thickness in each gland.

Observations

The average weight of the paired adrenal glands from 105 adult Jamaicans was 8.58 g. (4.55 to 14.14 g.). The average of the 67 males was 8.78 g. (4.55 to 13.94 g.) and of the 38 females 8.22 g. (5.08 to 14.14 g.). In the 10 male cases of sudden and usually violent death the average paired adrenal gland weight was 7.33 g. (5.40 to 10.38 g.).

The average paired adrenal gland weight of 46 normotensive males was 8.59 g. (4.55 to 13.82 g.), of 21 hypertensive males 9.21 g. (4.58 to 13.94 g.), of 22 normotensive females 8.10 g. (5.13 to 14.14 g.), and of 16 hypertensive females 8.39 g. (5.08 to 13.35 g.). The paired adrenal gland weight was independent of the body weight (Fig. 1).

The cortical weight, but not the medullary weight, was directly proportional to the adrenal weight (Fig. 2). The average cortical thickness as measured in 20 glands was 1.13 mm. (0.85 to 1.80 mm.).

FIG. 1.—Combined adrenal gland weight in Jamaicans is independent of the body weight, and in most instances is less than the European average combined adrenal gland weight.

FIG. 2.—Cortical but not the medullary weight is proportional to the total adrenal gland weight.

Discussion

The average combined adrenal weight in the Jamaican male (8.78 g.) was less than that in the European male (13.82 g.) (see Table) and the difference was statistically

significant (observed difference was 15.0 times the standard error). In the Jamaican female it was 8.22 g. and in the European female 12.66 g., and the difference was also statistically significant (observed difference was 11.16 times the standard error).

Average Combined Adrenal Gland Weights in Europeans and Jamaicans

	No.	Average Combined Adrenal Gland Weight	σ
European males (Roessle and Roulet, 1932)	328	13.82 g.	± 2.80
European females (Roessle and Roulet, 1932)	277	12.66 g.	± 2.90
Jamaican males	67	8.78 g.	± 2.43
Jamaican females	38	8.22 g.	± 2.18

Since the cortical but not the medullary weight was directly proportional to the adrenal weight (Fig. 2), the smaller adrenals in the Jamaican are almost certainly due to a reduction in the all-important cortical mass. This was not an unexpected finding, since the majority of Jamaicans are of African or mixed African and Caucasian descent, and Swinyard (1940) and Allbrook (1956) have demonstrated a smaller cortical mass in the African than in the Caucasian.

Further evidence of a reduced cortical mass in the Jamaican was obtained by measuring the cortical thickness. Only one report of cortical thickness for purposes of comparison could be found. Goldzieher (1946) gives figures of 2.1 to 2.5 mm. These measurements were made presumably on glands from subjects of Caucasian descent. In our material the average cortical width in 20 glands was only 1.13 mm. (0.85 to 1.80 mm.).

No general agreement exists on whether the adrenal glands in the male are heavier than in the female. Roessle and Roulet (1932), in a large series, found that they were, but Swinyard (1940), in a small series, found the adrenal glands in the female were larger in both the white and negro races. Goldzieher (1946) thought the male glands were larger, but Dawson (1956) found no difference. In the present series the slight increase in the male as compared with the female average was statistically inconclusive.

Enlargement of the adrenal glands has been described in a number of conditions, including hypertension (Dawson, 1956). In Jamaican hypertensive cases the average adrenal weight was higher than in the normotensive cases (9.21 g. to 8.59 g. in the male and 8.39 g. to 8.10 g. in the female), although the difference was statistically inconclusive. These values are far below the corresponding figures given for European hypertensive cases by Dawson (1956).

Biochemists investigating steroid metabolism have noticed that the endocrine pattern of Africans differs from that of Europeans. Barnicot and Wolffson (1952) report that the mean 24-hour urinary 17-ketosteroid excretion in Africans is about half that of Europeans and that this finding applies to Africans living in London as well as to those in Nigeria. Friedmann (1954) has found a similar low excretion in Southern India. It has not yet been possible to estimate steroid excretion in Jamaica, but Thorn tests carried out on 18 patients taken at random from the surgical wards suggest a functional adrenocortical deficiency (Keating and A. Bras, 1957, unpublished data). Circulatory insufficiency during and after surgery which responds to cortisone treatment is fairly common here (Keating, 1956), and it would appear that an inadequate adrenocortical reserve may well be usual in Jamaican coloured patients.

What part a small adrenal cortical mass plays in the different pattern of disease in the Jamaican as compared with the European can only be a matter of conjecture, since so many variables are involved. Nevertheless it is of interest that in Jamaica a high proportion of renal as opposed to essential hypertension is encountered, that myocardial infarction is relatively rare, and that polyarteritis nodosa is practically unknown. Also, a different or rather exaggerated response

to injury is suggested by the frequency of keloids and by a curious dissociation between peptic ulceration, which is common enough, and perforation, which is unusual.

Summary

The adrenal glands in Jamaicans are smaller than in Europeans.

This reduction in size is probably due to a reduced cortical mass.

It is suggested that this reduced cortical mass is concerned in the poor response to shock reported in Jamaicans and others of African descent. It may also play some part in the different pattern of disease encountered in Jamaica.

We thank Professor G. Bras for criticizing the text, Mrs. L. Chuck for statistical advice, Mr. L. G. Edwards for photographic reproductions of the graphs, and Dr. C. Hutchison for collecting adrenals.

CONVERSION TESTING OF SCHOOLCHILDREN AFTER B.C.G. VACCINATION

BY

K. NEVILLE IRVINE, D.M.

Adviser in B.C.G. Vaccination to the Oxford Regional
Hospital Board

In the absence of a specific test to measure resistance after B.C.G. vaccination, tuberculin conversion is generally accepted as the criterion of successful vaccination. The consistently high level of conversion produced by the Danish fresh B.C.G. in this country has raised the question whether testing after vaccination is necessary. The nurse, who may be exposed to repeated and heavy tuberculous infection, can legitimately expect a conversion test to confirm the success of her vaccination; this applies equally to other contacts. But where mass vaccination is given to individuals not at special risk there is not the same necessity for individual testing, provided that a vaccine is used which is known consistently to produce a satisfactory conversion rate.

In 1954 the medical officers of health of the nine local health authorities in the Oxford Region* organized a joint scheme for recording and analysing the results of the vaccination of 13-year-old schoolchildren; the object of the scheme was to find out whether the conversion rate was high enough to warrant dispensing with the conversion test in schoolchildren.

*Dr. T. Anderson (Oxfordshire County Council), Dr. G. F. Bramley (Gloucestershire County Council), Dr. E. C. H. Huddy (Berkshire County Council), Dr. E. Hughes (Reading County Borough Council), Dr. C. D. L. Lycett (Wiltshire County Council), Dr. C. G. Payton (Northampton County Borough Council), Dr. C. M. Smith (Northamptonshire County Council), Dr. G. W. H. Townsend (Buckinghamshire County Council), Dr. J. F. Warin (Oxford County Borough Council).

Standardization of Procedure

Only non-contact schoolchildren were included in the scheme; contacts were referred to the appropriate chest physician. One test only was used for prevaccination- and conversion-testing; in five areas the single test was a Mantoux 10 T.U., and in the other four it was the Heaf test. Tuberculin-testing and vaccination was carried out at the appropriate school or clinic.

At the first session the child was given either a Mantoux 10 T.U. or a Heaf test on the left forearm; the standard preparations of P.P.D. issued by the Ministry for each test were used. The second session was held two to four days later, when the test was read; the criterion for a positive Mantoux was 6 mm. of induration and over. Negative reactors were vaccinated intracutaneously with 0.1 ml. Danish fresh vaccine (0.75 mg./ml.). The third session was held not earlier than four weeks after vaccination, and the test used at the first session was repeated on the right forearm. The fourth session was held two to four days later, when the test was read and the vaccination reaction inspected.

The results were recorded on a special card which was coded at the Regional Records Department and punched on Powers-Samas cards. Only those record cards which showed that this standard procedure had been followed throughout were classified as valid for statistical analysis.

School Year, 1954-5

This year was spent in getting the scheme started. School medical officers were learning the technique of vaccination, while the medical officers of health were enlisting the aid of headmasters and obtaining consent from parents. Seven of the areas began vaccinating during the year, but two did not start until the following school year. Buckinghamshire County Council was unable to carry out conversion testing throughout, owing to staff shortages; figures from this area have therefore been omitted. The results for 1954-5 from the six areas are given in Table I, but in view of the many growing pains the results from this year are excluded from the final analysis.

TABLE I.—Vaccination Results for the School Year 1954-5

	Mantoux 10 T.U.	Heaf Test
Number of B.C.G. vaccinations	2,610	634
.. validly tested for conversion	2,387	632
.. of positive reactors	2,139	624
.. of negative reactors	248	8
Conversion rate	89.6%	98.7%

School Year 1955-6

This year saw the scheme in full operation, and it was hoped to reach a conclusion by the end of the summer term. Unfortunately the Ministry reported that the P.P.D. issued for Mantoux testing had been found to be substandard; this defect was observed in the autumn of 1955 and was rectified in April, 1956. The P.P.D. for the Heaf test was not affected. In consequence, although the Heaf test conversion rate of 98.1% was reliable, the Mantoux conversion rate of 94.7% had to be regarded as unreliable; it was therefore decided to continue the scheme for a further year. The results for 1955-6 are given in Table II.

TABLE II.—Vaccination Results for the School Year 1955-6

	Mantoux 10 T.U.	Heaf Test
Number of B.C.G. vaccinations	5,352	3,034
.. validly tested for conversion	4,756	2,869
.. of positive reactors	4,504	2,814
.. of negative reactors	252	55
Conversion rate	94.7%	98.1%

School Year 1956-7

No further troubles occurred during this year. Forty different batches of vaccine were used and valid conversion

tests were done on 10,422 schoolchildren. The results for 1956-7 are given in Table III.

TABLE III.—Vaccination Results for the School Year 1956-7

	Mantoux 10 T.U.	Heaf Test
Number of B.C.G. vaccinations	6,917	4,867
.. validly tested for conversion	5,676	4,746
.. of positive reactors	5,471	4,647
.. of negative reactors	205	99
Conversion rate	96.4%	97.9%

Discussion

It is generally held that a conversion rate of 95% to a Mantoux 10 T.U. is adequate. The Medical Research Council's current tuberculosis vaccines clinical trial found that a conversion rate of 85.8% to a Mantoux 3 T.U. P.P.D. produced protection.¹ The Tuberculosis Research Office of the World Health Organization gives figures showing the correlation between the Mantoux 3 T.U. and 10 T.U. after vaccination. In a group of 262 vaccinated persons, 235 were positive (6 mm. and over) to a Mantoux 3 T.U.; all except one of the negative reactors were given a Mantoux 10 T.U., and a further 23 became positive.² This suggests that 10 T.U. will discover about 10% more positive reactors after vaccination than 3 T.U. If a conversion rate of 85.8% to 3 T.U. produces protection a conversion rate of 94.4% (85.8+10%) to 10 T.U. should theoretically be adequate. This line of reasoning is admittedly tenuous, but it does give some grounds for accepting 95% as the criterion of satisfactory conversion to a Mantoux 10 T.U.

As the conversion rate to a Mantoux 10 T.U. was 96.4% and to a Heaf test 97.9% using 40 different batches of vaccine, it was decided that the conversion testing of non-contact 13-year-old schoolchildren is unnecessary.

Summary

A trial was carried out in the local health authority areas of the Oxford Region to determine whether conversion-testing after B.C.G. vaccination of non-contact 13-year-old schoolchildren is necessary.

The conversion rate of 5,676 children to a Mantoux 10 T.U. P.P.D. was 96.4%.

The conversion rate of 4,746 children to a Heaf test P.P.D. was 97.9%.

Conversion-testing of non-contact 13-year-old children is unnecessary.

I should like to thank the Medical Research Council for grants made to me, the Oxford Regional Hospital Board for the facilities they afforded me, and the Regional Records Department for coding and analysing the results.

POSTSCRIPT.—The conclusion reached by this trial was accepted by the Ministry and has been incorporated in Memo 322/BCG (Revised 1958). The introduction of Glaxo freeze-dried B.C.G. has created a new problem, as it is desirable that laboratory control should be supplemented by clinical control on a sample of each batch. The Ministry has therefore requested the personnel of this trial to form a B.C.G. Control Centre at Oxford for this purpose. The Control Centre will make clinical observations on the conversion rate and the local reactions to vaccination.

The United States Council on Library Resources has awarded a grant of \$73,800 to the National Library of Medicine, Washington, for the purpose of setting up and administering a research project on methods of improving bibliographical services through the use of mechanical equipment. The aim is to improve the efficiency of publication of comprehensive periodical indexes in broad subject fields. If successful, the methods will be used to produce the *Current List of Medical Literature*.

TUBERCULOUS MENINGITIS FOLLOWING B.C.G. VACCINATION

BY

MARY R. KERR, M.B., Ch.B.

Assistant Physician, King's Cross Hospital, Dundee

AND

J. M. DUNBAR, M.D., B.Sc.

Lecturer in Bacteriology, University of St. Andrews, Queen's College, Dundee

It is well recognized that B.C.G. vaccination may frequently be followed by complications due to the strain of organism in the vaccine. Such complications are usually limited to adenitis with or without supuration and ulceration (Ministry of Health, 1958). In a few instances of tuberculosis developing after B.C.G. vaccine administration, it is the resulting immune process that has been overwhelmed by subsequent infection with virulent strains of mycobacteria. Miliary and meningeal forms of tuberculosis following B.C.G. vaccination are thought to be rare. This report is concerned with the development of tuberculous meningitis in a baby nine months after B.C.G. vaccination.

Case History

The patient was a baby girl of 11 months whose parents were known to suffer from pulmonary tuberculosis. She did not react to tuberculin, and on June 29, 1956, was given B.C.G. vaccine. When retested eight weeks later the tuberculin reaction had converted, giving an area of induration of 9 mm. and erythema of 12 mm. with O.T. 1:1,000. On April 1, 1957, over nine months after receiving B.C.G. vaccine, the baby was admitted to the meningitis unit, King's Cross Hospital. She had become ill eight days previously with listlessness, anorexia, vomiting, and insomnia. Loss of weight had been noticed, and immediately prior to admission the baby had become rigid.

On examination she was pale, irritable, slightly dehydrated, and had a high-pitched meningeal cry. Abnormal clinical findings were confined to the central nervous system. Signs of meningeal irritation were present with a moderate degree of cervical rigidity and Kernig's sign. The baby when disturbed was extremely irritable. There was no motor or sensory loss and cranial nerves were intact. Examination of optic fundi showed no papilloedema, and choroidal tubercles were not seen. Cerebrospinal fluid: pressure increased; cells, 230 per c.mm. (polymorphs 40%, lymphocytes 60%); protein, 180 mg. per 100 ml.; sugar, 7 mg. per 100 ml.; microscopic examination of the spider-web clot showed scanty acid-fast bacilli. Lung fields were normal on x-ray examination. Mantoux reaction: positive with dilution of 1:10,000 O.T. Blood leucocyte count, 17,000 per c.mm. (polymorphs 80%).

Treatment and Progress

Streptomycin, 0.05 g., was given intrathecally daily for seven days and 0.5 g. intramuscularly daily for 28 days. Isoniazid, 0.1 g., and para-aminosalicylic acid (P.A.S.), 2.5 g., were given daily by the oral route for a period of six months. The child's condition improved steadily and her temperature fell to within normal limits after one week. Signs of meningeal irritation disappeared. The cerebrospinal fluid examinations indicated a gradual return to normal levels. After four months the cell count was fewer than 10 cells per c.mm., and after six months the protein was less than 40 mg. per 100 ml. and the sugar content more than 45 mg. per 100 ml. No complications developed, and the baby was discharged from hospital in February, 1958, 10 months after admission. At the time of discharge she appeared to have made a complete recovery and was attempting speech and almost walking unaided.

Epidemiology

Some years before, in another area, the mother was found to have pulmonary tuberculosis and had two 90-day courses of streptomycin and P.A.S. Later, in August, 1952, typical acid-fast bacilli were demonstrated in sputum specimens on two occasions, but no further specimens have yielded acid-fast bacilli. The sensitivity patterns of the strain are not known, since the organism was not grown on culture. The father also was found to have a pulmonary lesion believed to be inactive, though it was still being observed at three-monthly intervals. The only other member of the family in the home, a brother of 19 years, had a lung cavity demonstrated radiologically in 1956, but at no time have acid-fast bacilli been observed or isolated from sputum specimens. The appearance of this lesion is improving on combined streptomycin and isoniazid therapy.

The source of infection of the child is not known for certain. A possible sequence of events is that the brother may have been infected from the mother, and he, in turn, may have infected his sister, since he had probably the most active disease in the family at the time of the baby's infection. Until the patient became ill, the family of four resided in a caravan which, however commodious in itself, was a "single apartment." Since three members of the family had evidence of tuberculosis the ready transference of infection is understandable.

Bacteriology

Isolation.—Paired Löwenstein-Jensen slopes inoculated with spider-web clot and deposit from two specimens of cerebrospinal fluid yielded innumerable discrete colonies after 26 days' incubation. Although it was noted at the time that the colonies tended to appear less craggy and dry than the typical human variety, they were not considered to be bovine in origin.

Sensitivity Pattern.—The strain was sensitive to 10 µg. of streptomycin per ml., 0.2 µg. of P.A.S. per ml., and 0.2 µg. of isoniazid per ml.

Virulence: Catalase Test.—The method used differed from that recommended by Middlebrook *et al.* (1954) in that individual colonies were selected and transferred to tubes containing equal quantities of 20-volume H₂O₂ and 10% "tween 80" solution. Control tubes containing a comparable inoculum of the H₃₇Rv variety of *Mycobacterium tuberculosis* and a selection of recently isolated strains including atypical mycobacteria allowed of a comparison of the enzyme activity to be made. The time of appearance and the amount of oxygen liberated, shown by the bubbles at the surface with the strain under investigation, were similar to that of H₃₇Rv and recently isolated virulent strains.

Animal Inoculation.—Various weighed inocula, 0.1–0.5 mg. of the test strain, were injected intraperitoneally and intramuscularly into four guinea-pigs. Examination at necropsy six to eight weeks later showed progressive generalized tuberculosis. Typical acid-fast bacilli were demonstrated in the spleen, liver, and lung, and, in addition, after intramuscular inoculation caseous lymph nodes were observed in inguinal, lumbar, and tracheo-bronchial sites. Typical cultures were isolated from such lesions. Following intravenous injection the strain did not produce progressive tuberculosis in a rabbit.

Summary

A case of tuberculous meningitis is described occurring in an 11-months-old baby who had been given B.C.G. vaccine nine months previously. The infecting organism was shown to be a virulent strain of *Mycobacterium tuberculosis* of the human variety.

Our thanks are due to Dr. W. H. Findlay, area chest physician, Perth, for details of the medical history of the family.

HYPOPROTEINAEMIA AFTER PARTIAL GASTRECTOMY CORRECTED BY GLUTEN-FREE DIET

BY

JOHN W. B. FORSHAW, M.D. M.R.C.P.

Senior Medical Registrar, Royal Southern Hospital, Liverpool

The nutritional disturbances following partial (Polya) gastrectomy are usually produced by defective absorption of iron, fat, and the vitamin-B complex (Wollaeger, Comfort, and Weir, 1946; Welbourn, Hughes, and Wells, 1951; Wells and MacPhee, 1954), and although nitrogen absorption is sometimes impaired, this rarely produces hypoproteinaemia (Wollaeger *et al.*, 1946). The deficiency of iron and vitamins may be corrected by giving large doses of these substances either by mouth or parenterally, but in order to correct serious deficiency states the Polya may have to be converted to a Billroth I gastrectomy, in which the blind loop is undone (Bruce, 1955).

It has been established that in most cases of idiopathic steatorrhoea the defective fat absorption is induced by gluten, and that after removal of gluten from the diet fat absorption returns to normal (French, Hawkins, and Smith, 1957). In addition it has been shown that a gluten-free diet corrects the associated faulty absorption of vitamins, minerals (French *et al.*, 1957), and nitrogen (McIver, 1952; Forshaw, 1957). There would appear to be no reason to expect that gluten could be responsible for the malabsorption following partial gastrectomy, and there have been no reports of the trial of a gluten-free diet in such cases.

The purpose of the present report is to describe the beneficial effect of a gluten-free diet in a patient in whom a low plasma albumin level producing oedema followed a partial gastrectomy; and to emphasize that severe impairment of nitrogen absorption may rarely occur without any apparent disturbance of fat and iron absorption.

Case Report

A man aged 47 was admitted to hospital in October, 1957. He had had a Polya gastrectomy for a duodenal ulcer five years previously. Following the operation he developed attacks of sweating and flushing of the face immediately after food, but otherwise his condition had been satisfactory for four years; he then developed diarrhoea and continued to pass between four and eight pale loose motions daily. During the past three months his mouth and tongue had been sore, and three weeks before admission he developed swelling of both feet and legs and a rash on the legs and abdomen. He thought that he had lost a small amount of weight since the partial gastrectomy, but his weight at the time of operation had not been recorded. There was no history of any significant previous illnesses.

On examination severe glossitis, cheilosis, and angular stomatitis were present. Both feet and legs were moderately swollen, and there was a patchy excoriated erythematous rash on the legs and abdomen. There were no abnormal neurological signs. His weight was 7 st. 2 lb. (45.4 kg.).

Investigations.—Radiographs of the chest and long bones were normal. Radiological examination of the gastrointestinal tract showed that the stoma functioned normally and there was no evidence of stomal ulceration; there was no flocculation of barium in the small intestine, and the barium had been completely evacuated from the bowel

within 24 hours. Barium-enema radiographs showed no evidence of a fistula between the colon and the stomach or small intestine. The blood picture was normal: haemoglobin, 13 g. per 100 ml.; plasma proteins, 4.6 g. (albumin 2 g., globulin 2.6 g.; electrophoresis of globulin, normal); serum calcium, 8.1 mg.; serum sodium, 345 mg.; serum potassium, 18 mg.; serum iron, 105 µg.; serum bilirubin, 0.4 mg.; serum alkaline phosphatase, 8 King-Armstrong units; serum amylase, 120 units; and thymol turbidity, 2 units per 100 ml. Urea clearance test was 60% of average normal and urine normal. The glucose-tolerance curve showed a rise of the blood-sugar level to 180 mg. per 100 ml. half an hour after 50 g. of glucose and then a fall to 40 mg. per 100 ml. one hour later. Faeces contained no undigested muscle fibres; faecal fat content, 11.5 g. per 100 g. of dried faeces. A fat-balance test over seven days showed 91% fat-absorption.

Treatment and Progress.—Ascorbic acid, 500 mg., thiamine, 250 mg., nicotinamide, 160 mg., riboflavin, 4 mg., and pyridoxine, 50 mg. ("parenterovite"), were given daily intramuscularly for seven days, and subsequently vitamin-B complex was given by mouth for six weeks. The changes in the mouth and tongue rapidly improved, completely clearing up within three weeks of starting treatment. Treatment with a high-protein diet was given for one month, but during this time the oedema of the feet and legs persisted and the plasma protein level fell to 4.6 g. per 100 ml. (albumin, 1.6 g.; globulin, 3 g.) (see Chart). At this time his

weight was 6 st. 13 lb. (44 kg.). On November 20, 1957, a treatment was started with a gluten-free diet. Within a month the oedema had completely cleared up, he had gained 7 lb. (3.2 kg.) in weight, and the plasma proteins had risen to 6.2 g. per 100 ml. (albumin, 3.6 g.; globulin, 2.6 g.).

On April 2, 1958, the improvement was maintained, and the plasma proteins were 6.4 g. per 100 ml. (albumin, 4 g.; globulin, 2.4 g.). He was feeling well and the mouth and tongue were normal. He still had slight sweating and flushing of the face immediately after food, and was passing three or four motions daily.

On July 9 he attended hospital complaining that the rash and swelling of the legs had returned a month previously, and he admitted that during the previous two months he had not been keeping strictly to the gluten-free diet. On examination there was oedema of both legs and the plasma protein level was 5.2 g. per 100 ml. (albumin 2.7 g., globulin 2.5 g.). He agreed to keep strictly to the gluten-free diet, and when seen on August 20 the oedema of the legs had cleared up and the albumin level had risen to 3.2 g. per 100 ml.

Discussion

Following both total and partial (Polya) gastrectomy the absorption of nitrogen is rarely impaired sufficiently to pro-

duce hypoproteinaemia. Blake and Rechnitzer (1953) found that the plasma protein level was invariably normal in nine patients at an interval between nine months and three years after total gastrectomy, and Welbourn *et al.* (1951) found that the plasma protein level was below 5.5 g. per 100 ml. in only one out of seven patients following a Polya gastrectomy, and this patient did not have oedema. Wollaeger *et al.* (1946) have shown, however, that after partial gastrectomy there is occasionally a slight excess of nitrogen in the faeces, and in one of their patients who developed hypoproteinaemia and oedema the nitrogen excess was considerable. Furthermore, they noted that excess faecal nitrogen did not tend to occur more often in those patients who lost the most fat in their stools.

The factors which have been thought to be responsible for the absorptive disorders following gastric operations are as follows: (1) impairment of the mechanism which stimulates the flow of pancreatic secretions and bile; (2) imperfect mixing of the food with digestive ferments owing to the shunting of the gastric contents away from the duodenum; (3) intestinal hurry: Wells and Welbourn (1951) decreased the amount of fat excreted in the faeces by slowing the rate of peristalsis with ganglion-blocking drugs; and (4) growth of bacterial flora in the stagnant loop may compete with the host for vitamins and damage the intestinal mucosa (Witts, 1955). Baird and Dodge (1957), however, found slight abnormalities in the jejunal mucosa in only 8 out of 31 patients following partial gastrectomy, and they conclude that the impaired absorption of fat and iron following partial gastrectomy cannot regularly be attributed to structural alteration in the jejunal mucosa. Most probably the relative importance of these aetiological factors varies considerably, thus accounting for the variation in the relative degree of absorption of fat, nitrogen, vitamins, and minerals in different cases.

In the case described here the correction of the low plasma albumin level by a gluten-free diet was unexpected, but the explanation that the impaired nitrogen absorption was primarily induced by gluten and unrelated to the partial gastrectomy seems too coincidental to be readily accepted. It will be necessary, however, to try the effect of a gluten-free diet on a number of such cases before a conclusion can be reached. If it is assumed that the impaired nitrogen absorption was produced by the partial gastrectomy, then the mechanism by which gluten contributes towards the absorptive disorder remains to be discussed. French *et al.* (1957) have suggested two possible explanations for the mechanism of defective absorption in cases of idiopathic steatorrhoea. Firstly, that gluten may produce an allergic reaction in the intestinal mucosa resulting in an increased secretion of mucus which delays absorption. Secondly, that there may be a failure to digest gluten which may lead to the development of toxic substances by intestinal bacteria. Although there is no evidence as yet to support either of these explanations, it is tentatively suggested that partial gastrectomy may occasionally produce a disturbance of gluten digestion, thus leading to the production of toxic substances capable of damaging the jejunal mucosa.

Summary

A case is described in which severe impairment of nitrogen absorption following a partial (Polya) gastrectomy was corrected by a gluten-free diet. The impaired nitrogen absorption produced a selective fall in the plasma albumin level, the globulin level remaining within normal limits.

Severe impairment of nitrogen absorption occurs only rarely after partial gastrectomy, and the nutritional disturbances are more usually produced by impaired absorption of iron, fat, and the vitamin-B complex. In the present case, although there were clinical manifesta-

tions of riboflavine and nicotinamide deficiency, there was no anaemia, and fat absorption was only slightly impaired.

My thanks are due to Dr. E. N. Chamberlain for permission to publish this case.

Medical Memorandum

Arthropathy due to Gastric Carcinoma

Certain gastro-intestinal diseases are recognized causes of arthropathy or of finger-clubbing; for instance, ulcerative colitis (Schlicke and Bergen, 1940), steatorrhoea (Bennett *et al.*, 1932), and amoebic or bacillary dysentery (Rappaport *et al.*, 1951). Arthropathy may also be the presenting symptom in carcinoma of the bronchus (Berg, 1949; Holmes *et al.*, 1950; Ellman, 1953), but carcinoma of the alimentary tract associated with arthropathy is very rare, although finger-clubbing has been described in cases of carcinoma of the small bowel and colon (Mendlowitz, 1942) and of the stomach (Willemse, 1922).

There is no report of gastric carcinoma causing arthropathy, and so a case with this association is worthy of record.

CASE REPORT

A single woman aged 64 had had periodic blood-stained vomits for 10 months, and for five months she noticed that food seemed to "stick" at about mid-sternal level, though she was able to eat solids normally. She had lost a few pounds in weight. For four months she had had pains in her knees, ankles, wrists, and small joints of the fingers. The pains in the fingers were so bad that she could not make a fist or grip with either hand, and had been taking 8 or 10 aspirin tablets daily.

Examination showed her to be well nourished, with moderate pallor. There was grade 1 finger-clubbing. The proximal interphalangeal joints and metacarpophalangeal joints of both hands were swollen and tender, and movements were limited in these joints. The wrists, ankles, and knees were not swollen, but movements were painful, and the ankles were tender. The dorsum of each hand appeared swollen. There was no bony tenderness.

Investigations.—Hb, 7.7 g./100 ml. (52%); M.C.H.C., 26%; M.C.V., 71 cubic microns; P.C.V., 30%; W.B.C., 11,200/c.mm.; E.S.R., 29 mm. fall in one hour (Wintrobe). C-reactive protein, +++; Rose's test (D.A.T.), 1 in 8. Serum proteins, total 5.8 g./100 ml. (albumin, 3.6 g.). Barium-meal examination showed a new growth of the cardiac end of the stomach close to the oesophageal opening.

Mr. D. Ioan-Jones removed the carcinoma, a well-differentiated adenocarcinoma with one lymph node involved. The joint pains disappeared two days after operation, and the swollen joints became normal within three weeks. Five weeks after operation the C-reactive protein was +; Rose's test (D.A.T.), 1 in 2.

DISCUSSION

Pathogenesis.—The mechanism of a carcinomatous arthropathy is not clear. Removal of the primary tumour is known to relieve arthropathy at once (Clagett *et al.*, 1952;

Ellman, 1953), and simple section of the vagi, which is thought to abolish a "neural reflex," has also caused instant relief of arthropathy (Flavell, 1956). The vagi were cut at gastrectomy in the present case, and so the prompt relief of her joint pains could have been due either to interruption of a vagal reflex arc or to removal of the gastric carcinoma. Our patient showed no signs to support two other hypotheses—"dyspituitarism" (Fried, 1943), and "toxic absorption" (Wooler, 1948) due to delayed gastric emptying (Preble, 1898; Dennig, 1901), and so the pathogenesis of her arthropathy cannot be defined.

Incidence and Sex.—Arthropathy is said to occur in 50% of cases of pleural tumours (Clagett *et al.*, 1952), but it has not been reported in carcinoma of the stomach, although Willemse (1922) described two cases with marked finger-clubbing and solitary gastric cancers. Analysis of the case records of the last 200 patients with a proved gastric carcinoma at this hospital has shown that not one had joint pains, only four had finger-clubbing, and two of these four had chronic lung disease more than likely to cause such finger-clubbing. The patient described above is a female, whereas osteoarthropathy associated with intrathoracic neoplasms (Bamberger-Marie syndrome) is much commoner in males (Gall *et al.*, 1951; Shapiro, 1956).

Joints Involved.—The joints which are involved most often in an arthropathy associated with carcinoma are the ankles, knees, wrists, and interphalangeal joints. Only these joints were affected in our patient, and the distribution of her arthropathy could well have been mistaken for early rheumatoid arthritis. Craig (1937), Berg (1949), and Frank (1952), have all stressed that rheumatoid arthritis may be confused with arthropathy due to carcinoma, especially when the primary tumour itself causes no symptoms.

Investigations.—Many workers stress that the E.S.R. is very high in patients with arthropathy due to carcinoma; for instance, Hansen (1952) and Holmes *et al.* (1950) report values of 70–120 mm. fall in one hour. This is not always the case, however, as Pattison *et al.* (1951) report values of 23–32 mm., which accord with the E.S.R. of 29 mm. (Wintrobe) in our patient. It is interesting to note that in our patient the Rose test (D.A.T.) titre fell from 1:8 to 1:2 after operation, and as 1:16 is the lowest significant titre for rheumatoid arthritis (Kellgren, 1957), this test might be useful in differentiating from the arthropathy due to carcinoma. A fever, often reaching 101 to 102° F. (38.3 to 38.9° C.) (Fischl, 1950), and a normocytic anaemia (Temple and Jaspin, 1948) may occur in pulmonary osteoarthropathy, but our case had different features: a low-grade fever, to 99° F. (37.2° C.) only, and a hypochromic anaemia due to blood loss.

I thank Dr. William Phillips and Mr. D. Ioan-Jones for permission to publish this case report, and Dr. Phillips for his constant help and encouragement.

Reviews

RENAL DISEASE

The Kidney. An Outline of Normal and Abnormal Structure and Function. By H. E. de Wardener, M.B.E., M.D., F.R.C.P. (Pp. 338+viii; illustrated. 45s.) London: J. and A. Churchill, Ltd. 1958.

The enduring impression which this book will leave in the minds of those who know something about renal disease will be one of gratitude to the author for having had the will be one of gratitude to the author for having had the courage to write a monograph on this most difficult of all subjects. There is probably no branch of medicine in which the scatter of knowledge is so great, so obvious is the contrast between the tremendous advances in our understanding of renal function in health and disease on the one hand, and our almost complete ignorance of the causation and rational treatment of most types of renal disease on the other.

On the whole de Wardener has overcome the difficulties with as much success as could be expected. His chapters on renal structure and function are clear and instructive and will appeal to the intelligent reader, and he avoids the temptation of over-simplifying and thus bringing his material down to the level found in most textbooks of medicine. With the difficult question of classification he is rather less successful. Wisely he tries to avoid the unnecessary and irrational complications of classification brought about by successive authors on renal disease, and prefers to describe syndromes of renal disease as they are found in practice. This treatment of the subject, sensible though it may be in some respects in the present state of our ignorance, tends to leave the reader with a fair impression of kidney disease as it may present itself at a certain stage of its development, but fails to give him as good a picture of renal disease observed over a period of years. Admittedly the information can be found in the book, and to those who already have long experience of renal disorders there is no difficulty; but it is rather like using a somewhat complicated map which is of more value to one who already knows the district than to one who has never been there before.

The book is intended primarily for students, and, though they will find much valuable material in it, one wonders whether the end-result will not be to confuse rather than to enlighten all but the best of them; but, as the less intelligent ones probably never read monographs, this may not matter very much, and the book can be strongly recommended to anyone who has a working experience of kidney disease and wants to get up to date with new knowledge.

ROBERT PLATT.

HORMONAL RESEARCH

Biochemical Contributions to Endocrinology: Experiments in Hormonal Research. By Sir Charles Dodds, M.V.O. (Pp. 76; illustrated. 18s.) Stanford, California: Stanford University Press. London: Oxford University Press. 1957.

The book is based on the Lane Medical Lectures of 1956 at Stanford University. It largely covers the researches of Sir Charles Dodds and his colleagues in the Courtauld Institute of Biochemistry, Middlesex Hospital, during more than thirty years. The development of highly active artificial oestrogens, of which the first was diethylstilboestrol (now more commonly known as stilboestrol), was a most striking contribution of Dodds and his colleagues, and in the chapters on the relation of chemical structure to oestrogenic activity he discusses how these developments came about. The account of the investigations which led from the first purely synthetic substance with oestrogenic activity, capable of inducing a full oestrus response in the ovariectomized rat in a dose of about 100 mg., to substances about a million times as active, is a most interesting and illuminating one. The agricultural application of synthetic oestrogens, discussed in a chapter of the book, is an outcome of wide importance of these investigations, while

another is the use of stilboestrol in the treatment of carcinoma of the prostate. The pituitary gland and the control of gastric secretion, still a matter of discussion, the lack of simple relationship between the metabolic rate and the symptoms of myxoedema, the production of simpler substances with some of the activities of morphine, are other subjects touched upon in this interesting volume. The final chapter deals with the discovery of aldosterone at the Middlesex Hospital Medical School by Drs. Simpson and Tait. The full significance of this very important discovery is not yet finally elucidated, but it is certain that aldosterone will not remain the only or main representative of such a highly oxygenated naturally occurring steroid with biologically important properties. The researches of Sir Charles Dodds and his colleagues in the field of endocrinology have indeed been most fruitful, and this account of the master mind behind them is of outstanding interest.

F. G. YOUNG.

PHYSICS FOR ANAESTHETISTS

Physics for the Anaesthetist: Including a Section on Explosions. By Sir Robert Macintosh, D.M., F.R.C.S.E., F.F.A., R.C.S., William W. Mushin, M.A., M.B., B.S., F.F.A., R.C.S., and H. G. Epstein, M.A., Ph.D., F.F.A., R.C.S. Illustrated by Miss M. McLarty and Miss M. Beck. Second edition. (Pp. 443+xii. 60s.) Oxford: Blackwell Scientific Publications. 1958.

Before 1946 the knowledge of physics possessed by the average anaesthetist was distinctly sketchy, being based on hazy recollections of his First M.B. lectures. Attempts to remedy the deficiency were frustrated by the dearth of books dealing in simple language with the special problems which concerned him. One result was that many ingenious modifications of apparatus (and the anaesthetist is a notorious individualist) failed for lack of appreciation of some fundamental physical law.

When *Physics for the Anaesthetist* first appeared it was an immediate success and became the recognized textbook on the subject. The authors adopted the principle of using short and clear description supplemented by specially drawn diagrams which eliminated irrelevant factors while remaining essentially accurate. Some of the diagrams were in colour. This technique caused raised eyebrows among some of the pure physicists but has proved to be admirably suited for its purpose, and many a successful candidate for the F.F.A. R.C.S. has cause to thank the authors for it. The book has been out of print for five years and an up-to-date edition is most welcome. Dr. H. G. Epstein has joined the two original authors in revising and adding to the text. The main alteration is a section of over 130 pages on explosions, which are dealt with in exhaustive fashion. The dangers of induced currents from surgical diathermy are mentioned, but the risk of burns and explosions from secondary earths might be emphasized with advantage in future editions. The subjects of reducing valves and the flow of fluids have also been dealt with in much more detailed fashion than in the first edition. A list of conversion factors and some biographical notes on leading physicists add to the completeness and interest of this excellent book, which can be recommended without reserve.

C. LANGTON HEWER.

MEDICAL DISCOVERY

Modern Medical Discoveries. By J. G. Thwaites, M.B., B.S. (Pp. 234+xii; illustrated. 30s.) London: Routledge and Kegan Paul Ltd. 1958.

In the U.S.A. at the present time much concern is expressed about the difficulty of recruiting scientists. Great resources are available for buildings and equipment, but there are not always the men to use them. The reasons for this are complex, but there has been a tendency for politicians and educationists to treat education as a means of securing social conformity or equality rather than of promoting intellectual competition. Samuel Smiles and his doctrine of self-help are out of fashion and the modern shibboleth is "together-

ness." Nevertheless, a change is occurring, as it is realized that the struggle for survival will be hard in this overcrowded century and we shall need the best scientists we can produce. One way to get them is to make young people interested in science, to show them what the scientific life is like, and to encourage them to take it up.

Dr. Thwaites has written his book on modern medical discoveries for just this purpose and just this audience. It is addressed to readers of 16 to 18, but it will be of interest to intelligent people of all ages. It can be particularly recommended for non-medical graduates and technical assistants in medical laboratories as an introduction to medical research. It begins with three chapters on infectious diseases, their causes, prevention, and treatment. Then follow chapters on cancer, hormones, and blood, and three chapters on various aspects of radiology and ionizing radiations. Finally Dr. Thwaites deals with anaesthesia and surgery.

The author of a book of this kind must steer a course between over-simplification or dramatization on the one hand, and on the other so many reservations and qualifications that the book becomes dull and unreadable. Dr. Thwaites's writing is both vivid and accurate and his range of knowledge is wide. The chapter on radiation hazards is particularly well balanced and informed. Of course, the reviewer can always dot a few "i's." Ludwik Gross's work on virus in mammalian leukaemia and neoplasia is a good deal more convincing and exciting than Gye's, though it does not get us far in therapy, as it seems to suggest that most of us inherit and carry latent cancer viruses. The book is well illustrated. One hopes that it will be so successful that it will be possible to reduce the price of future editions.

L. J. WITTS.

MENTAL DEFICIENCY

Mental Deficiency. By L. T. Hilliard, M.A., M.B., D.P.M., and Brian H. Kirman, M.D., D.P.M. With the Assistance of Four Contributors. (Pp. 517+xvi; illustrated. 60s.) London: J. and A. Churchill Ltd. 1957.

After the 1914 war the Fountain Hospital developed a considerable reputation through the enthusiasm and keen observation of Dr. Brushfield. Since the 1939 war the reputation has been revived by Drs. Hilliard and Kirman, and it is interesting to note the change in the field of research and in the outlook on mental deficiency. We are now in the midst of biochemistry, metabolic syndromes, well-founded genetics, sociology, and psychological researches. Indeed, some psychiatrists may be startled by Dr. Kirman's statement that mental deficiency is hardly a separate branch of clinical medicine, but the prime responsibility of the educationist and sociologist. However, he shows clearly in the rest of his 200 pages that it is really a subject which must be guided and controlled by men of medicine and of psychiatry. Whereas a generation ago there was too much emphasis on genetics as then understood, the present authors seem to have swung too far towards reliance on environmental conditions as causes and on their social improvement as treatment. Indeed, in some of the discussion of what ought to be there is almost a tone of propaganda, which is unexpected in a medical work.

The book is essentially a statement of the Fountain school of thought, and the views of its six authors are well integrated by Dr. Hilliard, who acted as editor besides writing the chapters on administrative and legal procedures. In the nature of mental deficiency there can be no very satisfactory classification, but that used here is logical and useful and the chapters are signed. Psychology and employment are by the psychologists, Drs. Tizard and O'Connor; causation and pathology are covered by Dr. Crome; while Miss Williams deals with education and training from the standpoint of the teacher. The clinical subjects are all set out by Dr. Kirman. All the subjects are presented in a thorough and sensible way, with no more repetition than is inevitable with a multiple authorship. Each chapter has its own extensive list of references, and there is some un-

usually full history of the progress of thought and practice in the subject.

This is a necessary book, and it is a comfort that it is written in such good and easy English, and so well presented by the publishers. Only two small errata were noted for correction in the next edition.

N. H. M. BURKE.

TUMOURS OF BONE

Bone Tumors: General Aspects and an Analysis of 2,276 Cases. By David C. Dahlin, M.D. (Pp. 224+viii; illustrated. 87s. 6d.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1957.

The topic of bone tumours is encumbered with two difficulties—a somewhat spurious nomenclature, and the fact that few individuals are able to acquire in a lifetime an adequate experience of these rather rare growths. Dr. Dahlin, by adopting without argument the names currently in fashion, does nothing to resolve the first, but he has been able to overcome the second by drawing on the superbly organized resources of the Mayo Clinic. The unique value of his book is that his statistics of sex and age incidence, localization, and other characteristics are based on substantial numbers of cases, each personally reviewed histologically and classified in a uniform and contemporary manner. The heterogeneity that often results from accepting the diagnosis of others, as in compiling reviews of cases from the journals, is thus avoided. The numbers in many of the groups are impressive—109 osteoclastomas, 80 chordomas, 70 reticulum-cell sarcomas, 141 Ewing's tumours, and so on. Osteogenic sarcoma, correctly defined as bone-forming, is identified by the direct formation of neoplastic bone, or histologically identified osteoid, by the proliferating malignant connective-tissue cells; the 469 cases are subdivided into osteoblastic, chondroblastic, and fibroblastic varieties according to the predominant line of differentiation. Bone that appears in a chondrosarcoma is held to result "from the differentiation of chondroid substance," and not directly as in the osteogenic sarcoma with cartilage. The point is arguable, but forms a practical basis for the classification, since it is here shown to have resulted in a marked distinction of characteristics of behaviour.

The excellent illustrations of radiographs, gross specimens, and micro-sections make the book an acceptable atlas which will serve a useful purpose. A few references are given at the end of each section, but there is no discussion of the literature, and the presentation is avowedly dogmatic and brief. Apart from its value as a concise, well-illustrated description of bone tumours, Dr. Dahlin's book is a considerable and original contribution to bone pathology on account of its factual record of a large experience simply, but carefully, analysed.

D. H. COLLINS.

Clinical Biochemistry, by Ivan Maxwell, is intended primarily for medical students, but may also serve as a compact reference book of test procedures for general practitioners. It is written by a former teacher at the University of Melbourne. The seventh edition (389 pages; 75s.) is available in this country from the Cambridge University Press.

Practitioners' Conferences, Vol. 5, edited by Claude E. Forkner (396 pp.; Appleton-Century Crofts, Inc., New York, 1957; \$6.75), continues the series of verbatim reports of conferences held at the New York Hospital-Cornell Medical Center. These conferences have as their object bedside teaching and are intended for physicians, surgeons, general practitioners, and specialists. The present volume reports 14 conferences on a variety of subjects.

In *Eye Surgery*, first published in 1946, Mr. H. B. Stallard provides a full account of the technique of those operations which have an accepted place in current ophthalmic surgery. The third edition, now available from John Wright and Sons, Bristol (899 pp., 671 illustrations; 95s.), has been thoroughly revised and in part rewritten. It contains over 200 pages more than the previous edition; 150 illustrations have been discarded and 275 new ones, many drawn by the author himself, have been added.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY OCTOBER 25 1958

PROGNOSIS AND TREATMENT OF DISSEMINATED SCLEROSIS

Despite the variable clinical course of disseminated sclerosis, it is commonly assumed that all patients sooner or later become severely disabled. That this fact is regrettably true of the majority cannot be denied, but there is some evidence that a more benign form of the disease may exist. As D. McAlpine¹ has pointed out, there are some patients who make a good recovery from an initial attack of the disease, and relapses may then be mild and infrequent or may cease altogether. Of a series of 586 cases observed at the Middlesex Hospital, 13% of those followed for 15 years showed no disability.² L. Alexander and his co-workers³ have confirmed that the disease exists in severe and mild forms, but point out that there is some overlap between the two. They believe that it is possible, five years after the onset, to predict into which of these two groups any individual patient will fall. This assessment is derived from a complex method—first devised by Alexander in 1951⁴—of allotting a numerical score to the various symptoms and physical signs roughly in proportion to the severity and significance of the resulting disability. Alexander claims that when different observers were asked to calculate the score for any single patient the results were remarkably consistent. By making this calculation at frequent intervals it was possible to obtain a graphic representation of the course of the disease. On this scale a score of 0 would be given if there were no symptoms or physical signs, while a totally disabled patient would achieve a figure of approximately

500. It is now suggested⁵ that, if a patient should have a total score of less than 125 after the illness has been in progress for five years, a mild course can be confidently predicted, while if it is over 200 the progress of the disease is likely to be comparatively rapid and the consequent disability severe. Despite the obvious dangers in such a method of assessing disability in a clinically pleomorphic disease—dangers which are even more apparent in simpler indices of severity such as the ten-point scale devised by J. F. Kurtzke⁶—laborious measurements of this type do at least give a degree of objectivity which may be useful in attempts to assess the effect of treatment.

Though there may be some encouragement to sufferers, and to those who care for them, in the knowledge that the disease may sometimes be mild, the discovery of an effective treatment must remain a principal aim of research, since so many patients become crippled at a comparatively early stage. The multiplicity of remedies advocated at one time or another shows how many and varied have been the theories about the aetiology of the disease. Thus numerous bacterial vaccines have been given in the belief that the disease may be infective, as have arsenic and fever therapy.⁶ There is little evidence that these methods have any value, though McAlpine¹ continues to advise arsenotherapy in some cases. Because narrowing or spasm of blood vessels has been suggested as an aetiological factor, histamine⁷ and other vasodilators such as nicotinic acid have been tried. R. M. Brickner⁸ believes that remedies of this type may have some benefit during acute episodes of the disease, but his results have not been confirmed. Many diets have also been devised from time to time, the latest being the low-fat diet of R. L. Swank,⁹ but the rationale of this method is far from convincing. Treatment with liver extracts or vitamin B₁₂ is extensively used in Britain, though there is little reason for prescribing these remedies and they are probably given *faute de mieux* rather than as rational therapy. Isoniazid, which has also been widely used, has been found to have no significant effect upon the course of the disease.¹⁰ Physiotherapy is occasionally very helpful, though it has no direct influence upon the disease process, simply helping to relieve symptoms, as do drugs such as mephenesin, chlorpromazine, and zoxazolamine, which may sometimes reduce spasticity.

Much publicity has been given to the Russian vaccine which A. Shubladze and S. Gaidamovitch¹¹ claimed to be an effective treatment. This vaccine was prepared from the so-called E.H.A. virus isolated from cases of disseminated sclerosis in 1942 by Margulis, Soloviev, and Shubladze. At the begin-

ning of this year Professor G. W. Dick and his co-workers¹² in Belfast reported that the virus from which the Russian vaccine was made was indistinguishable from rabies virus and that the vaccine might therefore be dangerous. A few weeks ago Professor Shubladze expressed his agreement with the findings of the Belfast workers in a letter¹³ signed also by Professor Dick and published in this *Journal*. As a treatment for disseminated sclerosis this vaccine therefore no longer has any standing.

That disseminated sclerosis might be an allergic reaction of the nervous system to a variety of sensitizing agents was first suggested by L. van Bogaert¹⁴ in 1932. Quite apart from the similarity between histological changes in the nervous system in this disease and those of acute encephalomyelitis, there is now more clinical evidence to support this view, to which an increasing number of workers subscribe.^{2 15 16 17} Certainly there is evidence that relapses may follow non-specific infections, as they may follow fatigue, trauma, or emotional stress.¹ It is therefore not surprising that A.C.T.H., cortisone, and related remedies should have been tried in disseminated sclerosis. Results have been conflicting. G. H. Glaser and H. H. Merritt¹⁸ reported that some of their 33 cases improved, as did T. Fog,¹⁹ but H. G. Miller and J. L. Gibbons²⁰ concluded from their experience in 7 cases with acute neurological episodes that A.C.T.H. had no effect. However, Alexander and his co-workers,³ using their "scoring" method of assessing disability, now believe that A.C.T.H. has a significantly beneficial effect upon the course of the disease. But no similar benefits were seen after treatment with cortisone or prednisone, and the authors suggest that the improvement was due to some adrenal hormone other than cortisone, a view which must be accepted with some reserve. It was also found that weekly blood transfusions reduced the liability to relapse, possibly through some factor in the donor's blood which enabled the patient to resist further encroachments by the disease process. In the absence of adequate controls it is impossible to be certain that these methods have a real place in treatment, but there is an increasing body of opinion which now favours a course of A.C.T.H., cortisone, or prednisone during acute episodes of the disease.

A lack of controls also makes it difficult to assess the findings of H. V. Smith and her co-workers,²¹ who reported that intrathecal injections of purified protein derivative (P.P.D.) of tuberculin might modify the course of the disease. Their observation that Mantoux-positive cases of disseminated sclerosis show a modified reaction in the cerebrospinal fluid when P.P.D. is injected, as if a cortisone-like substance

were being spontaneously produced, is of the greatest interest, but it is difficult to see exactly why treatment with P.P.D. should arrest the disease. Possibly it may act by producing widespread vasodilatation in the central nervous system. It is apparent that this is one of several methods of treatment arising out of recent research work which merit investigation in a series of carefully planned controlled trials. With the lively interest now being taken in disseminated sclerosis the patient with this disease and the doctor who must care for him may now discern a glimmer of hope.

THE DEAF CHILD

The possibility that her child may be born deaf is not one that usually occurs to the mother. Only if she is intimately connected with the problems of deafness, or if she has a fear of a hereditary tendency, is she likely to make observations on her child's reaction to sound. Fortunately only a few children are born with a defect of hearing, probably not more than one per thousand, but even so it is by no means a negligible problem. Deafness alone is serious enough, but it always has accompanying defects of speech and general development if it is not treated at an early stage. Thus the problem of early diagnosis is of fundamental importance.

The detection of deafness is not easy early in a child's life, for in the first few weeks the general behaviour of normal and deaf babies is much the same, but about the age of 4 weeks a normal child first becomes responsive to sounds associated with natural life such as the mother's activities and attentions and the sounds of other children. Later the normal child's response becomes more versatile, though not always predictable, for a given sound may not evoke the same response in all situations.¹⁻³ It is in observing these reactions that the parent is in a privileged position; indeed, many of the young deaf children referred to clinics are first discovered by parents because they noted abnormal responses at these early stages.

Deafness in early childhood may be due to a number of causes which include hereditary factors, prenatal infection, effects of chemotherapy, and mishaps at birth. Collaboration between doctors, parents, and audiologists can assure that, should one of these causes be suspected, adequate investigations can be carried out. In recent years school medical

officers have taken great interest in the subject and more and more clinics are being set up where children suspected of deafness can be tested at ages from under 1 year onwards.⁴ Dr. Mary Sheridan's article at p. 999 of this issue gives clear guidance about simple and effective tests of hearing which can be carried out in any quiet room.

The development of screening programmes, which some local authorities have also introduced, should be a valuable contribution, and adequate screening should dispel unnecessary worries. In such tests, carried out with great patience, observation is made of the child's response to quiet sounds similar to those occurring in normal home life rather than intense sounds which might arouse a fear reaction, with consequent lack of co-operation. Failure to pass screening tests indicates that the child should be referred to a deafness clinic for assessment of the degree of impaired hearing and the future treatment to be given. Here the aetiology and history are considered together with the problems of mental growth and the development of personality. While occasionally deafness may be amenable to medical treatment, in general the parent must be reconciled to deafness as a permanency and guided in the important task of accepting the fact so that he can assist fully in ensuring that the child gets the best treatment. Much is owed to Dr. Irene Ewing and Professor A. W. G. Ewing, of Manchester University, for their pioneering work in this field, and practically every deaf children's clinic in the United Kingdom and the Commonwealth is modelled on, or considerably influenced by, the clinics and procedures developed by them.^{5 6} It is fitting therefore that the recent International Congress on the Educational Treatment of Deafness was held at Manchester and that one of the main subjects for discussion and demonstration was the problem of the young deaf child. It was apparent at this congress that many workers now consider auditory impairment to be a complex defect, and there was some evidence that in many cases of early deafness the central nervous system is defective as a result of trauma or maldevelopment, with or without peripheral defect.⁷ It was stressed at the congress that many deaf children have begun to achieve similar patterns of development to that of a normal child through home training and integration in family life.

The problem of acquired deafness is different. Owing to the initial period of normal hearing the child will already have acquired some speech and understanding, and it is a question of conserving good speech by adequate educational treatment. In all this work the teacher of the deaf plays an important part.

Great developments have taken place in hearing-aids during the last 20 years, and they are of particular importance in assisting the education of pre-school and school children. Reduction in size allows hearing-aids to be used on the youngest children, but they need to be used intelligently if they are to be of greatest assistance. In view of recent opinion that some deafness may be due to central damage without peripheral involvement, it would appear unwise to use intense amplification indiscriminately, whereas, if peripheral deafness is serious, high amplification may be required to stimulate the hearing organ effectively. In the schools, group aids are becoming widely used on a high fidelity system and there is evidence that this extension of the high frequency range, with consequent improvement of consonant articulation, is beneficial to many deaf children. In addition the loop or induction system is now in common use, permitting great freedom of movement, since no wires are connected between the children and the main amplifying system. The modern viewpoint on the educational treatment can thus be seen to exploit the advantages of normal speaking so far as possible, but on occasions deafness is accompanied by additional handicaps such as educational subnormality or functional disability. Here different treatment is necessary and the child may be unable to make progress by a purely oral method, so that finger spelling and greater use of writing have to be introduced.

SEPARATION OF CRANIOPAGUS TWINS

The condition in which Siamese twins are joined by the heads is referred to as craniopagus. It is the most infrequent situation for the union to occur, the incidence having been estimated at 1 in 2-4 million births. Of these the majority are stillborn or die very shortly after birth, and none have so far survived more than a few years, in spite of the fact that many of these children are apparently normal apart from the defect. A preliminary report on another case has recently appeared¹; final separation is not to be attempted before the first birthday.

The site of junction is most frequently parietal, though occipital and frontal cases also occur. The axis of one child relative to the other varies from case to case, and the union may be asymmetrical. The intimacy of fusion differs in degree, so that vascular systems, meninges, and cerebral tissue may or may not be

united. The cause of the anomaly is unknown, but histological studies suggest that the fetuses are separate at an early stage and that union occurs after development is well under way, as though one was grafted on the other.²

Early attempts at separation were usually made after the death of one of the children, and none survived. The first successful attempt was made by O. Sugar in 1952.³ Only one of these children lived, and he is developmentally retarded. The other died a month after operation without regaining consciousness. This was due to lack of duplication of the superior sagittal sinus, which made it necessary to divide much of the venous return from the brain of this child in order to effect its removal. The first operation in which both twins survived was performed by H. C. Voris in 1955.⁴ The dural coverings of the brains were fused but separable, except for a portion of the superior sagittal sinus, which had to be split and covered by gelatin sponge. One child has developed normally, but the other has a prominent, though epithelized, cerebral hernia, and a left hemiparesis. Two years after separation, at the age of 28 months, she could nevertheless sit up unaided and say a few words. The most successful case so far was reported in August this year by M. Baldwin and A. Dekaban.⁵ The children were craniopagus frontalis, the other two cases having been parietalis. One twin had a transient post-operative hemiparesis, but the later development of both was normal at the age of 1 year. So far as is known none of the skull defects has been repaired.

Although joined together, such children have independent personalities and an independent physiology. The electroencephalographic tracings differ. One can be asleep when the other is awake, one hungry when the other is replete. Although other anomalies may occur, the abnormalities are usually confined to the area of fusion. Having determined the degree of perfection of the individuals, the surgeon has then to discover how intimately they are joined, and to plan a means of providing epithelial covering for the defect which results from their separation. Plain radiographs may be difficult to interpret if the children do not lie in the same longitudinal axis, but an idea of the area of union and any cranial deformity elsewhere can be obtained. The greatest hazard to survival is the presence of anomalies of the dural venous sinuses. This is not surprising, since these sinuses develop within the layers of the dura, which may be fused. If there are not two satisfactory channels which can be separated, the venous return from one brain is jeopardized. Arterial union is less likely. Angiography is of assistance in showing separation of the circulations, but has not given conclusive evidence. Sinusography may be impossible owing to maldevelopment of the dural venous sinuses. Radioisotopes have not so far been used, but would appear to offer a possible means of confirming independence of the vascular systems. The electroencephalogram may show independent function of the two brains but does not offer proof that they are not

united. In the case of Baldwin and Dekaban⁵ direct fusion by a core of white matter was present (the E.E.G. was not done pre-operatively). This core was 2 cm. in diameter and contained a lacy network of vessels and one artery, which constituted the only major vessel that had to be divided. Ventriculography does little more than exclude other lesions of the brain, such as hydrocephalus, which was suspected in the less successfully treated twin of Voris and colleagues.⁴ Deformity of the skull and brain, with flattening of the gyri and damage to the cortex, can be produced by pressure of the conjoined heads *in utero*.²

One of the major problems of these operations is to provide skin coverage for the two cranial defects. In the first two successful operations scalp flaps were gradually mobilized in preliminary operations, and their sources were grafted. Baldwin and Dekaban used the interesting technique of free grafts of "reconstituted human dura and skin" from a tissue bank, which were placed on the exposed dura. These provided temporary cover, and grafts of calf embryo skin were applied later. If the dura of the two children cannot be separated to cover the two brains, there is a grave risk of cerebral hernia, cerebrospinal fistula, and meningitis.

INTRACRANIAL NEOPLASMS AND PREGNANCY

Some diseases pose serious problems of management when the sufferer becomes pregnant—for instance, heart disease, diabetes mellitus, and thyrotoxicosis. The effect of pregnancy on chronic disorders of the nervous system has received less attention, though it is recognized that the course of epilepsy and disseminated sclerosis may sometimes be altered, a subject discussed in the Section of Neurology and Neurosurgery at the Annual Meeting of the B.M.A. at Birmingham recently.¹ It now appears that pregnancy may sometimes exacerbate symptoms in patients with intracranial neoplasms. E. R. Bickerstaff, J. M. Small, and I. A. Guest² point out that this is particularly true when the tumour is a meningioma.

These authors report two striking cases in each of which symptoms and signs indicating compression of one oculomotor nerve appeared during pregnancy, but regressed after delivery, only to recur during the course of one or more subsequent pregnancies. In one patient symptoms had been present during each of three pregnancies over sixteen years, with periods of apparent good health in between. Eventually unilateral visual failure appeared, and a sphenoidal wing meningioma was found to be present behind the affected eye. In

⁷ Weyand, R. D., MacCarty, C. S., and Wilson, R. B., *Surg. Clin. N. Amer.*, 1951, 31, 1225.

the second case there had been similar attacks of diplopia, occurring during three pregnancies and sometimes in the premenstrual week, but each time resolving after parturition or during menstruation. Again a sphenoidal wing meningioma was discovered. Although this course of events is not common it has been reported by other workers,³⁻⁷ and, as Small pointed out during the Birmingham symposium, a similar exacerbation of symptoms during pregnancy may occur in patients who have intracranial or intraspinal neurofibromas or angiomas.

A number of possible explanations for this relationship have been offered, among them that hormonal influences are responsible; but, as Bickerstaff and his colleagues suggest, it seems probable that a simple mechanical explanation is the correct one. Excess water is retained in the body during pregnancy and the blood volume is greatly increased. Presumably there is a parallel increase in the fluid content of these slow-growing intracranial tumours, and, because of their close anatomical relationship to the trunks of certain cranial nerves, even a very slight increase in size is sufficient to produce symptoms. R. D. Weyand and his colleagues⁷ removed a meningioma from a pregnant patient and found unusual histological changes in the tumour, changes which were compatible with an increase in fluid content.

It is easy to understand why many patients who develop ptosis or diplopia during successive pregnancies should be regarded as cases of disseminated sclerosis or even myasthenia gravis, but, as Bickerstaff and his colleagues point out, the occurrence of oculomotor defects or unilateral scotomata during the latter half of pregnancy should lead to serious consideration of a diagnosis of sphenoidal wing, parasellar, or suprasellar meningioma. In such a case careful radiological investigation is worth carrying out, and, if necessary, surgical exploration of the area, since these neoplasms are easier to remove in the early stages. If left alone, they may cause irreparable visual loss or hemiplegia resulting from strangulation of the internal carotid artery.

SEX EDUCATION FOR STUDENTS

The demand from medical students for some instruction in dealing with sex problems is the inevitable outcome of the present trend in medicine to treat the patient as a whole. Of necessity this includes an understanding of the sexual development and adjustment of men and women. But the student's demand presents his teachers with some serious problems, for he is asking for a bridge across the gap that lies between his rather scanty factual knowledge of the physiology and anatomy of sex and an understanding of the complex emotional problems of sexual adjustment and maladjustment. The scope of the subject is wide, including as it does the

physical and psychological aspects of coitus, conception and its control, the wide range of sexual behaviour encountered in practice, sexual maladjustments, and their causes and prevention, and the role of the doctor in sex education.

The first problem is who should be selected to teach the student and how he should be selected, what qualifications and experience, if any, he (or she) should have, and what kind of personality. Some decision might have to be taken on which department of the teaching hospital should be responsible for this type of education. Secondly, who shall be taught? Some students are scarcely sufficiently mature and stable to accept the emotional effort entailed in studying a subject of this kind. Not only is the student unaware of the emotional problems involved in marriage, but often ignorant of his own ideas, fantasies, and prejudices about the sexual and marital relationship. If students are to be selected for this teaching it would seem that only self-selection by means of a voluntary system could be acceptable. The drawback to this is the danger that those struggling with their own emotional problems are particularly attracted to the subject, and the resulting strain may precipitate a breakdown. Probably the subject should be included only during the senior years—which leads to the recurring problem of the overloaded curriculum and the proximity of final examinations.

The best method of teaching the subject is likewise debatable. Didactic lectures are valuable in providing a factual background, but do not prove a very successful method of teaching on emotional problems. Though books can be helpful, they are not sufficient in themselves. Perhaps most is learned from hearing patients talk of their anxieties and difficulties, but this is frequently rendered impracticable because the presence of the student inhibits free discussion by the patient. Case discussion groups of an informal nature may be more instructive, and this method has already been tried out at a few medical schools. In one London teaching hospital, as a result of some pilot experiments on these lines, a regular course of four case discussions, of an hour each, is now to be included in the curriculum of the obstetric and gynaecological clerkship, in addition to the voluntary attendance of students at contraceptive and dyspareunia clinics. Instruction is probably best carried out by a member of the staff who can be available to the students for discussion of their own emotional problems. When difficulties are encountered in starting this kind of training, help can be, and indeed is, sought from doctors who have had experience of dealing with marital problems through their work with the Family Planning Association and the Marriage Guidance Council.

As in all new undertakings, the way ahead remains rather obscure as yet, though the response of students to the sex education that has been attempted suggests that they themselves recognize a need for it.¹ No doubt trial and error will play its part in developing sound methods of teaching, so that young men and women will qualify better equipped to understand and help their patients than they sometimes are at present.

ARE MICROWAVES DANGEROUS?

In the light of past experience it is only proper to inquire into the potential health hazards associated with any innovation. The proposed use of high-intensity electromagnetic microwave radiations in civil and military communications is a case in point. The postal authorities are interested in them because they may offer an economic substitute for public inter-urban telephone links. Such centimetric radiations (i.e., radiations of waves a few centimetres in length) have been used by the Services for communication and other purposes for many years. But the question whether they represent hazards has become more acute only recently because the power fluxes at which the radiations are becoming available are much higher than before.

When non-ionizing electromagnetic energy is absorbed it is dissipated as heat. More specifically, when any tissue is exposed to microwaves its temperature rises. First, therefore, the question may be asked: Is there any part of the body which, on exposure to a given dosage of radiations of a specified wave-length, becomes so overheated that normal physiological cooling mechanisms fail to prevent permanent damage?

Although there is some disagreement on whether the crystalline lens or the testes are more exposed to danger, no one doubts that these two tissues are the most sensitive to temperature, because they cannot be effectively cooled by the blood stream. Consequently much work has been directed to elucidating the mechanism of dissipating microwave energy in these two tissues, largely in dogs and rabbits. An exposure of about 0.1 watt per sq. cm. for a total period of one hour failed to produce a lesion in either tissue in any experiment. Higher dosages can produce damage in the absence of alleviating circumstances: the animal heads are then virtually immobilized and the testes unprotected. It is sometimes said that a dosage of 0.1 watt per sq. cm. is bound to be harmless also when applied for very long periods because this represents the radiant power we receive from the sun on a cloudless day. However, the solar dose contains many types of wavelength, which are either absorbed more superficially or diffused more deeply than are centimetric waves, hence the radiation from the sun does not constitute a specific hazard for these two tissues.

Three instances have been reported in which patients are alleged to have suffered from exposure to high microwave fluxes. Two of the cases^{1,2} are ill-attested and due to unreasonable risks having been taken. The third patient, also exposed to a relatively high intensity, suffered only transient ocular damage. On the other hand, numbers of Service personnel were, at one time or other, exposed to dosages of about 0.01 watt per sq. cm. for prolonged periods of time. No accident occurred. It is therefore of interest that the North Atlantic Treaty Organization has adopted as a safety

limit one-twentieth of this figure—namely, 0.0005 watt per sq. cm. If this value errs it is, commendably, on the cautious side. It would appear, however, that such a limit would require a very extensive “sterilized” zone in front of the aerial system in the case of the high-power transmitters and large aerials now contemplated.

On the other hand, the proposal to use these waves indefinitely in 24-hour beams, as would happen in inter-urban radio links or in radar scanning, raises a problem altogether different. Feeble light intensities, when applied for a short time, may fail to blacken a photographic plate noticeably or to stimulate the eye, but can be successful after a prolonged exposure. The plate and eye are said to be able to summate intensities which for a brief exposure would be sub-threshold. Can temperature-sensitive tissues likewise summate successive sub-threshold microwave exposures? This question cannot be answered yet. There is some indication that, above a certain threshold, partial summation may occur in connexion with the crystalline lens, but that it is not as effective as photographic or visual summation.

What scanty evidence there is indicates that dog testes may summate more efficiently than the lens. Here efficient summation would be taken to mean that, if a given dose produces an effect in a given time, halving the dose would necessitate doubling the time for the same result to be achieved.

Beyond this the evidence is indirect. Glass-blowers used to suffer from cataract (their occupational disease) roughly three times as frequently as the remaining population. In the course of their work they are exposed to power dosages of up to 0.5 watt per sq. cm. This power represents largely light and infra-red radiation: the microwave contents of the energy are negligible. The glass-blowers tended to develop cataract after 10 to 15 years of continuous work. Although their type of cataract is not necessarily the same as that produced by high microwave fluxes, this example illustrates that the possibility of summation cannot be ruled out and that it may act only slowly. But the glass-blowers' 0.5 watt per sq. cm. is much higher than the N.A.T.O. microwave limit of 0.0005 watt per sq. cm.

In short, no hazard from microwaves is known for moderate exposures to fluxes lower than 0.0005 watt per sq. cm. in the absence of all protection. As to exposures extending over years, some risk may exist even with low dosages, but the probable temporal course of the hazard allows time for the requisite experimental investigation of the problem. Reliable answers to the questions it poses can be provided only by producing experimental lesions in man. As this is hardly practicable, the solution of the difficulty lies with electronic designers and engineers. Their task consists in by-passing man or so improving receiver sensitivities that low-power transmission becomes feasible. But, while the position cannot be viewed with complacency, there seems to be, at present, no cause for great alarm.

Drug Treatment of Disease

SEDATIVES AND TRANQUILLIZERS: PART I

BY

WILLIAM SARGANT, F.R.C.P.

Physician in Charge of the Department of Psychological Medicine, St. Thomas's Hospital

Introduction

In considering the new sedatives and tranquillizers, it is worth remembering that it may take a year or more to learn how to use any one new drug skilfully and selectively; and all one can do is to keep a range of well-proved sedatives in use, and to look among all the new drugs for others likely to fill some of the present treatment gaps. It is certainly unwise to try one new tranquillizer after another in the hope of finding some universally applicable drug. There cannot be one, because of the number and variety of psychological reactions to life's stresses, and because of the different constitutional types of person showing them. These different types of person may all need handling in quite different ways with drugs. In this article advice will be given only on drugs which the writer has himself tried to learn how to use in as practical a manner as possible over the years. This does not mean there are not other similar ones, just as good, which may not happen to have been tried out and tested as thoroughly.

Two most important points about the giving of sedative drugs must be emphasized before discussing any of them in detail. Experiments on animals have shown that different constitutions may need quite different dosages of any drug used. In Pavlov's dogs, for instance, those with “strong excitatory” temperament often needed up to eight times the body-weight dose of sedative required by those with “weak inhibitory” temperament if an induced experimental neurosis was to be satisfactorily treated; until the right dose of any drug was found, the use of sedatives could often worsen rather than improve a neurotic state. It is the same with human beings.

Dosages of sedatives differ very widely in different illnesses and different constitutional types of person. This is shown, for example, in the response of the “strong excitatory” epileptic to a sedative drug such as phenobarbitone. He may thrive on 4–6 gr. (260–400 mg.) a day, given as a maintenance dose to prevent fits and to keep him in active nervous health. But a “weak inhibitory” hysterical patient may fall about and be greatly worsened by being given as little as ½ gr. (32 mg.) of phenobarbitone twice a day. Unless these large individual differences in response to drugs are recognized, the proper use of sedative drugs can be very difficult to learn, and the results obtained with standardized dosages can be most misleading.*

The other general point to mention is the possibility of harmful addiction to all such drugs. Any drug which successfully treats anxiety and tension, especially if it also creates states of euphoria, is likely to have

*This is in fact one of the outstanding faults of most of the double-sampling tests of to-day. Moreover, neuroses and psychoses may get lumped together in such tests, and often more misinformation than information is gained about the skilled use of a drug being tested. As a good example of this, many schizophrenics are now thriving and having their symptoms held at bay with doses of chlorpromazine that may have to be as high as 300–500 mg. a day. On this dosage they are also possibly able to do a full day's work. Every doctor has other neurotic and depressive patients who complain of a marked worsening of their symptoms when more than 25 mg. of the same drug is given three times a day for comparatively short periods.

strong addictive tendencies. In this article it is impossible to go into all the ethical considerations involved, but it is clearly our duty to try to confine ourselves to those drugs that do the least harm and have the least serious side-effects when from time to time they may have to be withdrawn or curtailed. To do this, it is wise to try to adhere, whenever possible, to drugs which, though they combat anxiety and tension, do not also create too much undesirable euphoria. Man's constant search for happiness can make these the hardest to give up.

The Older Sedatives

Bromides.—Before the second world war potassium bromide was one of the most widely prescribed drugs in the *British Pharmacopoeia*. In recent years, however, it has tended to become discredited and to be replaced by the barbiturates. Bromide began to fall into disrepute when the numerous cases of bromide intoxication came to be more generally recognized. Its disuse, however, may now have gone too far. Intoxication rarely occurs, except in the elderly, the arteriosclerotic, and in patients with impaired renal function. Intoxication can practically always be avoided by not prescribing it for these types of patient, and by insisting that the patient taking this medicine should also take adequate salt. There are some strong and chronic tension states in which large amounts of barbiturate are necessary to bring any real sedative relief, and this often causes severe addiction, and even greater tension when attempts are later made to lower the dose of barbiturate or to withdraw the drug. There are patients with reactive depressions and strong body-builds, and those who show explosive outbursts of anger and tension, who can still be helped better by bromide in doses of 20–30 mg. three times a day than by barbiturates. Bromide should certainly not be forgotten by the physician in search of a suitable sedative for some of his patients with chronic tension. It may also be useful in supplementing a smaller daily dose of barbiturate. It is hard to believe that the enormous vogue for the bromides over so many years was without any foundation whatever.

Chloral.—This is another drug which has also had a long innings because of its excellent sleep-producing qualities, but which is now tending to be replaced by the barbiturates. However, with the increasing tendency to barbiturate dependence so often seen at the present time, and because of the craving that can be aroused by too injudicious a use of the short-acting barbiturates, the writer is finding that chloral still has a valuable role as an alternative sedative to the barbiturates, especially to avoid the building up of tolerance to barbiturates so that sedation may be given over long periods of time. Chloral should generally be given in doses of ½–1½ drachms (1.7–5.2 ml.) of the B.P. mixture, and it can sometimes be used to supplement smaller doses of longer-acting barbiturates, each enhancing the effect of the other.

Paraldehyde.—Paraldehyde is now less useful than formerly as a sedative and tranquillizer. It is an exceedingly valuable drug, and still has its limited place in helping to cope with the withdrawal symptoms of the alcoholic, especially in the “strong excitatory” and confused patient. But it is a bad sedative for routine use because of its unpleasant smell and its consequent social drawbacks. It acts quickly, effectively, and safely in an emergency. But where routine administration of paraldehyde has been indicated in the past, the giving of one of the new tranquillizers such as chlor-

¹ Hirsch, F. G., and Parker, J. T., *Arch. Industr. Hyg.*, 1952, 6, 512.

² McLaughlin, J. T., *Calif. Med.*, 1957, 86, 336.

promazine, together with smaller amounts of other sedatives is now often preferable, especially for the elderly. It does, however, still have a real place in the efficient sedation of physically ill and restless patients in hospital. Because it can be obtained freely without prescription, it is not advisable to give it out too liberally in general practice, especially to the alcoholic, the compulsive barbiturate addict, and all the other potential seekers after chemical euphoria and temporary oblivion, in particular the hysterical psychopaths. Doses of 1-4 drachms (3.5-14 ml.) can be safely prescribed by mouth, and it is worth remembering that 2-4 drachms (7-14 ml.) can be injected intramuscularly when necessary in an emergency.

Barbiturates.—The long- and short-acting barbiturates have now become the main standby of physician and psychiatrist alike. And they are often the sedative of choice both for the neurotic and for the normal patient. In general, the barbiturates are much cheaper than the newer tranquillizing drugs. However, the short-acting barbiturates have more addictive dangers than, say, the bromides, and this is possibly because they are often more efficient drugs for the purposes for which they are prescribed. The enormous range of barbiturates, and the number of different preparations of each, make it impossible to learn to use anything like all the possibly valuable ones. A clinician should choose for himself a few selected long-acting and short-acting barbiturates and learn how to use and vary these in his many different types of patient. Barbitone sodium, for instance, still seems to be an excellent long-acting sedative when given in doses of 5-15 gr. (0.32-1 g.) at night. It is often the drug of choice in depressive states, when early waking is much more of a problem than is getting to sleep at night. Long-acting barbiturates also seem to have less addicting and tension-creating qualities on withdrawal than do the shorter-acting ones. Phenobarbitone can be a satisfactory daily sedative for neurotic patients, in doses of $\frac{1}{2}$ gr. (32 mg.) three times a day to 1 gr. (65 mg.) twice a day, and many of the patients who used to be kept on bromides three times a day are now being maintained on this drug.

The short-acting barbiturates, of which sodium amylal and quinalbarbitone are good examples, can be very good indeed in relieving tension during the day and in bringing about sleep at night. The trouble is that they are often too efficient, and it is becoming more and more clear to the writer that short-acting barbiturates, when taken continuously over long periods, can perpetuate states of tension as well as relieve them. Great relief may be obtained for an hour or two after taking these short-acting barbiturates, but tension is soon created again, and further short-acting barbiturates are then demanded. Once the total dosage of amylal has reached 9 gr. (0.6 g.), or of quinalbarbitone 6 gr. (0.4 g.), in the 24 hours a vicious circle of self-perpetuating tension has often been created. The writer has seen some patients who have had one, two, or three modified leucotomies for relief of unbearable tension and who have turned out later to be barbiturate addicts. Their tension has finally subsided or been greatly reduced once this fact has been recognized and their drugs withdrawn or altered. When patients come to doctors complaining of states of chronic persistent tension, or a marked increase in recent tension for which they are demanding short-acting barbiturate medication, it should never be forgotten that addiction to and a previous unwise prescribing of such barbiturates may be the cause rather than the cure.

Despite these objections, the short-acting barbiturates can still be some of the most useful drugs we have at our disposal. They can be especially helpful in patients who have developed recent phobias of going out in the street, travelling by train, going in an aeroplane, or tackling any special new situation because of the anxiety aroused. But they should be used only occasionally and not as a routine in such anxiety-creating situations. Sodium amylal 1-3 gr. (65-200 mg.) or quinalbarbitone $\frac{1}{2}$ -1 $\frac{1}{2}$ gr. (50-100 mg.) may be given one hour before the patient tackles the phobia. Another of the new tranquillizers, meprobamate, also seems to be helping this particular group, and therefore may

be able to replace the short-acting barbiturates in some cases. But the other new tranquillizers, such as chlorpromazine, have not proved at all useful in this particular group of patients, who can often be so difficult to help.

One of the most popular combinations of drugs in recent years has been the giving of small doses of amylal and dexedrine together in the form of "drinamyl." One tablet only is taken in the morning at 8 o'clock and possibly again at lunch-time. The combination is of the greatest value as a tranquillizer in some mild depressive and tension states, but it is of no value in deep depressions, and can make patients with severe anxiety states more anxious. Because of the euphoria it creates this combination is in great demand by the chronic neurotic patients and should be prescribed sparingly. Those patients who benefit most by it should also be advised not to use the drug on at least two days in the week, so as to avoid tolerance to it being established too quickly.

Intravenous Use of Barbiturates.—The sedative value of barbiturates given intravenously can be great in certain psychiatric emergencies. If, following an accident or a shock of some sort, the doctor is called to see somebody who has suddenly lost the use of an arm, or voice, or is showing sudden onset of other hysterical symptoms, the slow intravenous injection of a short-acting barbiturate, such as sodium amylal or pentothal, to a point of relaxation and euphoria, combined with the use of immediate and strong suggestion by the doctor, will often break up and resolve the whole acute hysterical picture, and continued sedation for a few more days may then keep it broken up. In the last war the rapid treatment of acute hysterical reactions by the use of intravenous barbiturates has saved an enormous amount of pensionable chronicity since, and there is still a place for this valuable first-aid method in civilian practice to-day. Once hysterical or acute anxiety reactions are allowed to get fixed for even hours, let alone days, they can become much more difficult to get rid of again later.

(To be concluded)

PRIORY CHURCH OF ST. JOHN OF JERUSALEM

RE-DEDICATION BY ARCHBISHOP OF CANTERBURY

The Priory Church of St. John, Clerkenwell, heavily damaged by a German air raid on the night of May 10-11, 1941, and now restored, at a cost of £80,000, not only as the church of the Order of St. John of Jerusalem but also as the Order's assembly hall, was re-dedicated by the ARCHBISHOP of CANTERBURY, Prelate of the Order, on October 17. The DUKE of GLOUCESTER, Grand Prior of the Order, opened a memorial cloister and garden commemorating those members of the Order of St. John and of the St. John Ambulance Association and Brigade who lost their lives in the 1914-18 and 1939-45 wars. The church's crypt (Fig. 2), which escaped war damage, is one of the finest examples of 12th-century church building in London.

The original church of St. John Baptist was the chapel of the 12th-century Priory of Clerkenwell; it had a choir, which forms the present building, and a round nave larger than that of the Temple church and believed to have been destroyed in Wat Tyler's revolt of 1381—its outline is now traced in the roadway. Just after 1500 Prior Thomas Docwra constructed the large perpendicular windows of the choir and made other improvements, and the present Docwra family have given the wrought-iron gates which lead to the new memorial cloister.

The restored building is divided into three main sections—the church, with its crypt; the guard house; and the war memorial cloister and the staircase hall. The guard house contains a robing-room and vestibule and makes a striking entrance to the cloister (Fig. 3). Here an ancient piece of stonework found on the site has been incorporated in the

tracery and provides the inspiration for the cloister's design. The crucifix can be seen from the street through the wrought-iron gates. The interior of the walls of the 60-ft.-square church have been whitened, showing the texture of the medieval aeval stones and the Tudor brickwork; the only colour is supplied by an occasional banner. This simplicity accentuates the beauty of the altar with its reredos incorporating 18th-century carving salvaged after the bombing and the two wings of the Weston triptych. The latter was given to the church by Grand Prior John Weston about 1480 to commemorate the Order's victory at the siege of Rhodes; unfortunately the centrepiece of this exceptionally fine example of 15th-century Flemish art is missing. Curtains can be pulled across in front of the altar to screen it during an investiture or conference. The lion-head handles on the church doors which were found in the ruins of the Muristan, site of the Order's original hospice in Jerusalem, were presented by Sir Harry Luke. The architects responsible for the restoration were Messrs. Seely and Paget.

The priory in Clerkenwell was never a hospital treating the sick, like St. Bartholomew's and St. Thomas's. It was

the administrative headquarters of the Order of St. John in England, responsible for its estates here from which revenue was sent to Jerusalem and Rhodes for the Order's activities, both military and charitable. The Clerkenwell priory also recruited young noblemen to fight in the wars against Islam. After the reformation the buildings disappeared bit by bit, except part of the church, which remained as a chapel and was restored by Simon Mitchell, from whom it was purchased in 1723 by the Commissioners of Queen Anne's Bounty and made into a parish church. It ceased to be this in 1931 when it became again the church of the

Order of St. John. Members of the St. John Ambulance Brigade throughout the Commonwealth have subscribed just over £4,500 for the furnishing of the restored church. Of the structural cost of the restoration, £20,000 has still to be found.

The restored church of St. John is not open to the public but may be viewed by appointment with the Curator of the Order, Miss Daphne Edmonds (Clerkenwell 6644), who will also show those interested the Order's museum at St. John's Gate, a part of the priory buildings erected in 1504.

FIG. 3.—Guard house and Docwra gates, showing the crucifix and part of the memorial cloister beyond.

WHY SUFFER FROM RHEUMATISM ?

A REVIEW OF 157 "CURES" SUBMITTED TO
THE RESEARCH SUBCOMMITTEE OF THE
EMPIRE RHEUMATISM COUNCIL*

Since ancient times man has been searching not only for the elixir of youth and the prevention of old age, but also for cures for the various aches and pains which harass the bones, muscles, and joints of mankind. These aches and pains derive from a very large number of mental and physical disorders, but all are loosely labelled "rheumatism" or "fibrositis" by the lay public, and even to-day there is in this country relatively little use of the terms "rheumatoid arthritis" or "osteoarthritis" by them. Accurate diagnoses aided by the use of new diagnostic methods are only now taking their proper place among members of our profession; it is by no means remarkable, therefore, that the layman lags behind. Unless an accurate diagnosis is made the effect of various therapeutic remedies cannot mean anything, for what benefits one patient's "rheumatism" will probably have no effect on another whose "rheumatism" is due to an entirely different pathological process. Indeed, it is estimated that there are over 70 different conditions which may give rise to so-called rheumatic pain. This simple fact is responsible for many of the false claims in the past: Mrs. A, who suffers from a traumatic disk protrusion, will begin to benefit (as her condition naturally subsides) whilst being treated with substance X, while Mrs. B, on the same substance but suffering from a progressive type of rheumatoid arthritis, worsens. Seldom do people outside the medical profession distinguish between the various arthropathies—rheumatism is rheumatism, fibrositis is fibrositis, and that is the end of it. Nature cures and family remedies may indeed have benefited some sufferers at some stage of their illness, but what that illness was in the majority of cases is never exactly known. *Post hoc, ergo propter hoc* is as common an argument to-day as it was under the Caesars, and just as difficult to resist.

It is with an open but not over-optimistic mind, therefore, that we have reviewed 157 remedies sent to us at the Empire Rheumatism Council in the last five years from all over the world. We are extremely grateful for these contributions, for from such as these may spring the next great therapeutic advance. Many contributors have been at great pains to give details and have gone to considerable trouble on behalf of the rheumatic sufferer. While most are submitted by people outside medicine, a minority come from members of our own profession. To all we would gratefully tender our thanks.

Analysis of "Cures" Submitted

The cures and remedies sent to us fall into three main groups. Group 1 states in effect that if you take X (or Y or Z) you will never have rheumatism; group 2, that if you take Y (or X or Z) you will get better from rheumatism; group 3, that if you never take Z (or X or Y) you will never get rheumatism.

The last (or never-never) group is the smallest. Five substances have been advanced as aetiological agents; if these are always avoided the patient will continue to remain free from symptoms. They have a homely ring: salt, tap-water, milk, tea, and marmalade. It may well be that sensitivity factors may play a part in causing pains due to allergic factors, but it is hard otherwise to make a case for these five agents of evil. Perhaps Western civilization suffers from the rheumatic disorders because of the breakfasts it eats, the United States being only partly saved by preferring coffee to tea. Three other contributions emphasize that tea is to be avoided at all cost. In addition, freedom from rheumatism may be assured by avoiding gases and certain fumes, eye-strain, and certain postures and stances. Here again it can be seen how certain mild painful disorders could be

*Compiled by the Research Subcommittee of the Empire Rheumatism Council.

alleviated by attending to these factors, but not the more serious diseases such as rheumatoid arthritis.

Group 1, comprising the prophylactic agents, is also a small one compared with the therapeutic group 2. Iodine lockets, string shirts, underwear made of special material—for example, flannel, which is useless unless it is red—pendants, and bangles of various sorts are quoted. Many of these "cures" are almost as old as civilization; they are essentially lucky charms in many cases, protecting the wearer by their own particular magic. Some harness modern science to the ju-ju by incorporating iodine (or sodium carbonate) in a locket worn round the neck. A cord round the waist will apparently prevent disk herniation to-day just as effectively as yesterday it prevented lumbago and rheumatism in the back, and the day before that the evil eye, the ague, or the creeping palsy.

In the second therapeutic group the largest single subgroup is regrettably the "secret remedies," of which there are 14, details of which were to be revealed only at a price or on proper compensation. Nevertheless it is important and encouraging to note that all the remaining 143 writers offered and wished to give their remedy to mankind with no mention of any payment or reward, and this point must be strongly emphasized. Next most common were external applications (11), fluids and salts of different sorts taken by mouth (10), herbs (9), special diets (9), and special baths (7). After this came a large number of cures and remedies with relatively few supporters. It is of interest that in this scientific age there were only four remedies depending for their effect on radioactive substances, three on certain rays and emanations, and one on electromagnetic packs, whereas applications of mud had four supporters, "old-fashioned medicines" dispensed by senior chemists and practitioners two, and herbal remedies as noted above nine. Many, such as bee venom (3), gold salts (4), salicylates (3), to mention only three, have been, and are being, used in medicine to-day.

On the physical side, deportment (2), massage (1), various rays (3), a certain warm climate (1), and an unspecified mechanical device (1) were suggested; on the psychological or spiritual side a strong magnetic personality (1) and psychokinetic education (1).

Some of the Remedies

Water.—Water, externally or internally, has since the beginning of time been used in the treatment of the rheumatic disorders. In this series two cures depend essentially on the drinking of large amounts of plain water. In one, simple boiled rain-water is advanced as a cure; three-quarters to one pint, filtered through cotton-wool, must be taken early each morning to abolish rheumatism completely. A second cure is even simpler, depending essentially on drinking tap-water whenever the opportunity presents, all day and every day, and arranging one's life accordingly. A rival claim is that simple tap-water contains mineral salts and elements which initiate an allergic state which, by depositing salts in the joints, causes rheumatism; by avoiding these contaminants one can remain free from rheumatism. Ten cures depend essentially on consuming fluid in which certain curative salts are in solution in different combinations. These solutions may be naturally occurring ones from certain springs or may be made in the home—for example, Epsom, Glauber, and Rochelle salts and potassium "filtrate"—of this mixture one teaspoonful must be taken each morning.

Herbal Cures.—These are still much in evidence, and with special diets come fourth in popularity, nine of each type of remedy being submitted. Of these herbal cures one depends essentially on celery seeds, one on garlic, one on mistletoe, one on parsley, one on buttercup paste, one on yerba maté, one on mixed nettles, dandelion, and burdock leaves, and so on. They are essentially the old countryside prescriptions popular in the homes in the last century and obviously still widely used to-day. Only some depend on purgation for their effect, and, one, buttercup paste, on local inunction. To give an example in greater detail, one, yerba

maté, or Paraguay tea, is a beverage prepared from the leaves of the *Ilex paraguariensis*, a member of the holly family, Aquifoliaceae, which grows wild in parts of South America, and is also largely cultivated and has been used from time immemorial by the Indian natives. It contains up to 0.9% caffeine, and to this may perhaps be attributed much of its restorative and stimulatory properties. It contains no tannin and is preferred to either tea or coffee by many once the slightly bitter taste is acquired. It is, according to *Chambers's Encyclopaedia* (1950), the universal drink of 15 million South Americans, and is also popular in the United States. Our informant made the observation that when the quality of tea available during the war became very poor he changed to yerba maté. After the lapse of two to three years he noted that the fibrositis in his shoulders from which he had suffered for very many years disappeared; but his wife, unable to take the tea because of its effect on her digestion, remained unimproved. This last point is important; for herbal teas, although widely used for centuries, may on occasion in certain subjects be productive of most unpleasant symptoms.

Diet.—Nine different varieties of diet were submitted, most depending on calorie reduction and increased fruit-juice content. There is no doubt that even in severe rheumatoid arthritis one does occasionally see relief and remission occurring on such regimes; fasting is one of the oldest of remedies in this field of medicine. What is not usually recorded is how long such remissions last and how many failures are to be set against each success.

Discussion

The first point that emerges very forcibly from the vast majority of the statements about curative agents submitted is that the diagnosis of the disorder that has been cured is completely unknown. When efforts have been made, as was done for the Empire Rheumatism Council by Dr. E. T. D. Fletcher and his unit at the Royal Free Hospital, London, some six years ago, to clarify diagnosis in connexion with a lay study of the importance of climatic variations, the patients with "rheumatism" and "arthritis" were found on examination to have a wide variety of conditions ranging from rheumatoid arthritis to cases where no disease process whatsoever could be found. One does not know, therefore, what disorder has been "cured" except in very few instances. A second point is that with very few exceptions the numbers cured are not given, nor are the numbers not so cured on the same treatment—that is, the failures. Many cures are quoted on one case only, usually that of the writer of the letter, and these are in most cases the only ones where any detailed history is given. The third point is the complete absence of any comparable untreated control group with which the treated group may be compared; this is hardly surprising in view of the large number of papers written on similar lines still appearing in medical journals in some parts of the world.

Finally, the probability that a natural remission has produced the beneficial effect rather than the curative agent is high in many if not most instances. It is well known to the medical profession that complete or partial remission may occur in any of the rheumatic disorders; gout aborts in a few days, rheumatoid arthritis may subside rapidly for no apparent reason after months or years of continuous activity of the disease, and even degenerative joint disease may rapidly or gradually become less painful or even entirely pain-free. The fact that natural remission of disease occurs and that pain can disappear spontaneously does not seem to be properly appreciated by the layman. Effect, particularly if he is the patient, must be in his eyes preceded by a cause. Finally, faith in a therapeutic substance or method, even though misapplied, may often be followed by symptomatic relief, even if only temporarily.

Happily the sufferer with any form of rheumatic disease is usually an optimist, and he will try anything within (and sometimes without) reason which might conceivably help his

painful condition, however bizarre it may seem. This high optimism is of the utmost therapeutic and prognostic importance; without it the patient becomes a tired, exhausted cripple who has given up the fight. Almost anything which preserves his optimistic attitude and helps to keep the flame alight is worth while unless it is dangerous to health, crippling to joint, or exhaustive of pocket. Medical treatment may have to be extremely bad if it is to delay natural remission and recovery in some cases. It is a field of medicine, for this reason, that has attracted, perhaps in the past more than to-day, many odd forms of treatment and many unusual practitioners both within and without the medical profession.

Conclusion

The fact that so many communications have been received is extremely heartening. In the not very remote past the lay public was perhaps rather more concerned with the problems and prevalence of the rheumatic diseases than, regrettably, was the medical profession. The fact that large numbers of laymen attack the problem on their own and from their own particular points of view is not only encouraging but potentially of great importance, if only because some chance observation may well lead future research into fruitful new fields and herald some new major advance. We are extremely grateful, therefore, for the large number of communications received. All of them are recorded, and all are available should any research worker wish to consult them on any particular point. Where causes are unknown it is impossible to say that any factor, however seemingly improbable, may not later prove to be of the greatest importance.

BRITISH INTERPLANETARY SOCIETY

SYMPOSIUM ON SPACE MEDICINE

[FROM A SPECIAL CORRESPONDENT]

On October 16 and 17 the British Interplanetary Society held a symposium on space medicine at B.M.A. House. If not the first international conference in the world to be devoted exclusively to the medical and biological aspects of space flight, it was certainly the first on this side of the Atlantic. Speakers came from the Netherlands, Sweden, and the United States, as well as from Britain. The chair at the four sessions was taken in turn by Dr. L. R. SHEPHERD, chairman of the British Interplanetary Society, Dr. J. B. PARRY, an Air Ministry scientific adviser, Dr. H. A. CLEGG, Editor of the *British Medical Journal*, and Professor E. P. SHARPEY-SCHAFER, professor of medicine at St. Thomas's Hospital.

Scope of Space Medicine

Hitherto the British Interplanetary Society has been mainly interested in the logistic and mechanical aspects of space travel. By comparison the human factors have been somewhat neglected, but upon these depend whether manned space flight is possible at all.

The likely physiological and psychological stresses of space flight are of two main sorts. First there is the question of survival for days or even months in a hermetically sealed, artificial microcosm. With increasing altitude there is a progressive loss of the protective and life-sustaining qualities of the atmosphere: physiologically speaking, space begins at sea-level. At only 40,000 ft. (12,000 m.), the ambient pressure falls too low for even a 100% oxygen atmosphere to fully oxygenate the blood, so that pressure-breathing or a pressure cabin becomes necessary. Above 52,000 ft. (15,850 m.), where the ambient pressure falls to

foot or hand control (see Diagram). When the latter is depressed the compressed gas passes to the ram, which applies a thrust to the piston of the syringe and empties it. The release of the foot or hand control immediately exhausts the gas in the ram to atmospheric pressure. In practice we have used only two gauge settings—one of 90–120 lb. per sq. in. (6.3–8.4 kg. per sq. cm.) for injection through a catheter, and the other of 25–35 lb. per sq. in. (1.8–2.5 kg. per sq. cm.) for intravenous injection. The actual pressure applied to the ram is seven times that indicated on the gauge.

When employing selective angiocardiology a cardiac catheter of the largest bore possible is passed under fluoroscopic control through a peripheral vein into the heart. The catheter tip is placed in the superior or inferior vena cava, right or left atrium, right ventricle, or pulmonary artery, the exact site depending on the type of case under investigation. For thoracic aortography the catheter is inserted into the radial artery immediately distal to its origin, and is advanced into the ascending aorta so that its tip lies 2 in. (5 cm.) distal to the aortic valves. Alternatively, a polythene tube may be inserted percutaneously into brachial, carotid, or femoral arteries, and its tip advanced to the same site. The patient is then moved into position on the film changer and the catheter connected to the syringe on the injector chassis. On depressing the hand control, rapid injection at a predetermined rate is achieved. In general, injection rates of 20–30 ml. per second are employed. The accompanying Table illustrates the various injection times which can be achieved by the use of this apparatus.

Quantity of Contrast Medium Injected	Size of Cardiac Catheter	Injection Time in Seconds
70 ml.	10	2
60 „	9	2½
50 „	10	2
40 „	9	2½
30 „	10	1½
25 „	9	2
20 „	8	2½
15 „	10, 9, and 8	1–1½
10 „	10, 9, and 8	1
5 „	7	2
3 „	9, 8, and 7	1–1½
1 „	9 and 8	½
	7	1

The above injection times are obtained with a gauge reading of 90–120 lb. per sq. in. (6.3–8.4 kg. per sq. cm.).

The use of the 50-ml. and 25-ml. syringes facilitates accurate measurement of the smaller doses of contrast medium required in children and infants. Furthermore, the lower bore/stroke ratio and reduced friction of the smaller syringes permit an adequate injection rate even through a No. 7 catheter, which may be the largest that can be employed in the very young patient.

The injector has been used over 350 times at the Middlesex Hospital and the London Chest Hospital for angiocardiology and thoracic aortography. The only untoward incident ascribable to the apparatus was the rupture of an arm vein on three occasions. These accidents were undoubtedly due to incorrect positioning of the metal cannula employed at the time. Such have not been experienced since the metal cannula was replaced by flexible tubing or cardiac catheter.

The advantages of the injector are the provision of rapid safe injection of contrast medium into the chambers of the heart or the great vessels, and simplicity in design and operation. It is cheap to buy and maintain, and has given satisfactory results over the past six years.

The apparatus is manufactured by the Talley Anaesthetic Equipment Ltd., 37a, New Cavendish Street, London, W.1. A succession of registrars and assistants have used the injector, and at their suggestion several modifications have been incorporated in the design.

To-day's Drugs

In this column we publish from time to time authoritative notes on a selection of drugs in current use.

Tenormal (Imperial Chemical Industries Ltd.).

Perolysen (May and Baker Ltd.).

These are preparations of pempidine tartrate (1:2:2:6:6-pentamethylpiperidine hydrogen tartrate) in tablets of 5 and 10 mg. Pempidine is a tertiary amine which lowers blood pressure by ganglion blockade. When given by mouth it is freely absorbed from the gut, and diffuses easily into tissues, readily crossing the blood-brain barrier. It thus closely resembles mecamylamine in its action, the most important difference being its quicker excretion. Thus, in contrast to mecamylamine, which is slowly excreted, acts for up to 12 hours, and is administered twice daily, pempidine acts for 6 hours and is usually given four times daily. The hypotensive action is usually observed within an hour.

Pempidine may prove to be an improvement on mecamylamine, for all the drug in the plasma is active, in contrast to mecamylamine, 25% of which is bound to plasma protein. Furthermore, the rapid excretion helps to prevent toxic accumulation of the drug. The excretion of both drugs is influenced by urinary pH, the clearance being increased in acid urine and decreased in alkaline urine. But variation in excretion is less with pempidine, and its hypotensive effect is therefore less likely to be influenced by changes in acid-base balance than that of mecamylamine.

Treatment may be started with 2.5 mg. orally four times daily, increasing each dose by 2.5 mg. daily until the desired control of blood pressure is achieved. A smooth hypotensive effect throughout the day may be expected. The indications for pempidine are those applicable to ganglion-blocking agents in general—severe, complicated, or malignant hypertension. The same side-effects, such as faintness, nausea, and constipation, must be watched for, though they may be less severe.

N.H.S. basic price: Tenormal and perolysen, 50 5-mg. tabs., 7s. 6d.; 50 10-mg. tabs., 13s. 4d.

Compicillin-V Filmtabs (Abbott Laboratories Ltd.).

These are tablets of the hydrabamine salt of phenoxymethylpenicillin (penicillin V). They are available as 125-mg. tablets (200,000 units) or 250-mg. tablets (400,000 units). The advantage of penicillin V is that it resists destruction by the hydrochloric acid in the stomach, and adequate blood levels can therefore be obtained when it is given by mouth. Further information about penicillin V was given in this column on August 16 (p. 445). It is a convenient means of administering penicillin in cases of infection by organisms sensitive to it.

Peganone (Abbott Laboratories Ltd.).—This is ethotoin (3-ethyl-5-phenylhydantoin) made up in tablets of 500 mg. It is of the same family of chemicals as phenytoin sodium, and is also closely related in its chemical formula to methoin (5-ethyl-3-methyl-5-phenylhydantoin). The hydantoins as a class are fairly well tolerated by mouth, and they have a specific anticonvulsant effect, the nature of which is unknown. Each chemical in this family has different toxic effects, though, apart from rare blood dyscrasias, they have not been severe. The present member of this family has been subjected to an extensive clinical trial; no severe toxic reactions have so far been reported, and it does not appear to have any toxic effects not already encountered in its widely used predecessors. It is likely to be of use for major epilepsy, and for focal attacks, but not for the petit mal of childhood.

N.H.S. basic price: 100 tabs., 26s. 8d.

Correspondence

Because of heavy pressure on our space, correspondents are asked to keep their letters short.

Appendicitis in the Aged

SIR,—Dr. Erik Christensen's paper on "Appendicitis in the Aged" (*Journal*, October 4, p. 832) draws attention to this problem. The following observations on its statistical aspects, made as part of a larger study undertaken in this unit, may also be of interest.

Before the 1939–45 war, in both England and Wales and the United States, the reported death rate from appendicitis was no higher in the very old than in late middle-age. To-day in these countries the position is quite different (see Fig.), as the death rate reported for those aged more than 80 is over twice that of those aged 60–64. For example, mortality in women aged 80–84 in England and Wales during 1954–6 was 97 per million; for women aged 60–64 it was 25 per million.

Appendicitis death rates per million. Sources: Volumes of Registrar-General's Statistical Review of England and Wales and Vital Statistics of the United States

Three possible mechanisms that could have produced this change seem worth consideration. Firstly, there might have been a real change in the disease—either that it now attacks middle-aged people less, or that those currently middle aged have by reason of some feature of their previous experiences a lowered susceptibility to the disease. Secondly, for many diseases recent improvements in treatment have benefited younger rather than older people, and it is possible that the new pattern of the death rate has been produced by this change. Finally, an increased liability to die from appendicitis in old age, compared with middle age, may have existed for a long time; but only now is this being recognized clinically. It is well known that the diagnosis

of appendicitis is not always easy. Diagnosis of strangulated hernia in the old is probably less difficult, and it is interesting to find that the death rate from this condition increases sharply with age to-day, and, in contrast with appendicitis, did so before the war.—I am, etc.,

Dosage of Pancreatin

SIR,—It has come to our notice that general practitioners and others treating children who suffer from cystic fibrosis of the pancreas are finding some difficulty in regard to the dosage of pancreatin. Until recently there were on the market two strengths of pancreatin, standard B.P. and triple strength. The dose required of triple-strength pancreatin was as much as 10 g. per meal.

The 1958 edition of the *British Pharmacopoeia* gives a new standard strength which is approximately the equivalent of the triple-strength pancreatin. A new concentrated pancreatin is also available, the equivalent of 15 times the old B.P. strength and 5 times the 1958 standard. This concentrated pancreatin is now being widely used. The dose should be about one-third of the dose of the triple-strength pancreatin. Experience shows 0.25 g. with each feed to be sufficient for small babies and up to 2 g. for older children. The cost of the five times concentrated pancreatin is about half the cost of an equivalent dose of the standard strength. In all cases the dose given is determined by the effect on digestion and on the stools. In the case of babies some irritation of the skin of the lips, chin, and buttocks may occur if an excessive dose is given. The taste of the five times strength is much stronger than that of the standard, and for this reason some children are unable to tolerate it. In practice almost all of them become used to it and even develop a liking for it.—We are, etc.,

After Dinner

SIR,—The heart of every reader of your annotation "After Dinner" (*Journal*, October 11, p. 904) must be moved to pity for the habitual guest at annual medical school dinners: most of all, perhaps, for the editors of our medical journals, who have to attend so many but never speak at them. Does this silence express an agreed self-denying ordinance amongst editors, or indicate that their hosts do not realize that men who have an assured command of the written word are, at worse, not less likely to make a good show with the spoken word than some senior whose fame rests upon other things than eloquence or a nice wit?

The apparent poverty of good after-dinner speakers amongst us probably arises from our methods of choice. I do not doubt that there are men and women who can speak the Queen's English with elegance and point, but whom we are never allowed to hear in public. If one may generalize from experience, it seems that the surgeon who has no ideas of his own falls back upon anecdote when called upon to speak, while the physician, in like plight, takes refuge in compliments and platitudes, thus preserving his cherished respectability, but not redeeming himself from the charge of essential dullness. Of course he gets fewer laughs than the surgeon so easily commands for his idiom. However, few would seriously dispute that the anecdotal sequence as the basis of an after-dinner speech is the last hope of the culturally destitute. A good speech is a work of dramatic art, carefully prepared, and appropriate in form and substance to its end. The speech that wasn't worth preparing can scarcely be worth listening to. Nevertheless, those who attend these dinners to listen or to speak cannot find the situation as intolerable as you suppose. Were it so, old students would not return to them year after year as they do, and men with nothing particular to say and no gift for saying it would not be found to be so universally delighted as they are to be invited to speak. Don't let us waste our

pity. Our audiences don't expect much, and our speakers have a mysterious confidence in their ability to be coherent and amusing without topic or preparation. As you say, Sir, the toast of the guests is always the nadir of after-dinner oratory. It would be a healthy custom if every proposer of this toast who started on the *Who's Who* tack were swiftly and silently removed from the room. Nothing less will save us from these unimaginative bores. Not all spell-binding speakers are cultured, as the politicians have taught us. Yet eloquence is a part of culture. Out of a simple desire to be constructive I suggest that the Royal Colleges might add to their many and varied diplomas a conjoint diploma for eloquence and pith in spoken and written speech. All future officers of these Corporations would of course hold it as a preliminary to becoming eligible for office. Clinical professors and teachers of medicine and surgery would be expected to sit for it as often as might be necessary to gain it, while its possession, though no secret, might be a condition of the grant of a merit award. Such a plan would in a single generation not only resolve the particular situation you so rightly deplore, Sir, but it would transform the medical scene. It would render unnecessary all the dreary debates about medical education by providing a *corps d'élite* of men and women securely possessed of perhaps the most essential weapon in their role as educators: the power to move the hearts and the minds of their students.—I am, etc.,

London, W.1.

FRANCIS WALSH.

Anthrax from Bone Meal

SIR,—I was most interested in your recent annotation on the subject of anthrax from bone meal (*Journal*, October 4, p. 844). You say that human disease is not often traceable to this material. While this may be true for bone meal *per se*, it is less accurate so far as other bone products are concerned. I feel that this statement requires some qualification, because in some parts of this country the association between bone products and human anthrax is well known, and has been so since 1947. Human cases of anthrax due to bone material have received mention in the reports of the Ministry of Health^{1,2} and the reports of the Chief Inspector of Factories.³⁻⁶ In 1953 a paper was published by Dr. D. G. Davies and myself on dried bones as a source of anthrax,⁷ which reviewed some of the literature on the association of bone products and anthrax in man and animals. We also recorded the occurrence of 14 cases of human anthrax in connexion with a chemical factory using crushed bones as raw material. The crushed bones were imported from the Middle East and from Pakistan. A second paper was published in 1955 on the isolation of *Bacillus anthracis* from imported bones,⁸ in which we recorded the isolation of the organism from 5 out of 41 cargoes of imported crushed bone (12.2%). We made the point that this was probably a considerable underestimate of the true figure and gave reasons for this statement. Apart from the isolation of *Bacillus anthracis* from the crushed bones, it has also been isolated from sacks which had previously contained bones. Such sacks have been occasionally incriminated in the spread of anthrax.⁹

The second point I should like to make is your reference to the obligatory disinfection of bone. This is not merely a question of economic feasibility. Heat treatment of crushed bones is incompatible with their use as the raw material for gelatin manufacture. Gelatin is a most important export of this country and involves considerable trade with the North American continent. Heat treatment of bone meal does not always result in the destruction even of organisms of the salmonella group, which do not form spores. A treatment sufficient to destroy anthrax may well be very difficult to apply. The difficulties of the task of sterilization of bone products should, of course, not be used to prevent the study of the problem. This is particularly so in view of the fact that this material is also a potential source of salmonella infection. Of 49 samples of crushed bones examined, all have without exception showed the pre-

sence of salmonellae. Each specimen contained anything from two to ten serotypes.

Finally, the absence of an efficient sterilization process does not mean that we have no means at our disposal for minimizing anthrax infection due to bones. The number of cases seen has declined since the introduction of more efficient mechanical handling of the raw material in the factory concerned.^{3,4} It is only fair to say that the management of the factory have been extremely co-operative in introducing improvements suggested by the authorities. It is perhaps in this approach to the problem that the short-term answer may lie.—I am, etc.,

Cardiff.

Reactions after Polio Vaccine

SIR,—I was interested to read the report by Dr. A. Fowden (*Journal*, October 4, p. 835) on a probable reaction to penicillin in poliomyelitis vaccine, and your annotation (p. 843). With increasing use of the vaccine, problems of this sort may be frequently encountered; and several difficulties arise in their assessment. Reactions may occur not only to penicillin or streptomycin but to other substances in the material—for example, the other antibiotics occasionally present, various proteins and formaldehyde, etc. When reactions are seen in patients who have no history of having had penicillin, or of being sensitive to it, are these to be regarded as irrelevant, or as reactions to the other substances? When they occur after the first injection the second is often withheld and, ironically, uncertainty is perpetuated. This point is shown in many of the American papers on the subject, few clearly showing the responsibility of penicillin as does that of Zimmerman.¹

We saw recently a child who developed an unusual rash a few days after the first injection. There was no history of sensitivity to penicillin. Intradermal tests to the British and to the Salk vaccine and to penicillin and streptomycin were negative, and the second injection was given after the situation had been explained to her mother; there were no ill effects.

There is at present no simple answer to the problem. Some writers have advocated desensitization if sensitivity is suspected or shown; many would doubt the virtue of this, when the chances of producing lupus erythematosus and related disorders in this way have been stressed. Intradermal tests are unreliable. The relative risks must be balanced in deciding whether or not to give a second injection. In considering the matter in a patient known to react to penicillin, it may be noted that Stroud *et al.*² say that most of these people have been safely vaccinated. It would probably help if a careful descriptive record were to be kept of all reactions; a general picture might emerge and, at least where the skin alone is involved, the irrelevant coincidental rashes of impetigo, scabies, and the like excluded.—I am, etc.,

London, E.1.

SIR,—During the past few weeks I have seen three cases of sulpha-drug reaction; one of these occurring in an adult and two in children. All had previously been treated with the drug and had suffered no ill effects. On investigation a coincidental factor was shown to be a recent poliomyelitis vaccination, the children having had Salk and the adult the British vaccine.

Case 1.—A girl of 6 was seen at the evening surgery with a recurrence of her frequent sore throats. She was given her

usual treatment of sulphadimidine. Half an hour after the initial dose she developed a bronchial spasm, angioneurotic oedema of the face, and an urticarial rash on the body. Intramuscular antihistamine was given, and the following morning she showed a marked improvement. The child had received her second Salk vaccination ten days before.

Case 2.—A lady aged 38 had two injections of the British vaccine a month previous to taking "dosulfon" for an inflamed throat. A few hours later she developed a generalized pruritus and maculo-papular rash. There was some difficulty in swallowing, due to oedema of the soft tissues of the throat, and some puffiness of the face was evident. Antihistamines were given, but it was a full week before the swelling of the face subsided.

Case 3.—A male child aged 3 had been vaccinated against poliomyelitis in February, 1958, with Salk vaccine. Two months later he was given sulphadimidine for an upper respiratory tract infection. In the evening he developed an urticaria and bronchial spasm. An antihistamine cleared the rash within 24 hours.

It would be interesting to discover whether other practitioners have had a similar experience and whether there is reason to suspect cross-sensitization.—I am, etc.,

Bradford, 7.

J. SAMUEL.

Immunization Card

SIR,—With the increase in the number of diseases for which immunization is available it has become almost impossible for the average man or woman to remember or perhaps even to understand what they or their children have been protected against. The situation would not be so serious if the family doctor had a complete record, but unfortunately this is impossible as so many protective inoculations and vaccinations have been carried out in the public health clinics, H.M. Forces, etc., and these records are not easily available. Further, the general practitioner has no suitable place on the N.H.S. medical record card to register the immunizations in tabular form.

For some years now in this partnership we have stamped the table illustrated below on the back of forms E.C.5 and the table illustrated below on the back of forms E.C.5 and have recorded on it all

Sensitivities					
BLOOD GROUP		Rh.			
		Diphtheria	Pertussis	Tetanus	T.A.B.
1st					
2nd					
3rd					
Boost					
Boost					
Mantoux		B.C.G.		Other Inocs.	
M.M.R.					

our own findings and immunizations and those that have been notified to us; as a result of recent developments a column for poliomyelitis is now required on the stamp. But this does not help us as much as we had hoped, as only a few immunizations are notified to us by the public health authorities and none by H.M. Forces.

It seems to us that family doctors should be made aware of all immunizations carried out on their patients, and that the patient's medical card should be provided with some such table as is used in this practice. Public health authorities should be required periodically to notify general practitioners of protective inoculations carried out under public health auspices. On discharge from H.M. Forces notification could perhaps be done by amending form E.C.13 so that the clerk could copy the inoculation record from the man's paybook on to a portion of the form which the general practitioner could detach and retain. We feel that it is important to start some such arrangements soon, before routine immunization procedures multiply further. Vac-

cinia and B.C.G. scars can be confused, and, as many people react severely to A.T.S., it can be most important to know urgently the patient's state of immunization to tetanus, and helpful to know about diphtheria, whooping-cough, poliomyelitis, and enteric fevers also.

We have submitted these suggestions to our local medical committee and our medical officer of health. We would be interested to hear if any such scheme exists in another area.—We are, etc.,

P. J. K. FERGUSON.

Premonition of Death

SIR,—I should like to add a further case of premonition of death to those already given (*Journal*, October 11, p. 914). This took place in a ward of tuberculous patients, all of them from a particular area of Glasgow. During their enforced association within the confines of the ward, these patients, already bound by strong subcultural ties, naturally developed particularly intense relationships with each other. The patient concerned had, however, been partially separated from his fellows for many weeks by screens, since he was clearly dying and subject to rather frequent and distressing haemoptyses. Day and night about, each change of duty among the nursing staff carried with it the expectation of this man's death before the resumption of duty, and each return to duty brought renewed surprise at his continuing existence. His bed, I remember, lay in a corner at the end of the ward farthest from the door, and on the night of his death, and on that night only, this man called from behind his screen, in turn, correctly, bed by bed around the ward, the name of each of his fellows, most of whom he had not seen for months. To each he wished good night, and one who was already asleep drew the comment, "Aye, Lachlan, ye old bugger, ye're aye sleepin'." If this farewell was coincidental, it was certainly striking.

Many of the men of this ward came to a premature and lingering end, and a large proportion of them had full insight extending over long periods of time. Close association with such a community is not lightly forgotten. Beigler¹ has reviewed various ways in which organic disease can be detected from psychiatric and psychoanalytic evidence, and presents case histories in which this knowledge has been applied to diagnosis of impending death not indicated on ordinary clinical grounds. Sandford² has also contributed relevant notes on a dying patient.—I am, etc.,

Broxburn, West Lothian.

SIR.—A mother came to me worried about her daughter, aged 4 years. Her daughter told her that she was going to leave her, but she was not to worry because she was going to a very beautiful place. Her mother greatly scolded her and said, "Darling, how unhappy I would be if you left me; how unhappy we would both be." To which the child replied, "I shall be able to see you, but you will not be able to see me."

This was repeated over a number of days. The child was healthy, full of buoyancy—both physically and mentally—normally alert and psychologically normal.

After a short period of days—I cannot remember exactly, perhaps a week to a fortnight—the child suddenly developed acute meningitis and died in a few days. This was before the advent of antibiotics.—I am, etc.,

Worthing, Sussex.

J. C. JONES.

SIR.—I well remember, when I was resident medical officer at the Royal Albert Dock Hospital, the uncanny experience of seeing some of the seriously ill Lascars stripping off their night attire and saying, "Me die, Sahib." Sure enough that night they died, in spite of all we tried to do to save the poor creatures.—I am, etc.,

Thornton Heath, Surrey.

DOUGLAS BENTON.

Medical Education

SIR,—Dr. Hugh Gainsborough's letter (*Journal*, September 27, p. 795) is of particular interest to medical social workers and will encourage them greatly, since his conception of medicine as "a study of all aspects of man as he lives in society" comes very close to the ideal which social workers set before themselves. How wonderful it would be if from the beginning of their clinical course medical students were expected to concern themselves with people, their home background, family worries, and anxieties about hospital treatment.

I wonder, however, if Dr. Gainsborough is not expecting too much of human nature in suggesting that the specialists concerned are necessarily the people best qualified to teach what the attitudes aroused by particular forms of treatment are likely to be. Some very great physicians can do this; but perhaps most of us, when we have to carry out painful or humiliating procedures on others, cannot afford to think too deeply how the patient feels about it. We have to concentrate our attention rather on the ultimate benefit to the patient and on developing the most efficient and swiftest method of achieving this end. Moreover, even if ward rounds were more generally organized in such a way as to give patients the opportunity of a quiet talk with their consultant, I am not sure how free they would feel to tell of their fears. They know usually that the surgeon is doing what he considers necessary for their health, and the stiff upper lip seems the most courteous and helpful attitude to take with him.

In whom, then, is the patient most likely to confide about the things that are troubling him? Certainly in the general practitioner if he is already a trusted friend, and sometimes in a sympathetic and not too busy member of the hospital team. But in hospital the person to whom some patients talk most easily is the almoner. It takes a special skill to encourage people to talk freely about intimate fears which they may expect others to think ridiculous; it takes enormous patience and understanding to discover what is the significance of a particular operation for a particular patient, and it requires a conviction that there is value for the patient in talking about these things rather than in fighting them by himself. Moreover, from the patient's point of view the almoner stands a little apart from the rest of the hospital team and has less power over him. It is often through their understanding and support that almoners make their main contribution to the patient's recovery. I wonder, too, if medical schools might not use them more often than they have done in the past as sensitive instruments able to register and demonstrate to students the responses of their patients to hospital experience.—I am, etc.,

London, N.W.3.

ISABEL BOAG,
Almoner.

SIR,—The articles written on general practice and medical education (*Journal*, September 6, p. 577) seem to reflect a disquiet on this subject which springs, I feel, from a general experience that the training which we acquire at medical school and hospital is designed to produce hospital specialists rather than general practitioners. In fact, the majority of medical students do eventually become general practitioners. The staff of a hospital is becoming increasingly a body of specialists rather than people who have a wide medical experience, and many deplore the passing of the general hospital consultant. Further, his place is surely now taken by the general practitioner, who is, in fact, treating many of the conditions that required hospitalization in the past. It is precisely this elevation of status of the general practitioner that seems to be missing from the proposals made in the articles on medical education.

I suggest that the general practitioner needs to be reintegrated not only with local but also with the teaching hospital staffs; that he has an important part to play in the training of students, and that, as a general practitioner, he should be a member of the hospital staffs, not doing sessions in hospital as a consultant but still working as a general practitioner. Because of the nature of

medical students and their concern to pass examinations, as a first step the general practitioner should, I believe, be an integral part of the final examinations board. He should be present all along the line, both at the setting of questions, their marking, and at the vivas. I feel that to suggest less than this will have little effect on the present situation.

Because of the present relationship between general practice and the hospital services, and, in particular, what Dr. M. Balint calls "the perpetuation of the teacher-pupil relationship," it would probably be better for the general practitioner if such posts were chosen from an agreed panel drawn up by some qualified body such as the College of General Practitioners. This would obviate, to some degree, the appointment of unsuitable people who sometimes tend to be overawed in the atmosphere of hospital medicine.

Clearly a fundamental change is necessary in medical education, but, in the present set-up, I believe this proposal would be a first step. Suggestions of students visiting general practice for a fortnight, while admirable in themselves, have in fact been attempted for some time with little response; and until, I feel, the examination question is faced, not by some question being asked which would seem appropriate to general practice, but by shift of emphasis on the sort of answers that are required, little satisfactory progress will be made.—I am, etc.,

Orpington, Kent.

P. A. L. CHAPPLE.

"Sytron"

SIR,—We have seen your note on "sytron" (*Journal*, August 30, p. 562) and also Mr. C. Beaven's letter (*Journal*, September 27, p. 801) regarding this preparation of sodium ironedetate. In the last two or three years we have been trying out iron chelate substances in the treatment of iron-deficiency anaemia. Among those we have used is sodium ironedetate in two preparations—(a) a solution of the chelate suitably flavoured, and (b) capsules containing the chelate as a powder. In each case the dosage employed was 70 mg. of elemental iron three times a day. The liquid was given to 55 patients and the capsules to 26 patients, making a total of 81 cases. Diarrhoea occurred in 23 cases and was moderate or severe in 20 cases. Though it sometimes settled gradually, this was not always the case and it was indeed a major disadvantage. There was a minority of patients in whom severe constipation was improved. Nocturnal cramps in the legs also occurred in 16 cases but did not usually commence until nearly four weeks after the start of treatment.

Before a new preparation of iron is introduced there should be no doubt that it either has less tendency to produce unpleasant side-effects or is a better haematinic in view of the many satisfactory preparations available. This preparation was unsatisfactory in the former respect and had no special value from the latter point of view. As it was colourless and almost tasteless it was felt that it might have a limited place as a liquid preparation, but was certainly not suitable for large-scale therapy. We are reporting this work in detail at a later date.—We are, etc.,

Manchester, 13.

JOHN F. WILKINSON,
J. T. LEEMING.

"Nilergerx"

SIR,—In their recent letters Dr. A. Fry (*Journal*, September 6, p. 636) and Dr. R. P. Warin (*Journal*, October 4, p. 859) are critical of the claim that "nilergerx" has a very low incidence of side-effects. The former bases his criticism on one case, but Dr. Warin reports 6 cases of drowsiness out of 13 patients given the drug. Their figures compare very unfavourably with those reported from America (5 out of 602 patients). I have used nilergerx for the past eight months and have been impressed by the relative absence of side-effects. I have made careful inquiry about these from every patient because of the American claim.

In a preliminary survey of a series of cases intended for later publication, 67 cases have data available with regard to side-effects. A considerable further number are not included because

of as yet insufficient information. The accompanying Table shows the frequency of these effects in relation to the dosage given.

Doses as high as 72 mg. daily have been given, which are considerably higher than recommended by the manufacturers. In no cases were the side-effects severe. The figures shown for side-effects give an exaggerated impression of toxicity. Examination of the eight cases exhibiting drowsiness revealed that the case on 72 mg. daily had no drowsiness on 48 mg. daily. The same 72 mg. daily was only drowsy for a few days, she was equally drowsy the following week on dummy tablets, and when nilergerx was restarted at the same dose level there was no drowsiness. One case on 36 mg. daily had only very slight sleepiness.

Dosage mg.	No. of Cases	Drowsiness	Other Side-effects	No Side-effects
72	5	1	2	3
60	2	2	0	0
48	30	1	2	27
36	6	2	0	4
24	9	0	0	9
16	3	2	0	1
12 or less	12	0	1	11
Total	67	8	4	55

This leaves 4 cases out of 67 (6%) with definite drowsiness. I have the clinical impression that this was not as marked as with certain other antihistamines. Only two patients volunteered the information that the tablets made them feel sleepy. On the other hand one patient was emphatic that nilergerx gave her a feeling of greatly increased energy. Two patients had attacks of asthma whilst taking nilergerx, but these were probably not directly attributable to the drug, as they subsided without its withdrawal. One child was sick with the syrup. Another patient complained of a sensation of burning in the oral and nasal mucosa whilst taking nilergerx.

Without going into the merits of nilergerx as an antihistamine my series shows that it is a drug with noticeable freedom from side-effects—in particular, drowsiness. In this respect I find it as good as any other antihistamine and better than most. The absence of a sedative effect is not always essential in these drugs but of great value in those driving vehicles or working with machinery.—I am, etc.,

Glasgow

J. O'D. ALEXANDER.

Chemotherapy in Primary Pulmonary Tuberculosis

SIR,—I would like to thank Dr. J. K. Cameron, Professor I. D. Hay, and Mr. L. J. Temple (*Journal*, May 31, p. 1301) for replying to my letter (*Journal*, April 12, p. 887) and for clarifying their conclusions concerning the value of "antibiotics" in the treatment of primary pulmonary tuberculosis. Unfortunately it appears that the main point in my letter has escaped them. This was simply that in every case of active tuberculosis, child or adult, an effort should be made to rid them of their tubercle bacilli in order not only to prevent spread of disease and possible complications such as meningitis and bone and joint involvement, but also to minimize relapse at a later age.

Dr. Cameron, Professor Hay, and Mr. Temple raise several questions in their recent letter which I feel require answering: (1) The development of drug resistance: I cannot see the pertinence of this matter to a decision to give chemotherapy or not—but if chemotherapy is commenced, the chances of drug resistance developing are increased by giving ineffective doses. Therefore adequate treatment must be given. (2) The patient's own resistance in combating disease: I agree that this is a very significant factor in every case of tuberculosis. In a percentage of patients, however, this is not sufficient and complications and later relapse do occur—it is to prevent such occurrences, in every case if possible, that chemotherapy is recommended. (3) Is every child who converts a Mantoux test to be treated? If recent, I would again say yes, as a preventive measure. (4) Toxic side-effects of chemotherapy: There is no doubt that this danger exists and must be weighed against the possible good advantages of treatment. I feel that with careful management these can be kept to a minimum and that children should not be denied adequate treatment because of a possibility that they might appear.

One should remember that every child sterilized of tuberculosis germs, apart from being cured himself, may save many others from being subsequently infected with tuberculosis.—I am, etc.,

Adelaide,
S. Australia.

R. MUNRO FORD.

Thoracic Outlet Compression Syndrome

SIR,—In their paper in the *Journal* of September 20 (p. 709), Professor C. G. Rob and Mr. A. Standeven contend that the changes which they observed in the arms were due to local mural thrombosis of the subclavian artery followed by embolism or spreading thrombosis, and that this local thrombosis was due to extrinsic pressure in the region of the first rib. The evidence for the second of these propositions was the presence of a cervical or abnormal first rib, the presence of a systolic murmur in some of the cases, and the improvement which followed removal of the abnormal structure.

Some recent cases have made us doubtful whether this evidence is sufficient, at least in those over 40 years of age. As mentioned in the article, symptomless cervical ribs are common enough; systolic murmurs and thrills due to a stricture anywhere between the aortic valve and the supraclavicular fossa may best be detected at the latter site; and the improvement following surgery is unconvincing evidence of the cause, as sympathectomy was performed in each case and Case 4 was improved although the suspected rib was not removed and the artery damaged and repaired. The following cases have all been studied recently.

Case 1.—A sales manager aged 42 had experienced pain in the left arm for several weeks when he was aged 38 and again at 41. He had had coronary thrombosis at ages 37 and 41. He had impaired pulsation in the left subclavian and distal arteries with a coarse thrill and murmur in the left supraclavicular fossa. The blood pressure was 170/70 and 90/70 in the right and left arms respectively. Carotid pulsations were equal. Arteriography (see Figure) demonstrated narrowing of the subclavian artery between the origin of the vertebral artery and the thyroid axis.

Case 2.—A clerk of 58 was aware of a hissing noise coincident with the pulse. He had both effort angina and intermittent claudication. The physical signs were similar to those of Case 1, the blood pressure was 165/85 and 140/110 in right and left arms. Aortography revealed constriction of the left subclavian just above the origin of the vertebral artery.

Case 3.—A butcher aged 64 became dizzy on bending his head forwards and developed intermittent claudication in the right arm when splitting carcasses. He had gross impairment of pulsation in the right carotid artery with diminished pulsation in the right subclavian artery and a marked systolic thrill and murmur in the right supraclavicular fossa. Blood pressure was 105/90 and 165/85 in the right and left arms. At aortography the innominate artery was shown to be markedly narrowed 2 cm. from its origin.

Case 4.—A farm labourer aged 64 developed occipital headache whenever he slept on his left side, rapidly relieved by standing. The physical signs were similar to Case 3. The blood pressure was 135/105 and 210/105 in the right and left arms. This lesion is evidently in the innominate artery, but arteriography has not yet been performed.

This group all had evidence of arterial narrowing anatomically unrelated to the first rib and had no structural abnormality in the neck, but in each the thrill and murmur were best appreciated in the supraclavicular fossa. Had a cervical rib been found it would have provided a ready explanation for partial occlusion of the subclavian artery. Aortography and subclavian arteriography were performed by retrograde passage of a catheter following percutaneous puncture of a femoral artery, an investigation which we have found safe and of great value in establishing an exact diagnosis. We suggest that it would be wise to exclude other lesions of the subclavian artery before accepting pressure by a cervical or abnormal first rib as the cause of a patient's symptoms.—We are, etc.,

Pathogenesis of Fever

SIR,—Your review of the pathogenesis of fever in rabbits (*Journal*, October 4, p. 839) is timely in view of the important discoveries now being made in this field, but there is a regrettable omission of any reference to the British publications which are the only studies of man. It has been shown that the latent period in the action of bacterial pyrogen is greatly reduced if it is incubated *in vitro* in fresh human blood before injection.¹ The presence of a minimal number of leukocytes, probably polymorphs, in the blood is necessary for this property to be achieved.² Incubation of bacterial pyrogen in cell-free plasma or serum conversely inhibits the febrile response,³ and in this important respect man differs from the rabbit, in whom a similar preparation produces an accelerated and augmented fever.

We postulated that human endogenous pyrogen is produced by the *in vitro* incubation of leukocytes with bacterial pyrogen, and the properties of this substance were examined.⁴ Human endogenous pyrogen fails to pass an ultra-filter or a dialysing membrane, and unlike bacterial pyrogen is destroyed by heating to 70° C. for thirty minutes. In addition to the difference in latent periods, bacterial pyrogen fails to produce fever when injected intramuscularly, whereas endogenous pyrogen does so, and the repeated injection of endogenous pyrogen does not lead to tolerance. Endogenous pyrogen was present in the blood of a patient who had been previously injected with bacterial pyrogen.

So far we have failed to produce human endogenous pyrogen from human leukocytes alone, and it remains to be determined if this substance is released from white cells or whether the properties attributed to it are due to an alteration of chemical structure of bacterial pyrogen (lipopolysaccharide) by some action of leukocytes. In view of the different properties of human and rabbit serum, the results of animal experiments must for the present be carefully distinguished from the evidence derived from man. For this reason alone it is unfortunate that your annotator omitted to mention the human work.—I am, etc.,

London, W.2.

Ergometrine with Hyaluronidase

SIR,—I was most interested to read the paper by Drs. M. P. Embrey and W. J. Garrett (*Journal*, July 19, p. 138) and the letter by Dr. A. H. Labrum (*Journal*, October 4, p. 857) on the speed of action of ergometrine in conjunc-

tion with hyaluronidase. As a woman can lose a serious amount of blood even in the 4–6 minutes before the onset of the action of ergometrine accelerated by hyaluronidase, would it not be safer—and cheaper—to employ routine intravenous ergometrine at the end of the third stage? I would suggest that the injection—of 0.25 mg. intravenously and 0.25 mg. intramuscularly—be given after the delivery of the placenta to avoid its retention.—I am, etc.,

Drayton, Norfolk.

J. N. GALE.

The Peacehaven Syndrome

SIR,—I see every year a condition which I call the Peacehaven syndrome. The patient, let us call him Joe Murgatroyd, is from up North and is around the retiring age. He has been rather short of breath over the past few years and decides to buy a bungalow and retire to the South Coast to help his bronchitis.

When the move comes, his wife goes on ahead by train to get some food in, while Joe goes with the van to see that the furniture does not go astray. Joe usually gives the van-driver a beer on the road and has one or two himself. That night he is taken ill and is sent into hospital with what is called acute bronchitis. When he comes in, his bladder is up to the umbilicus, his blood pressure is sky high, and he is waterlogged. His prostate is enlarged. He is never the same man again, and his disconsolate widow may find herself, a year later, selling the house at a loss and returning to the North where her friends are. The only people who are happy are the house agent and the undertaker.

The moral, of course, is to make sure that you are fit enough before you make a serious change in your way of life.—I am, etc.,

Hove.

FORDE CAYLEY.

The Pharmaceutical Industry

SIR,—Among the criticisms of the pharmaceutical industry Dr. R. S. Inch (*Journal*, October 4, p. 846) makes no mention of the confusion, annoyance, and waste of time caused by the existence of several names for the same drug. In recent years new drugs with proprietary names such as "dindevan," "achromycin," "inversine," or "equanil" have been announced with a barrage of propaganda from the manufacturers. Later we have read articles in medical journals about phenindione, tetracycline, mecamlamine, or meprobamate, and have been subjected to more propaganda from other firms about the same drugs under other proprietary names, such as "tetracyl" or "miltown." According to the *British National Formulary* prednisolone has the following proprietary names: "codelcortone," "delta cortef," "delta cortril," "delta-stab," "di-adreson-F," "hydrodeltalone," and "precortisyl." Sulphanilamide was said to have over 40 proprietary names.

Unlike many of the other problems mentioned by Dr. Inch this one is capable of solution. If the pharmaceutical industry, in association with the General Medical Council, cannot solve it, I would favour legislation to ensure that one drug has one name.—I am, etc.,

Farnham, Surrey.

J. W. TODD.

Homosexuality

SIR,—Dr. Desmond Curran's review of four books on this subject (*Journal*, October 4, p. 837) is one of the ablest and most helpful I have read—on any topic. Far from being "ill-chosen asides," as implied by Dr. W. A. O'Connor (*Journal*, October 18, p. 979), Dr. Curran's criticisms are precisely the sort of comment that is really useful to a potential book-buyer; and his concluding suggestion of a truly informative book is exactly what the reader needs.—I am, etc.,

Manchester.

Obituary

HENRY WALLACE-JONES, M.Sc., M.D.
F.R.C.P.

Dr. Henry Wallace-Jones, formerly senior honorary physician and physician in charge of the department of cardiology at Liverpool Royal Infirmary, died suddenly at Johannesburg, South Africa, on October 8. He was 70 years of age.

Henry Wallace-Jones was born in Liverpool on August 1, 1888, the son of Dr. Henry Jones, and was educated at University College, Liverpool, and at Liverpool University, where he graduated first in science. Obtaining the B.Sc., with first-class honours, in 1910, he proceeded to the M.Sc. in the following year. Then, having decided to complete the course in medicine, he went on to take the degrees of M.B., Ch.B. in 1913, again with first-class honours. In 1914 he proceeded to the M.D., and also obtained the now obsolete diploma in ophthalmic surgery (D.Ch.O.). Elected a Member of the Royal College of Physicians of London in 1921—he had taken the London Conjoint diploma in 1912—he became a Fellow of the College in 1930. After taking his medical degrees he held the appointments of house-physician, house-surgeon, and house-surgeon to special departments at Liverpool Royal Infirmary. During the first world war he served as a captain in the R.A.M.C. and was pathologist to the Liverpool Merchants' Hospital in France. After the war he returned to Liverpool to practise as a consulting physician. He became honorary assistant physician at Liverpool Royal Infirmary in 1919, progressing to senior assistant physician, full physician, and ultimately senior physician. From the middle twenties until he retired soon after the end of the second world war he was medical officer in charge of the cardiology department at the Royal Liverpool Children's Hospital, and over much of the same period was head of a similar department at Liverpool Royal Infirmary. He was also consulting cardiologist to Waterloo Hospital and honorary consulting physician to Liverpool Maternity Hospital. He assisted Professor Ernest Glynn in the preparation of the report of the Medical Research Council (Special Report Series No. 79, 1923) on bacteriological and clinical observations on pneumonia and empyemata. In 1924 he contributed a paper to these columns on types of dextrocardia; in 1926 on congenital absence of the pectoral muscles; in 1927 (with Dr. Robert Coope) on the urea concentration test in nephritis and its prognostic value, and (with Professor John Hay) on trauma as a cause of auricular fibrillation, its medico-legal significance; and in 1928 on vital capacity in heart disease. He was the author, jointly with Dr. E. Noble Chamberlain, of *Electrocardiograms: An Elementary Atlas for Students and Practitioners*, a small manual published in 1939. A member of the British Medical Association for forty years, he was honorary secretary of the Liverpool Division from 1928 to 1930. In 1926 the Association awarded him a research grant. He leaves a widow.

G. S. SEED, F.R.C.S., D.L.O.

Mr. G. S. Seed, senior aural surgeon to the General Infirmary at Leeds and to St. James's Hospital, Leeds, died in London on October 13 at the age of 53.

George Sutcliffe Seed was born on April 27, 1905, and was educated at Heath Grammar School, Halifax, and at Leeds University, where he graduated M.B., Ch.B. in 1927. Three years later he obtained the D.L.O. of the English Royal Colleges, and in 1936 was admitted F.R.C.S. After graduation he held the appointments of house-surgeon and house-physician at the West Bromwich and District General Hospital, and senior house-surgeon at the Birmingham and

Midland Ear and Throat Hospital. He then returned to Leeds as resident aural officer at the General Infirmary, subsequently becoming aural surgeon to the infirmary and to St. James's Hospital. When the British Medical Association held its Annual Meeting at Harrogate in 1949 he served as a vice-president of the Section of Oto-rhino-laryngology. He leaves a widow and three daughters.

T. McM. B. writes: The privilege of working alongside a man of George Seed's integrity and selflessness is not given to everyone. He was brought up in Halifax, the only child of parents who themselves must have been admirable, for George of all people showed none of those weaknesses which sometimes betray an only child. He was educated at Heath Grammar School, Halifax, and there must have been laid down the foundations of the character which endeared itself to so many. The results of this early education in George's case were a fine example of all that is good in the British educational system. After graduation and the usual hospital appointments he returned to the General Infirmary at Leeds as resident aural officer, a post he held without blemish for seven years, probably a record term of office for any resident appointment in this hospital. It was typical of his assiduity of purpose that, after taking his F.R.C.S., he immediately decided to broaden his experience and knowledge by a prolonged tour of clinics in Zurich, Vienna, Berlin, and Scandinavia. On his return, and when the late E. W. Bain retired, George was the obvious successor, and he was appointed consultant not only to the infirmary but to St. James's Hospital and Dewsbury General Hospital. It was at this time that he first saw an auburn-haired almoner, and I well remember the shyness with which he contrived an introduction to the girl whom he married in 1939. A year or so before this he had joined the Territorial Army and was embodied in September, 1939. He saw service with the British Expeditionary Force in France, before Dunkirk, and later on had over three years in India, where for a period he served as a brigadier in his specialty.

On his return home George was always determined not to work in clinical isolation, and it was his vigour and his inspiration which resulted in the foundation of the North of England Otolaryngological Society. He became its president, and the youthful zest of its activities is a fitting tribute to his memory. He spent and enjoyed a lot of his spare time in clinical discussions, and a measure of the esteem in which his colleagues in many places held him is that he was a member by invitation of the Visiting Association of Ear, Nose, and Throat Surgeons of Great Britain, as well as of the Midland Otolaryngological Club. He had recently been elected a vice-president of the section of otology of the Royal Society of Medicine. It was always a joy to observe the delight with which his colleagues greeted him at the meetings of these societies. He visited clinics in America and, despite a prolonged and serious illness five years ago, continued these activities, and it was during one of these journeys that his life ended. His particular clinical interest was probably in malignant disease. He had written on this and other subjects, but his clinical abilities lay mainly in his thoughtful judgment of what was best for the patient rather than indulgence in exciting, probably short-lived, new theories. He was, however, ready to familiarize himself with new techniques, but in our weekly combined clinics a flitting frown of dismay would indicate a firm stand against unorthodox suggestions. Patience was one of his virtues, and despite his heavy commitments he was always an inspiration to the rest of us. His painstaking and unhurried methods in the diagnosis and care of his patients were a fine example to his juniors and students. After his long period of residence and prolonged absence abroad he had revelled in the joys of family life, and it is with gratitude that we know this was a happy one. He had enjoyed fishing in recent years, and very recently had returned from one such holiday in Scotland. His impish sense of fun made him a delightful companion, and his gentle nature a man who was liked by everybody who knew

him, and loved by many. The sympathy of his many friends will be extended to his widow and three daughters in the loss of one who was professionally so mature and yet who still retained his youthful enthusiasm. Perhaps his life can best be summed up by quoting from a letter I received from a mutual friend. He says: "George did as much and more for the infirmity by being selfless, generous, and unassertive as many have done with more aggression; his influence was entirely beneficent."

JANE H. TURNBULL, C.B.E., M.D.

Dr. Jane Turnbull, who died at Canterbury on October 15 at the age of 87, was formerly in charge of the Maternity and Child Welfare Division of the Ministry of Health.

Jane Holland Turnbull was born in 1871, the daughter of Lieutenant-Colonel Archibald Turnbull, of the Indian Army Veterinary Service. Both her parents died in India when she was still a young child. Some of her early education was in Edinburgh, but later she went to live in Reading with a friend of the family who kept a school there and for whom Dr. Turnbull had a great affection. After studying medicine at the London School of Medicine for Women she graduated M.B., B.S. in 1899, with first-class honours in surgery. Five years later she proceeded M.D. After graduation she became a demonstrator of anatomy at the London School of Medicine for Women and then obstetric assistant at the Royal Free Hospital. After a period of work at the East Anglian Sanatorium at Colchester she returned to London as R.M.O. and tutor in obstetrics at the Royal Free, where she did useful work in organizing the district midwifery service. She also began a long association with the Elizabeth Garrett Anderson Hospital (known then as the New Hospital for Women), where, after being house-surgeon and house-physician, she became assistant obstetrician. Another appointment she held was that of assistant surgeon to the Canning Town Medical Mission Hospital. After settling in private practice in 1905, Dr. Turnbull continued to serve the Royal Free Hospital as anaesthetist and lecturer in anaesthetics. An examiner to the Central Midwives Board, in 1913 she was appointed a member of the committee which established the South London Hospital for Women, and later she joined the staff of that hospital as assistant surgeon.

During the first world war Dr. Turnbull became Controller of Medical Services, Queen Mary's Army Auxiliary Corps, and she was appointed C.B.E. for her services in 1918. The Ministry of Health was set up in the following year and she joined its staff as a medical officer. She was chiefly concerned with the maternity and child welfare services and for three years worked as director of the Maternity and Child Welfare Division at the Ministry before her retirement in 1936. Thereafter she continued to make a useful contribution to the development of the work in which she was interested by serving as chairman of the National Association for Maternity and Child Welfare from 1939 to 1948, and for the next three years as vice-president of that association.

We are indebted to Sir ARTHUR MACNALLY for the following appreciation: Dr. Jane Turnbull's death at an advanced age brings to mind many memories. After service at the Royal Free Hospital, on the honorary medical staff of the Elizabeth Garrett Anderson Hospital and the South London Hospital for Women, and as Controller of Medical Services, Queen Mary's Auxiliary Corps, she was appointed a medical officer of the newly established Ministry of Health in 1919. I did not see a great deal of her in her first years at the Ministry, for she was chiefly occupied in the inspection of maternity and child welfare schemes and out of the office, but whenever I conferred with her on official subjects I found her a most helpful and understanding colleague. Her good work was especially valued by her immediate chief, Dame Janet Campbell, to whom she became Deputy Senior Medical Officer in 1929. On Dame Janet's retirement in

1933 Dr. Turnbull was put in charge of the Maternity and Child Welfare Division. She retired in 1936 after three years of excellent and strenuous work as acting S.M.O.

Dr. Turnbull participated in the comprehensive special investigation into maternal mortality in England, the report on which was published as a White Paper in April, 1937. One of the first results of this investigation was an improvement in the standard of midwifery practice, both domiciliary and institutional, through the Midwives Act of 1936. This provided a salaried domiciliary service of trained midwives throughout the country. In the establishing of this service by local authorities Dr. Turnbull's advice and experience were of value both to the Ministry and to medical officers of health. Much of Dr. Turnbull's work was unobtrusive. She succeeded in her aims to improve the well-being of mothers and children by wise administration, because her arguments were logical, tactfully expressed, and in matters of controversy given with appreciation of the other person's point of view.

Dr. Turnbull was of medium height, white-haired, and erect. She was alert and brisk, but reserved in disposition, and a lover of books and of flowers, which she cultivated in her garden at Princes Risborough. She had a dry sense of humour which occasionally revealed itself in the course of conversation. With a strong sense of vocation, she helped to make the world better than she found it, and for this she would wish to be remembered.

E. B. writes: Dr. Jane Turnbull was a Scot by birth, an Anglican by training, and a very gentle, courteous lady. All through her life she always believed the best once she had learned to like and respect anyone. She never made up her mind quickly on important issues, and always sought the help of those whom she knew were trustworthy. She had had her Edinburgh roots severed at too young an age and was never able to forget how gracious the old pre-war type of life had been, and she found it very hard to let people, even in times of emergency, relax the courtesies of life. In her later years she lived with a god-daughter, who helped her through her time in Canterbury Hospital after a fall last summer and a weary time with a fractured hip. But she made a good recovery and was able to be home for some time and enjoy the garden, and it is now from that quiet home that has come the news of her passing. Her gentle courtesy and beauty of early life will be long remembered by all to whom she endeared herself through a long and useful life.

J. K. J. HAWORTH, M.D., M.S.

Mr. J. K. J. Haworth, honorary surgeon to Sutton Hospital, Surrey, and surgeon to the Carshalton and District Hospital, died suddenly at Mullion, Cornwall, on October 4. He was 69 years of age.

James Kenworthy Johnston Haworth was born at Durham on December 9, 1888, the son of Canon Haworth, formerly principal of St. Hild's College, Durham. From Durham School he entered Durham University College of Medicine, going on to the Royal Victoria Infirmary, Newcastle upon Tyne, three years later. He graduated M.B., B.S. from Durham University in 1912 and proceeded to the M.D. in 1914 and the M.S. in 1920. After graduation he held a number of appointments at the Royal Victoria Infirmary, Newcastle upon Tyne, ultimately becoming resident medical officer. In August, 1914, he joined the R.A.M.C., and in October went to Lucknow with the 4th Battalion, Royal West Surrey Regiment. He also served in Egypt, Rangoon, and Mesopotamia, from where he was invalided back to Lucknow in 1916, and was not demobilized until September, 1919. While in India he lectured in anatomy and examined in surgery for Allahabad University. After the war he returned to his Newcastle appointment, but left there to go to Durban, South Africa, but came back to Britain in 1922 to become medical superintendent of St. Mary's Hospital, London. In the following year he was appointed senior assistant medical officer under the old Metropolitan

Asylums Board at Queen Mary's Hospital for Children, Carshalton, Surrey. Soon afterwards he decided to set up in practice in near-by Sutton, and became honorary medical officer to the Carshalton War Memorial Hospital and honorary surgeon to Sutton and Cheam Hospital. During the second world war he was a surgeon in the Emergency Medical Service. For some years he was an examiner in surgery for the General Nursing Council of England and Wales.

J. M. T. and T. H. W. write: Pat Haworth, as he was affectionately known locally, was interested in people, and felt that general practice was the most satisfying medical work. He began practice in Sutton in 1927, and after such a varied and distinguished professional experience both in this country and abroad the impact of his personality was soon felt. Within a short time he was appointed to the surgical staff of Sutton and Cheam Hospital and to the Carshalton War Memorial Hospital, where he practised surgery with skill not bettered in higher circles. In his work, care and thought for the individual were his chief concerns. There can be few general-practitioner and surgical colleagues in the district of his time who did not benefit from his wise advice and sage counsel. In private practice patients were assured not only of first-class individual attention but also of a degree of human kindness and interest in their ordinary affairs. Haworth was remarkable because he was both the best type of family doctor and a skilful surgeon. Outside medical practice Pat Haworth had many interests. He was a good listener and yet could talk wisely on most subjects. A keen observer of life in general from nature to politics, he brought a boyish enthusiasm to each new interest and to all that he did. Conversation with him could never be dull or uninteresting; he enjoyed an argument, and one usually left him having learned something. He was outspoken, vigorously supported what he considered ethically correct, and never took a pessimistic view of anything.

A serious illness in 1950 made him retire from active medical practice, and curtailed his physical activities, but his agile mind could not be curbed and he decided to read law. With zest and enthusiasm he became a student member of Gray's Inn. Intensely interested in this new sphere, he completed the whole of part I, and was hoping to take part II of the Bar examination, when he passed away. Considerable time in late years was devoted to hospital committee work, where his valued services were in much demand, and he had recently joined the management committee of Long Grove Hospital. Haworth was concerned for the welfare of the nurses at his hospitals and was interested in their training, and had been for many years up to his death an examiner in surgery for the General Nursing Council. He was a past president of the local medical society. Sutton and district is much poorer as the result of his passing, but his memory will live long with us, and in particular with those many patients who have such good cause to remember his kindness and skill.

D. R. CURNOCK, M.R.C.S., L.R.C.P., L.D.S.

Dr. D. R. Curnock, who was in dental practice with his brother, Mr. G. L. Curnock, in London for many years, died at his new home at Dorking, Surrey, on August 23. He was 65 years of age.

A. E. S. writes: Reginald Curnock died at Dorking in August a few hours after moving there with his wife from Wanstead, where they had lived for many years. He had been ill intermittently for some years and had to retire early this year. He and his brother carried on their father's dental practice in the City. When they were bombed out of Christopher Street they moved to Wimpole Street. Reginald had a large and devoted following. His great interests outside his work were Methodism and archaeology. His grandfather led the singing in the Methodist Conference. His father's cousin, the Rev. Nehemiah Curnock, discovered

the key to the cipher of John Wesley's *Journal*. Hymn tunes and Wesley's hymns were an endless delight to Reginald. In illness he always came up smiling and optimistic. His conversational powers never waned. One of his sons (Henry) is a doctor.

J. W. MURDOCH, M.B., Ch.B.

Dr. J. W. Murdoch, general superintendent of the mental hospitals in the State of North Carolina, U.S.A., died on September 16 at the Memorial Hospital, Chapel Hill, North Carolina. He was 58 years of age.

James Wilson Murdoch was born at Stonehaven, Kincardineshire, in 1900, and was educated at Aberdeen University, where he graduated M.B., Ch.B. in 1924. After graduation he held appointments at Inverness District Asylum and the Devon Mental Hospital, Exminster, before entering the Colonial Medical Service in 1928. Posted to Malaya, he was appointed second assistant medical superintendent of the Central Mental Hospital at Tanjong Rambutan, in Perak, later becoming medical superintendent. He left the Colonial Medical Service in 1941, and took up an appointment at the Hospital for the Insane, Claremont, Western Australia, returning to Britain at the end of the second world war. In 1947 he became superintendent of the newly opened Butner State Hospital in North Carolina, and three years ago was appointed head of all the mental institutions in the state. While at the Butner State Hospital he worked hard for reforms in the treatment of mental patients, and introduced a method of voluntary admission. He insisted that all patients, including those who were receiving custodial care, should have medical treatment. After he became general superintendent of the mental hospitals in North Carolina he extended the system to include all mental institutions. His profound sympathy for and understanding of the needs of the mentally ill were such that before very long he was able to introduce more humane methods of treatment. He lived to enjoy a good measure of support for his ideas from his colleagues and others interested in the problem. Soft of speech, he had a very likable manner which endeared him to all. By his death the State of North Carolina has lost a valuable member of the community and his patients a steadfast friend. He leaves a widow and one daughter.

A. McWATT GREEN, M.B., Ch.B.

Dr. A. McWatt Green, who was in general practice at Bo'ness, West Lothian, died suddenly on September 21. He was 43 years of age.

Alexander McWatt Green was born on May 28, 1915, in Bo'ness, though his early years were spent in India. After the family had returned to this country, he was educated first at Glasgow High School and thence at Glasgow University, where he graduated M.B., Ch.B. in 1939. In that year he joined the Royal Navy, and saw action in many parts of the world. He was a lieutenant-commander, R.N.V.R., at the end of the war, when he left the Service to enter practice with the late Dr. W. A. Shafto.

C. D. L. writes: Dr. A. McWatt Green packed much into his short life. He was a true general practitioner, with an inexhaustible liking for people and an extraordinary memory. He was an active member of the Edinburgh Obstetrical and Medico-Chirurgical societies. His well-informed clinical acumen was always thoroughly seasoned with kindly common sense. Each patient became a personal friend, and, although as a consequence Dr. McWatt Green's time was so little his own, he was incapable of saying an unkind word to anyone. His interests were many. For years he played Rugby football with distinction. He was a keen sailor and was vice-commander of the Upper Forth sailing club. He somehow found time for a little fishing, golfing, swimming,

Counsel then said that his third head of supplementary benefit was that a skilled pharmacist provided a better service of storage of medicines than an ordinary trader. As against these benefits, what was there in the debit scale?—the trifling inconvenience of not obtaining C.F. goods at grocers or self-service stores. If this constituted a substantial grievance, members of the public would have sprung forward to give evidence.

Interpretation of the Act

Mr. CYRIL HARVEY, Q.C., beginning his submissions for the Registrar, said that the Federation's case was based on a fundamental mistake. Mr. Roche had treated section 21 (1) (b) as merely a looking-glass reflection of section 21 (1) (a). But section 21 (1) (a) provided for the justification of a restriction if it were reasonably necessary to protect the public against injury, while section 21 (1) (b) provided for its justification if its removal would deny the public other substantial benefits. Mr. Roche had submitted that the restriction was necessary because it tended to make people buy chemical goods only at places where they could obtain good advice, and that because of that factor it came within section 21 (1) (a); but that, if the Court did not think chemists' advice was reasonably necessary to protect the public against injury, it could be regarded as a substantial benefit to the public and therefore justified within section 21 (1) (b). That submission was fallacious. All that the Registrar had to contend with was the argument that the skilled advice of chemists gave the public protection against injury.

Mr. JUSTICE DEVLIN.—If it be shown that chemists' advice is not reasonably necessary to protect the public against injury, could not the denial of chemists' advice be a disadvantage to the public?

Counsel said that the section was not dealing with disadvantages but with benefits.

Mr. JUSTICE DEVLIN.—We do not think that Mr. Roche has made out a *prima facie* case on fact in relation to his point about advice under either (a) or (b). We would like to hear you on the benefit said to be conferred by the standards committee; we do not want to hear you on the benefit by the preservation of the small chemist or the benefit in storage. We would also like to hear your argument on the construction of the Act.

Counsel said that the restriction left uncovered a substantial part of the consumer purchases of the relevant products and it was necessary to bear that in mind in asking what "reasonably necessary" in paragraph (a) meant. He would submit, on the test proposed by Mr. Justice Boddey in *Stanford v. Roberts*, that it meant the restriction that a reasonable man might consider necessary and that it meant more than "desirable" or "required." That was the relevance of the fact that the restriction here did not work, for a reasonable man would not say that such a restriction was necessary for the protection of the public. As to paragraph (b) he (counsel) would draw attention to the words "specific and substantial benefits." A classic example of what was not specific was the point made for the Federation, the tendency of an undefined number of persons to resort to chemists' shops, where, if served by the pharmacist himself, they might, or might not, get advice. Even if that was a substantial benefit, it was not specific.

"On the Whole a Good Thing"

Conceding that the C.F. List was on the whole a good thing as regards the standard of products on it—and he was conscious of the justice of the criticism that only two or three items on the List had been attacked as being of dubious quality—there was no evidence to show that abolition of the List would lead to the break-up of the Federation or even that the removal of the main restriction would lead to the cesser of the List. Once the restriction was removed, there could be concentration on one limb of policy—that was the drawing up of one List comprising all products, whether of C.F. manufacturers or not, which were of good quality. But in any event the C.F. List tagged behind the point made about chemists' advice. It depended for its efficacy upon a series of mights—that the customer might be served by a pharmacist and not by an unqualified assistant, that the customer might seek his advice, and that the pharmacist, when his advice was sought, might refer to the C.F. List. Such cases must be very minute indeed.

On October 13, the sixth day of the hearing, Mr. ROCHE, making his final submissions for the Federation, said that

there were two possible constructions of the word "other" in paragraph (b) of section 21 (1). Mr. Harvey's construction was that it referred back to and covered benefits which were not within paragraph (a) of the subsection. The other construction, which he (counsel) submitted was the right one, was that, as registrable restrictions were deemed to be contrary to the public interest unless the Court was satisfied of certain circumstances, the word "other" was used to distinguish the noxious restrictions and those which were harmless. But, even if the Registrar's construction of the section were right, it did not make any practical difference because his (counsel's) case was a true "and/or." The difference of the C.F. scheme from that of any other body was that it not only exercised the negative control of preventing unworthy advertising but also had the positive advantage of promoting the sale of quality products.

The Court then conferred.

Decision of the Court

Mr. JUSTICE DEVLIN, giving the decision of the Court, said that the case involved a number of restrictions upon which they would have to pronounce in due course, but underlying them was one fundamental restriction described in the introduction to the *Handbook of the Chemists' Federation* as the principle in which chemists believe "that the correct channel for distribution of medicinal preparations is through premises registered under Section 12 of the Pharmacy and Poisons Act, 1933"—that was, premises under the personal control of a registered pharmacist. The Court, therefore, thought it would be helpful and desirable that they should consider that fundamental restriction first, before they dealt with the terms of the agreements, and they had so considered it. It was sought to justify it on the ground that it was reasonably necessary to protect the public from injury and alternatively that its removal would deny to the public benefits which were specific and substantial.

The Court was not satisfied that it came under either of those grounds, and it followed that they would have to declare it void. As this was the first case and some interesting questions of general importance had been raised they thought it desirable that they should put their reasons into writing. His LORDSHIP then invited counsel to consider the effect of the Court's finding upon the restrictions.

Mr. ROCHE, dealing with restrictions alleged by the Registrar, but not admitted by the Federation, stemming, *inter alia*, from the Federation's guidance to retailer members that personal recommendation should be given to C.F. products, asked the Court not to deal with these restrictions until after the Federation had had an opportunity of considering whether it desired to go on. As to the agreed restrictions, counsel said that No. 11, not to sell any C.F. product otherwise, in effect, than in the container in which it had been packed by the proprietor, was clearly severable, and so, possibly, was No. 5, that manufacturers should not supply any products eligible for inclusion in the C.F. List without first offering them for inclusion in the List.

Question of an Injunction

After an adjournment to allow counsel to take instructions, Mr. HARVEY said the Court could either go on and examine the evidence with regard to discrimination or—and as counsel on both sides would prefer—the matter could wait until after the Court had given their reasons for their decision. In the meantime the Registrar would be able to negotiate with the Federation to see whether or not they would be able and willing to give an undertaking which would have the effect of putting an end to the discrimination to which the Registrar objected. His (counsel's) submissions on restrictions 5 and 11 were that they were merely ancillary to the main restriction and must fall with it. The Registrar also felt that there should not merely be a declaration that the restrictions were void but that there should also be an injunction. As a general principle an injunction ought normally to follow such a declaration.

Mr. ROCHE agreed that it would be difficult to make further progress until the Federation had had an opportunity of considering the Court's judgment. As to the application for an injunction, his submission was that the Court, as a superior Court of Record, ought not to follow any principles other than those followed by any other Court of Record. There was no evidence that the Federation had the slightest intention to do anything that was illegal, and if it continued to exist there would be no objection to informing the Registrar as to its activities from time to time.

Conclusion

Mr. JUSTICE DEVLIN said that the order as to the alleged restrictions would be that the issue in relation to them should be stood over with liberty to either party to apply. The Court would hear argument as to restrictions No. 5 and No. 11 in the morning, and also any argument that either side wished to relate upon the proper judgment in relation to any of the agreed restrictions. The Court would deal with the application for an injunction when they gave their reasons for their decision.

The hearing was accordingly adjourned, and the next day (October 14) the Court heard counsels' arguments on restrictions Nos. 5 and 11. After thanking counsel for their assistance, Mr. JUSTICE DEVLIN said the reasoned judgment of the Court would be given at a later date.

DIMINISHED RESPONSIBILITY REJECTED

[FROM OUR LEGAL CORRESPONDENT]

On September 25 the jury at the trial of Donald Ferguson Forbes in Edinburgh on a charge of capital murder rejected his defence of diminished responsibility (*Scotsman*, September 26). Forbes was charged with assaulting Allan Fisher, a night watchman, by beating him with an iron bolt, with robbing him of a cigarette case, a lighter, and £11 10s., and with his murder.

Psychiatric Evidence

Sir David Henderson, formerly professor of psychiatry at Edinburgh University, who had examined Forbes as to his mental condition in Saughton Prison on September 17, gave evidence for the defence. He said that Forbes was in one of those difficult conditions when one almost hesitates to differentiate between what one calls sanity and what one calls a certain state of mental instability which from time to time can be exaggerated by the circumstances in which the person is placed. His was the nearest approach to what is called a "psychopathic constitution," where reason and intelligence are unimpaired but where a person for the time being is dominated by an episodic burst of conduct apt to come about in strained circumstances. He was not suffering from any form of mental unsoundness which would justify certification and admission to a mental hospital, but showed an amount of emotional instability which brought him within the category of diminished responsibility. He corresponded to the psychopathic type of person who is essentially a law unto himself, and that, in the witness's view, was a sign that he suffered from some form of mental disease, so that he came within the definition of diminished responsibility.

For the prosecution Dr. William Boyd, who had first examined Forbes in prison on June 10, said that in his opinion Forbes did not border on or approach to insanity, nor suffer from any form of mental disease or great aberration or peculiarity of mind. Although he had had three years' psychiatric treatment and supervision he was not suffering from substantial impairment of responsibility. Dr. Macrae, who examined Forbes on June 11, said that he found no evidence of diminished responsibility, mental disease, partial insanity, or peculiarity of mind.

Lord Wheatley in summing up told the jury that on the diminished responsibility the onus of proof was on the defence to prove their case on the balance of probabilities. Forbes had had unfortunate experiences as a child, and whether the maladjustment from which he suffered as a

child had subsided or proceeded into his present state and whether that condition, alone or in combination with other factors, had produced a defect of mind sufficient to justify invocation of the doctrine of diminished responsibility, had to be resolved by the jury. They were not entitled to hold diminished responsibility proved because they thought there were mitigating circumstances in Forbes's life, unless these circumstances constituted a condition of mind which in itself would justify the invocation of the doctrine.

The jury returned a majority verdict after an absence of an hour and a half, and sentence of death was passed. It was subsequently commuted to life imprisonment by the Secretary of State for Scotland.

Vital Statistics

Diphtheria

The 25 cases of diphtheria notified in England and Wales in the week ending October 11 were the largest total for nearly three years. Seven of them were in Essex, Barking M.B. (where one child has died), and 15 in London—Finsbury 10, Holborn 4, and Islington 1.

The outbreak at Barking is caused by the *gravis* strain. Two further cases were notified in the week ending October 18, and numbers of notifications exclude 14 carriers found by swabbing. The outbreak began in a single class of about 35 children in an infants' school. It has not so far spread beyond the children of that class and their home contacts. The child first to be detected with the disease has died, and two others have carditis. The other cases are mild.

The outbreak in London is caused by a virulent *mitis* strain. The cases are mild, and the majority of those notified were carriers detected by swabbing. The two initial cases were not clear-cut, and several cases are apparently primarily of tonsillitis but also carry the diphtheria organism.

Week Ending October 11

The largest rises in the number of notifications of infectious diseases in England and Wales during the week ending October 11 were 790 for measles, from 1,988 to 2,778, 70 for dysentery, from 442 to 512, 44 for acute poliomyelitis, from 69 to 113, and 20 for diphtheria, from 5 to 25; the largest falls were 87 for food-poisoning, from 316 to 229, and 51 for whooping-cough, from 551 to 500.

The number of notifications of acute poliomyelitis, 113, was the largest reported this year and is an exceptionally late peak incidence. These cases were 30 more for paralytic and 14 more for non-paralytic cases than in the preceding week. The largest returns were Lancashire 27 (Manchester C.B. 12, Blackpool C.B. 3, Padiham U.D. 3, Burnley C.B. 2); Yorkshire West Riding 16 (Leeds C.B. 5); Bedfordshire 8 (Bedford M.B. 8); Cheshire 8 (Stockport C.B. 2, Bebington M.B. 2); Durham 7 (Brandon and Byshottles U.D. 3); Middlesex 6 (Heston and Isleworth M.B. 3).

The number of notifications of diphtheria were the largest for almost three years, and are the subject of a separate report. The largest increases in the incidence of measles were 106 in Yorkshire West Riding, from 200 to 306 (Keighley M.B. 59, Royston U.D. 45); 94 in Cheshire, from 82 to 176 (Congleton M.B. 53); 87 in Devonshire, from 53 to 140 (Axminster R.D. 49); 58 in Lincolnshire, from 47 to 105. The largest fluctuations in the trends of scarlet fever were a rise of 22 in Lancashire, from 83 to 105, and a fall of 22 in Staffordshire, from 56 to 34. The total notifications of scarlet fever, 648, were 9 fewer than in the preceding week. No large variations in trend were reported in the local returns of whooping-cough.

For the fifth consecutive week the number of notifications of dysentery have increased. The chief centres of infection during the week were Yorkshire West Riding 98 (Leeds C.B. 22, Dearne U.D. 22, Ripon and Patley Bridge R.D. 14), London 69 (Islington 13, Hammersmith 11), Lancashire 44

(Liverpool C.B. 15), Warwickshire 41 (Coventry C.B. 24, Birmingham C.B. 10), Hampshire 31 (Southampton C.B. 25), Glamorganshire 29 (Cardiff C.B. 9, Penarth U.D. 9), and Essex 28 (West Ham C.B. 17).

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the years 1949-57 are shown thus - - - - -, the figures for 1958 thus ———. Except for the curves showing notifications in 1958, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending October 4 (No. 40) and corresponding week 1957.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the whole of England and Wales (London included). London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

† Includes primary and influenza pneumonia.
‡ Includes puerperal pyrexia.

Medical News

On Call to a Nation.—The B.B.C. marked the tenth anniversary year of the National Health Service with a documentary film of it at work. Shown at a peak viewing hour on the evening of October 22, the film, "On Call to a Nation," lasted 75 minutes and was the longest documentary programme the B.B.C. television service had done. There were no professional actors: the audience saw genuine doctors, dentists, and other medical workers, together with patients, in the natural setting of their relationship. The programme, however, was not intended as a study of the Health Service itself. It mainly pictured the daily life of doctors and how the Health Service affected them. Twenty-five of the 57 doctors appearing had something to say about it. Rural G.P.s, urban G.P.s, big-list men, and small-list men, and men in organized group practices, gave their views, such as time would allow, on general practice. At one extreme was a big-list town G.P. who entirely approved of the Service, and at the other was a semi-rural practitioner who entirely disapproved. In between were seven others who had reservations of varying degree and kind. Some of the criticisms were of other branches of the Service, and the criticisms were not confined to G.P.s. The audience saw a consultant dictating letters at the end of an out-patient session, and heard his comments on cases and on doctors' letters. The cost of the Service and the public's responsibility for financing it was plainly put by another consultant. The cost of drugs was emphasized in scenes in which a pricing bureau was shown dealing with millions of prescription forms, and the need for capital expenditure on hospitals was highlighted by several shots of antiquated buildings and makeshift premises whose span of service had long exceeded the few years originally intended for them. The programme's anchor was a family doctor's waiting-room. One at a time the doctor dealt with eight patients, and their cases served to move the programme from one aspect of the Health Service to another. Mr. Richard Cawston wrote and produced the film and Colin Wills spoke the commentary. Professional bodies were consulted in the first place, it was stated, but they had no part in planning the actual programme. The speakers' opinions, too, were their own and not those of any organization.

Wellcome Research Grants.—The Wellcome Trustees announce that among the grants sanctioned by them during the half-year ended August 31 were the following: (1) *Post-graduate Medical School of London.*—Up to £60,000 for the cost of including a Wellcome research library in the proposed new buildings. (2) *Institute of Psychiatry, Maudsley Hospital.*—Up to £37,000 to provide laboratories in which integrated research by the departments of neuro-endocrinology and neuropathology may be carried out. (3) *Department of Anatomy, Birmingham University.*—Up to £36,500 to extend the research laboratories and animal accommodation. (4) *Department of Zoology, Edinburgh University.*—Up to £25,000 to provide additional research accommodation. (5) *University of Western Australia.*—£50,000 to endow a Wellcome research department of pharmacology. (6) *Institute of Medical Research, North Shore Hospital of Sydney.*—Up to £17,000 to build and equip laboratories for experimental medicine and surgery. In addition, three electron microscopes are being purchased at a cost of approximately £34,000, for indefinite loan to the M.R.C. Biophysics Research Unit at King's College, London, the Sir William Dunn School of Pathology, Oxford, and the London School of Hygiene and Tropical Medicine.

Anglo-French Exchange Bursaries.—Applications are now invited for the bursaries which will be awarded in 1959 to young British doctors under the exchange scheme arranged by the French Embassy in London between the Institut National d'Hygiène in Paris and the Ciba Foundation in London. The value of the French grants is 60,000 francs

a month, tax free. Bursaries will be awarded for periods of two to four months to medical men who wish to obtain clinical experience or carry out research in France. Application forms and further details may be obtained from Dr. G. E. W. WOLSTENHOLME, Ciba Foundation, 41, Portland Place, London, W.1. The closing date is January 31.

P.R.C.P.I.—Dr. P. T. J. O'FARRELL, a past-president of the British Medical Association, has been elected President of the Royal College of Physicians of Ireland.

First Manson Oration.—On October 16 Sir PHILIP MANSON-BAHR delivered the first Manson Oration before the Royal Society of Tropical Medicine and Hygiene. He gave an autobiographical review entitled "The March of Medicine During the Last Fifty Years." The oration was at the Society's house in London.

"Clinical Science."—Professor G. M. BULL is to succeed Professor W. MELVILLE ARNOTT as editor of *Clinical Science* on January 1. Professor Bull is professor of medicine at Queen's University, Belfast.

"Nursing Times."—The layout of the *Nursing Times*, the journal of the Royal College of Nursing, has been attractively restyled as a result of a questionnaire to its readers. "Many of you besought us to look lighter and more readable," states the journal. Certainly the October 10 issue, the first to appear in the new uniform, looks thoroughly attractive.

W.H.O.—Dr. W. A. TIMMERMAN, assistant director-general of W.H.O. in charge of Central Technical Services, is retiring under the age limit. His successor has not yet been appointed. Dr. Timmerman, who joined W.H.O. in 1950, was previously director of the National Institute for Public Health in the Netherlands.

Chair of Paediatrics, Makerere College.—Dr. D. B. JELLIFFE, visiting professor of tropical medicine at Tulane University, New Orleans, has been appointed to the Unicef chair of paediatrics at Makerere College, University College of East Africa. Dr. Jelliffe graduated in medicine from the Middlesex Hospital in 1943.

General Board of Control.—The Secretary of State for Scotland has appointed Dr. ANNE N. M. BRITAIN a deputy medical commissioner of the General Board of Control for Scotland.

COMING EVENTS

Association of Industrial Medical Officers.—Meeting in London, October 30 (jointly with the Empire Rheumatism Council) and November 1. Details from the hon. secretary, 47, Lincoln's Inn Fields, London, W.C.2.

Mitchell Banks Memorial Lecture.—Sir GORDON GORDON-TAYLOR will lecture on "The Incomputable Factor in Cancer Prognosis" at 4.45 p.m. on October 29 at the New Medical School, Liverpool University.

Uses of Plastics in Medicine.—Six lectures on Wednesdays, 6.30-8.30 p.m., starting on October 29, at the National College of Rubber Technology, Holloway Road, London, N.7. Details from the head of the College.

Heath Clark Lectures.—Dr. KARL EVANG, of Norway, will give five lectures on "Health Service, Society, and Medicine" at 5.30 p.m. daily, from November 3 to 7, at the London School of Hygiene and Tropical Medicine.

Bradshaw Lecture.—Professor K. W. DONALD, D.S.C., will lecture on "Heart Disease and Exercise" at 5 p.m. on November 6 at the Royal College of Physicians, Pall Mall East.

McMurray Lecture in Orthopaedic Surgery.—Professor W. P. BLOUNT, of Marquette University, Wisconsin, will lecture on "Fractures in Children" at 5.15 p.m. on November 7 at the New Medical School, Liverpool University.

Stephen Paget Memorial Lecture.—Mr. RICHARD FORT, M.P., will lecture at 5.30 p.m. on November 18 in the lecture theatre, Zoological Society of London, Regent's Park, on "The Irrational in Public Life." The annual meeting of the Research Defence Society will follow the lecture.

Faculty of Radiologists.—Postgraduate course in radiology, November 22 and 23 at the Royal College of Surgeons. Further details from the Faculty, 47, Lincoln's Inn Fields, London, W.C.2.

Bethlem Royal and Maudsley Hospitals.—Medical staff ball, November 28, at the Kensington Palace Hotel. Tickets from Dr. BRIAN ACKNER at the Maudsley Hospital, Denmark Hill, London, S.E.5.

London School of Hygiene and Tropical Medicine Association.—Annual dinner at the Waldorf Hotel, Aldwych, London, W.C.2, on Thursday, November 27, at 7 for 7.30 p.m. (dinner jackets). Tickets, 30s. each (exclusive of drinks but including light refreshments at 10.30 p.m. and dancing until midnight), from Miss K. M. SHAW at the School. Guests may be invited.

Sixth International Conference in Planned Parenthood.—New Delhi, February 14 to 21, 1959. Further details from the conference secretary, 1, Metropolitan House, Dadabhai Naoroji Road, Bombay, 1.

NEW ISSUES

SPECIALIST JOURNALS AND ABSTRACTS

The journals listed below are obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

British Journal of Ophthalmology.—Issued monthly (£6 annually). The new issue, Vol. 42, No. 10, includes:

SPECIFICITY AND COMPARATIVE ACTIVITY OF THE CARBONIC ANHYDRASE INHIBITORS NEPTAZANE AND DIAMOX ON ANIMAL AND HUMAN EYES. M. E. Langham.
BENZOCAINES URETHANE SOLUTION IN OPHTHALMOLOGY. P. A. Graham.
CYBERNETICS OF OCULAR MOVEMENT. D. Stanley-Jones.
HISTOLOGICAL SIGNIFICANCE OF HEMISPHERICAL BODIES IN THE EYE. N. Ashton and A. F. M. Mohamed.
INTRA-OCULAR FOREIGN BODY. W. J. Levy.
FAMILIAL MACULAR DEFECTS. I. D. R. Gierory.
PENETRATION OF SODIUM AND THIOCYANATE INTO THE POSTERIOR AND ANTERIOR CHAMBERS. V. E. Kinsey and E. Palm.
ALTERNATIVE TO THE 3-SNP OPERATION FOR LACRIMAL DRAINAGE INSUFFICIENCY. C. Montague Ruben.
AMBLYOPIA DUE TO ETHYL ALCOHOL. M. Quatermass.
COMPLETE OPHTHALMOPLÉGIA IN A CASE OF ACUTE TOXIC POLYNEURITIS. F. R. Neubert.
UNUSUAL TRAUMATIC DEFORMITY OF THE LENS. P. Sivasubramaniam.
GLAUCOMA FOLLOWING RADIOTHERAPY. R. F. Jones.

Abstracts of World Medicine.—Issued in the first week of each month, this journal contains abstracts of important papers selected from the current medical literature of the world. Annual subscription £4 4s.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, October 27

GUY'S HOSPITAL.—At Anatomy Lecture Theatre, 5.15 p.m., lecture-demonstration in endocrinology by Dr. P. M. F. Bishop: Exophthalmos.
INSTITUTE OF CHILD HEALTH.—5 p.m., Guest lecture by Professor I. Dogramaci (Turkey): Malnutrition in Infancy and its Management.
MANCHESTER MEDICAL SOCIETY.—(1) SECTION OF ODONTOLOGY.—At Lecture Room, Dental Hospital, 4.30 for 5 p.m., Presidential Address by Mr. D. H. Cartledge: Our Dental Heritage. (2) SECTION OF GENERAL PRACTICE.—At Large Anatomy Theatre, Medical School, Manchester University, 8.30 for 9 p.m., Professor S. Alstead: Medical Truants.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Guest lecture by Dr. B. Ackner: Psychiatric Aspects of Termination of Pregnancy.

Tuesday, October 28

BRISTOL UNIVERSITY.—At Large Lecture Theatre, H. H. Wills Physics Laboratory (Royal Ford), 8.15 p.m., 47th Long Fox Memorial Lecture by Professor A. I. Darling: Decay of the Teeth (Dental Caries).
BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. G. S. Wilson: Infectious Enteritis.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. G. C. Wells: Dermal Connective Tissue.
ROYAL STATISTICAL SOCIETY.—At New Small Lecture Theatre, London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. O. M. Lidwell and Dr. R. E. O. Williams: Effect of Various Factors on the Incidence of the Common Cold.
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Institute Theatre, 5 p.m., Mr. David Currie: Miracle of Childbirth.
WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Dr. G. Parsons-Smith: neurological demonstration.

Wednesday, October 29

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. W. Riddell: Ringworm Infections.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. F. H. Scadding: Open lecture on the mode of presentation of carcinoma of the bronchus.
INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Mr. D. M. Wallace: Vesical Neoplasms.
LIVERPOOL UNIVERSITY: FACULTY OF MEDICINE.—At Large Lecture Theatre, New Medical School, Ashton Street, 4.45 p.m., William Mitchell Banks Memorial Lecture by Sir Gordon Gordon-Taylor, K.B.E.: Incomputable Factor in Cancer Prognosis.
● NATIONAL COLLEGE OF RUBBER TECHNOLOGY, Northern Polytechnic, Holloway Road, London, N.—6.30 p.m., Dr. S. A. Leader: Application of Plastics to Medicine and Surgery. (The first in a course of six lectures.)
OXFORD UNIVERSITY.—At Radcliffe Infirmary, 5 p.m., Litchfield Lecture by Dr. W. G. Spector: The Role of Endogenous Mechanisms in Acute Inflammation.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Guest lecture by Dr. P. Fourman: Magnesium Metabolism.
ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—3.30 p.m., Dr. Annie Sydenham: Maternity and Child Welfare Work in a Hong Kong Mission Hospital (illustrated).

Thursday, October 30

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. R. E. O. Williams: Epidemic Staphylococcal Infection in Hospitals.
HONYMAN GILLESPIE LECTURES.—At Anatomy Theatre, University New Buildings, Teviot Place, Edinburgh, 5 p.m., Professor A. G. R. Lowden: Emergency Re-operations in Abdominal Surgery.
INSTITUTE OF DERMATOLOGY.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. R. E. O. Williams: Epidemic Staphylococcal Infections in Hospitals.
INSTITUTE OF PSYCHIATRY.—At Maudsley Hospital, 5 p.m., Inaugural Lecture by Professor P. M. Daniel: Some Experimental Approaches to Neuro-pathology.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Thomas Vicary Lecture by Sir John McNee: Barber-Surgeons in Great Britain and Ireland.
ROYAL NORTHERN HOSPITAL.—2.45 p.m., Mr. R. J. McNeill Love: Abdominal Pain (cases and discussion).
ST. ANDREWS UNIVERSITY.—At Physiology Department Lecture Theatre, 5 p.m., Mr. Hedley Atkins: Three Pillars of Clinical Research.

Friday, October 31

COLLEGE OF GENERAL PRACTITIONERS: SOUTH LONDON FACULTY.—At King's College Hospital Medical School, 8.45 p.m., Professor J. S. Mitchell: Nuclear Fission in Relation to Medicine.
● INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. I. Muende: clinical demonstration.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. K. F. W. Hinson: clinical demonstration.
INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—(1) 3.30 p.m., clinical discussion for general practitioners by Miss Edith Whetnall: Advances in the Use of Hearing-aids. (2) 5.30 p.m., clinical lecture by Dr. T. V. L. Crichtlow: Some Oesophageal Problems.
KEIGHLEY AND DISTRICT MEDICAL SOCIETY.—At Victoria Hospital, Keighley, 8.30 p.m., Mr. A. B. Pain: Pain in the Arm.
MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES.—At 11, Chandos Street, W., (1) 7 p.m., 37th annual general meeting; (2) 8.15 p.m., Dr. B. F. Reeves: Variations in the Leucocyte Content of the Cervical Secretions; Dr. J. H. Eckersley and Dr. J. Barrow: Locan Pessaries in the Treatment of Trichomonas Vaginitis.
PLYMOUTH MEDICAL SOCIETY.—At Freedom Fields, 8.30 p.m., Dr. A. E. Clark-Kennedy: The Right to Die.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—(1) 10 a.m., Guest lecture by Professor P. A. Fitzserald: Adrenal Surgery. (2) 4 p.m., Guest lecture by Dr. E. N. Chamberlain: Rheumatic Carditis.
● ST. MARY'S HOSPITALS, MANCHESTER.—At Large Lecture Theatre, Clinical Sciences Building, York Place, Manchester, 4.30 p.m., Lloyd Roberts Lecture by Professor A. M. Clave: Teaching of Obstetrics—New Edition.

Sunday, November 2

COLLEGE OF GENERAL PRACTITIONERS: WELSH FACULTY.—At Maternity Hospital, Cardiff Royal Infirmary, 10.45 a.m., The Pathology Department and the General Practitioner. Speakers: Professor J. Gough, Dr. J. L. Withey, and Dr. R. A. Holman.
MANCHESTER UNIVERSITY: FACULTY OF MEDICINE AND NORTH-WEST ENGLAND FACULTY: COLLEGE OF GENERAL PRACTITIONERS.—At Theatre 1, Clinical Sciences Building, York Place, 11 a.m., Dr. F. R. Ferguson: Headache.
UNIVERSITY COLLEGE HOSPITAL.—10.15 a.m., meet in Front Hall of main hospital. Lecture-demonstration for general practitioners. Clinical demonstration by Dr. K. E. Harris: Cardiac Irregularities, Their Significance and Treatment.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Edwards.—On October 11, 1958, at Liverpool Maternity Hospital, to Phyllis (formerly Pinchin), wife of Dr. David G. Edwards, of 12, Childwall Park Avenue, Liverpool, a brother for Jacqueline—Robert David.
Oakenfull.—On October 7, 1958, at the Maternity Home, Scunthorpe, Lincs, to Isabel (formerly Heath), M.B., Ch.B., wife of Basil G. P. Oakenfull, F.F.A.R.C.S., a son (Andrew)—a brother for Michael.
Smith.—On October 9, 1958, to Loretta, wife of Colin McPherson Smith, M.B., F.R.C.P.(C), D.P.M., a brother for Joy and Colin—John Graham.

DEATHS

Barker.—On September 29, 1958, Robert Sidney Barker, M.B., B.S., of 13, Byway Road, Leicester, aged 75.
Beddows.—On October 3, 1958, at Ingleton, Gullane, East Lothian, Edward Charles Beddows, O.B.E., M.C., M.R.C.S., L.R.C.P., Brigadier, late R.A.M.C., retired, aged 72.
Cohen.—On September 30, 1958, at Park Hospital, Davyhulme, Manchester, Percy Cohen, M.R.C.S., L.R.C.P., of Manchester Road, Bolton, Lancs, aged 44.
Collard.—On October 5, 1958, Bevil Molesworth Collard, M.R.C.S., L.R.C.P., of 37, Elms Road, Leicester.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Anaesthesia for Forceps Delivery

Q.—What is your opinion of an anaesthetic for domiciliary forceps delivery consisting of 0.5 g. thiopentone sodium, continuing with N₂O and air (midwife's apparatus), and 50 mg. intravenous pethidine later if necessary?

A.—The suitability of a particular anaesthetic technique for domiciliary obstetric surgery must be judged against a background of many factors, not the least of which is the skill and experience of the administrator. The safe use of a combination of drugs such as this obviously requires familiarity with their clinical effects. In addition it requires a good knowledge of the hazards of general and intravenous anaesthesia in obstetrics, and of the special risks of this combination of drugs, such as extravenous and intra-arterial injection and respiratory depression of mother and child. Certainly the administrator should possess the skill and equipment for maintaining oxygenation during any period of respiratory insufficiency. Whether all these desirable conditions are likely to be found in the circumstances of domiciliary obstetrics is another matter.

Penicillin Sensitivity

Q.—Can penicillin lozenges (1,000 units) cause penicillin sensitivity when taken for a few days only?

A.—It is well known that penicillin is a potent sensitizing agent, particularly for the epidermis, and that the indiscriminate use of penicillin on the skin or by ingestion is discouraged. Allergic reactions have occurred after the oral use of penicillin, and, although it is unlikely, there is no reason to believe that oral penicillin could not cause sensitivity.

Dietary Treatment for Pseudo-hypertrophic Muscular Dystrophy

Q.—What is the rationale of a dietary treatment for pseudo-hypertrophic muscular dystrophy, and have any controlled studies shown its value in this disease?

A.—Evers' has advocated a dietary treatment of "progressive muscular dystrophy (Erb)." He quotes two patients of whom he believes to have benefited from this form of therapy. A note at the end of the paper indicates that the diagnosis in one case may have been polyneuritis. Details of the diet are not given but may be obtained from Dr. Evers; the rationale of the treatment is not discussed. There is no evidence that dietary treatment is of value in muscular dystrophy. Assessment of the efficacy of treatment in these patients may be difficult, as long periods of arrest are a characteristic feature of some forms of the disease.

Hiatus Hernia

Q.—What are the indications and contraindications for operation for hiatus hernia?

A.—About 85% of patients with hiatus hernia can be controlled moderately well on a medical regime with emphasis on weight reduction, sleeping with the shoulders raised above the level of the abdomen, avoiding stooping and bending, and the use of antacids. However, there is a small proportion for whom life remains a misery, and these are the patients to select for surgery. Some will have severe symptoms from peptic oesophagitis with much heartburn, and sometimes dysphagia from stricture forma-

tion. Others may have acute discomfort with a feeling of a heavy lump after eating. The presence of an associated gastric or duodenal ulcer accentuates the indication for operation. A gastric ulcer at the level of constriction at the diaphragm is a common site. Recurrent haematemesis and recurrent aspiration pneumonia are further indications. The operation is well tolerated and patients convalesce quickly. The contraindications are those for any abdominal operation: obesity particularly should deter a surgical programme. On no account should a patient without relevant symptoms ever be considered for surgery just because the diagnosis has been made radiologically.

Speaker's Fright

Q.—What advice and treatment would you suggest for those who are afflicted with nervousness and excessive salivation when faced with having to give a talk or make an after-dinner speech?

A.—The symptoms described are those of a mild anxiety-tension state which is quite normal and usual in the circumstances. The tendency to salivation is unusual, drying of the mouth being more common, and if there is enough of it to be an embarrassment it might perhaps be countered by a small dose of atropine. The anxiety and nervousness could also be relieved to some degree by a tranquillizer such as meprobamate, or if necessary by a small dose of a quickly acting barbiturate. Caution should be exercised in the latter event if alcohol is taken too.

The best long-term treatment for this syndrome is the gaining of greater experience. With a little practice, short speeches on social occasions soon become no trouble, even to those liable to anxiety. Having something one actually wants to say is a great help; if there is sincerity in what is said audiences are very tolerant indeed of anxiety or faults in presentation. The tyro after-dinner speaker is strongly recommended to put his speech entirely out of his mind during the dinner, and to concentrate on the conversation of his neighbours and the other pleasures of the occasion. If he has a few notes in his pocket, he can safely rely on them when the moment comes.

Keeping Toddlers in Cots

Q.—What is the best way to prevent toddlers falling out of standard hospital cots?

A.—Any form of restraint is certainly psychologically objectionable for toddlers, but unfortunately some form of restraint is necessary in hospital, and often at home, if the child is left alone in its cot to any extent. The string net covering the top of the cot and tying at the sides allows the most freedom and is probably the pleasantest. It allows a child to crawl about inside the cot, although the bigger toddler cannot stand upright. There is the risk that a child of 18 months and upwards will learn to untie the net and even to get its head between the net and the side of the cot, but for all that it is probably the best form of restraint for the small child. The alternative is the restrainer shaped like a waistcoat and tying at the back with straps sewn on at the sides just above the hips and tied to the horizontal sides of the cot. These are perfectly safe and do not involve risk of strangulation, but do not allow movement on the part of the child.

Fat at 15

Q.—An otherwise healthy girl of 15 has become rather rapidly overweight. The diet is already reduced to a minimum. Can any drug or hormone therapy be advised?

A.—Even though a "fat spurt" takes place at puberty, there can be little doubt that, whatever the ultimate cause may be, the mediating factor in this developing obesity is excessive calorie intake. If weight gain is continuing then the diet, far from having been reduced to a minimum, is still in excess of the actual physiological requirements; to bring about weight loss the diet must obviously be less than the physiological requirements, so far as total energy

content is concerned. The only drug therapy likely to be of value is some form of amphetamine such as dextro-amphetamine sulphate or methylamphetamine hydrochloride, which helps to control excessive appetite. No hormone therapy can possibly be of value, and in particular it may be mentioned that thyroid therapy is quite useless. Only by producing a state of thyrotoxicosis can it lead to weight loss, and if given in doses too small to do this it either has no effect or increases the appetite.

Treating Tapeworms at Home

Q.—Is there any treatment, short of hospitalization, for tapeworm infestation in a child of 3 to 5 years who has already been antagonized to any medicine by treatment with *Filix mas*?

A.—Domiciliary treatment for tapeworms is not advisable, for toxic effects not easily managed at home—for example, collapse—may occasionally occur. Moreover, the relapse rate at home is high because it is difficult to ensure complete starvation and proper administration of drugs. In the case in question treatment with dichlorophen could be tried, but experience shows that the relapse rate following such treatment is high. The usual treatment with dichlorophen consists of a single dose of 0.5 g. per 16 lb. (7.2 kg.) of the patient's body weight.

NOTES AND COMMENTS

Treatment of Schistosomiasis.—Dr. H. A. K. ROWLAND (Ibadan, Nigeria) writes: In "Any Questions?" (August 2, p. 339) the relative advantages and disadvantages of the available drugs for the treatment of schistosomiasis were briefly discussed. It was stated that sodium antimony gluconate gave rise to few side-effects but that after treatment twice as many patients continued to have symptoms as after sodium antimony tartrate. During 1954-5, a clinical trial of sodium antimony gluconate was carried out,¹ 148 patients suffering from urinary schistosomiasis being treated with total dosages of (1) 18-31.3 mg./kg. administered over periods ranging from 24 to 120 hours, and (2) 12.5-17.1 mg./kg. in 8 hours. The test of cure consisted of urine examinations by microscopy and hatching tests on the centrifuged deposit at monthly intervals for six months, the last examination being on three consecutive daily specimens. In addition a rectal biopsy was carried out at six months.² The criteria of cure were fulfilled in 67 of the 80 patients in group 1 and in 9 of 18 in group 2—cure rates of 83% and 50% respectively. Over one-half of these patients were followed to eight months and almost a third to 10 months. Side-effects were common, the incidence increasing as the duration of the course was shortened, but they were not severe, and only in one of the 148 patients treated had the course to be abandoned, and he was receiving the most intensive. It is difficult to compare the effectiveness of different drugs, as the criteria of cure and period of surveillance are frequently not the same. Results up to 100% have been claimed for intensive sodium antimony tartrate and short courses of "miracil D" (lucanthone). It is generally agreed that the standard course of tartar emetic—30 gr. in 30 days—can be expected to give cures in 75-80% of patients. It is doubtful whether more than a 60% cure-rate can be hoped for using stibophen, although 70% has been obtained using intensive courses, and the most optimistic figure for anthiomaline is 50%, even when given intravenously. Side-effects have been greatly reduced by giving sodium antimony tartrate well diluted and slowly, but on occasions have been so severe following lucanthone that courses have been abandoned; this has especially been noticeable in reports from Egypt. It would therefore appear that sodium antimony gluconate can give a high rate of cure with mild side-effects and with the added advantages of a short course and an ambulant patient. The preparation has, however, to be given intravenously; oral administration has been tried unsuccessfully.

OUR EXPERT replies: I agree with almost everything in Dr. Rowland's letter. His experience corroborates the statements given with answers to the original question. Even according to the figures he gives it may be deduced that persistence of symptoms following treatment with sodium antimony gluconate is commoner than after treatment with sodium antimony tartrate, for in his two series treated with the former there were cure rates of 83% and 50%, and, as he states, many workers have claimed a cure rate of 100% following treatment with sodium antimony tartrate. It should be pointed out, moreover, that

few have found treatment with sodium antimony gluconate to bring about a cure in up to 83% of cases. Using a very similar dosage regime and method of assessing cure as that which Dr. Rowland found to bring about cures in 83% of cases, Messent,³ working in Accra, obtained cures in only 55% of cases.

Extra Skin Crease.—Mr. DENIS BROWNE (London, W.1) writes: The value your expert ("Any Questions?" June 14, p. 1432, and "Notes and Comments," September 20, p. 753) puts upon asymmetrical skin folds as indicating possible congenital dislocation of the hip leads to the conclusion that the 40% of babies having them should be x-rayed at birth; but, as the sign is obviously useless in regard to double dislocations, all the rest should be x-rayed as well. Perhaps it would be both cheaper and better to study the mechanics of this mechanical accident, with due regard to family history, and investigate accordingly. If this is done, it will be found that the "Ortolani click" on abduction, though a true sign of dislocation, is a rare one, just as is "telescoping." According to my ideas suspicion should always be aroused by a valgus moulding of the foot; the earliest diagnosis I have made (at 16 hours of age) was because of this.

Medical Blood Donors.—Dr. J. W. TODD (Farnham, Surrey) writes: In reply to the question whether or not doctors and nurses should enrol as blood donors, your expert states ("Any Questions?" August 30, p. 574): "It may be argued that some doctors and nurses lead a particularly strenuous life, and that they should be spared any additional physical burden. Probably they should be discouraged from acting as blood donors, although they should surely be allowed to give blood occasionally (perhaps once a year) if they express a strong wish to do so." He thus implies, first, that the lives of doctors and nurses are peculiarly strenuous, and, secondly, that giving blood is a physical burden. I suggest that both these propositions are untrue, and that doctors and nurses should be encouraged to act as blood donors to the same extent as are other people.

OUR EXPERT replies: The phrase "it may be argued . . ." was meant to imply that the view stated was a not unreasonable opinion held by some people. I purposely included the word "some" before "doctors and nurses," wishing to emphasize that I did not consider that all of them led a particularly strenuous life, and I thought I had clearly implied that only those who were leading an unusually strenuous life should be discouraged from acting as regular blood donors. In the first paragraph of my reply (not quoted here) I pointed out that the chronic effects of blood donation are due mainly to iron depletion, although they can be adequately counteracted by taking iron. There is no doubt that, unless extra iron is taken, regular blood donation does produce iron depletion.¹⁻³ Thus blood donation is at least potentially a physical burden, although it is one which healthy people can most justifiably be asked to bear.

THE PHYSIOLOGICAL ACTIVITY OF D-THYROXINE

BY

RAYMOND GREENE, D.M., F.R.C.P.

Physician, Royal Northern Hospital and New End Hospital, London

AND

HELEN E. A. FARRAN, B.Sc.Melb.

Biophysicist, New End Hospital, London

The human thyroid gland produces only the laevorotatory isomer of thyroxine (Harington and Salter, 1930); D-thyroxine has, however, been produced synthetically and its properties appraised by many workers, using many different methods. All are agreed that its potency is considerably less than that of L-thyroxine, estimates of relative strength varying between 1:2 and 1:∞.

Estimates of their relative activity in human beings have been few, and much of the earlier work was vitiated by the fact that both preparations were partly racemized. Using purer isomers, Pitt-Rivers and Lerman (1948) found, on the criteria of clinical response and B.M.R., that D-thyroxine had only one-eighth to one-tenth of the potency of L-thyroxine. Starr and Liebhold-Schueck (1953) compared the effects of L-thyroxine, D-thyroxine, triiodothyronine, potassium iodide, and a placebo on the level of protein-bound iodine (P.B.I.) and on the uptake of radio-iodine. Their results were expanded by Starr (1958), and from these two papers some important conclusions may be drawn: (1) that D-thyroxine in a dose five times as great as that of L-thyroxine had an equal effect on the P.B.I.; (2) that by means of a sufficiently large dose of D-thyroxine it was possible to raise the P.B.I. to "thyrotoxic" levels without raising the B.M.R.; (3) that D-thyroxine had very little effect on the level of serum cholesterol; (4) that in hypothyroid patients even a fivefold dosage of D-thyroxine was unable to maintain a B.M.R. stabilized by L-thyroxine; (5) that, whereas the E.C.G. of myxoedematous patients was affected by as little as 0.1 mg. of L-thyroxine, as much as 10 mg. a day of D-thyroxine given for 18 consecutive days was ineffective; (6) that when almost complete suppression of the uptake of radio-iodine was achieved with a given dose of L-thyroxine the same dose of D-thyroxine caused a suppression to only about 40% of the initial uptake; (7) that these results were not vitiated by the iodine content of the thyroxines.

To summarize previous work, it would appear that the effect of D-thyroxine on the metabolic processes considered is extremely slight in comparison with that of L-thyroxine. On the basis of the E.C.G. it may be as little as 1/100 of that of L-thyroxine, and on the basis of the B.M.R. not more than 1/5 and perhaps 1/10. Yet its effect on the uptake of radio-iodine suggests that its depressant effect on the production of thyrotrophic hormone (T.S.H.) is about half that of L-thyroxine.

This observation, if confirmed, suggests several interesting corollaries. For instance, (1) If some forms of hyperthyroidism arise in the pituitary the suppression of the output of T.S.H. (without significant rise in metabolism) by means of D-thyroxine should control the hyperthyroidism. D-thyroxine might prove to be the tool by means of which the primarily thyroid case of thyrotoxicosis could be distinguished from the primarily pituitary case, if indeed two such types exist. (2) If exophthalmos, as is still believed by some despite evidence to the contrary (Greene, 1955; Gilliland and Strudwick, 1956), is due to an excessive production of T.S.H., it should be possible to reduce it by means of D-thyroxine without detriment to the patient.

Experiment I: Clinical Effects of D-thyroxine in Hypothyroidism

In the earlier cases, treatment was begun cautiously with a dosage of 0.25 mg. daily, gradually increased at fortnightly intervals to allow observations to be made at each dosage level. As experience has accumulated the initial dose has been raised.

Eight patients, diagnosed clinically and by laboratory tests as suffering from hypothyroidism, have been treated with D-thyroxine. The results were as follows.

Case 1.—Fibrosis of the thyroid and severe myxoedema. The patient became euthyroid when treated with D-thyroxine in a dosage of 8 mg. daily for a fortnight, and has since remained well on 0.4 mg. daily of L-thyroxine. The ratio of potency of L-thyroxine to D-thyroxine (L:D) is in this case 20:1.

Case 2.—Mild hypothyroidism with impalpable thyroid. She became euthyroid after 4 mg. daily of D-thyroxine had been administered for a fortnight, and has since been maintained in good health with 0.4 mg. of L-thyroxine. L:D=10:1.

Case 3.—Hashimoto's disease and extreme myxoedema. Improvement did not begin until D-thyroxine, 20 mg. daily, had been given for a fortnight. L-thyroxine has now been prescribed in a dosage of 0.5 mg. L:D=40:1.

Case 4.—Moderate myxoedema with impalpable thyroid. Ten mg. of D-thyroxine administered for a fortnight had no effect. She has since been maintained in good health with 0.5 mg. daily of L-thyroxine. L:D=>20:1.

Case 5.—Large diffuse goitre with mild clinical hypothyroidism. She responded in a fortnight to 10 mg. daily of D-thyroxine and has since been kept well with L-thyroxine 0.2 mg. daily. L:D=50:1.

Case 6.—Nodular goitre with mild hypothyroidism. She was relieved by 10 mg. daily for a fortnight, and has since remained well with L-thyroxine 0.4 mg. daily. L:D=25:1.

Case 7.—Moderate post-operative hypothyroidism. D-thyroxine 15 mg. daily for a fortnight had no effect. L-thyroxine was effective in a dosage of 0.5 mg. daily. L:D=>30:1.

Case 8.—Severe post-operative hypothyroidism. 15 mg. daily of D-thyroxine for a fortnight relieved her and she has remained well with 0.3 mg. daily of L-thyroxine. L:D=50:1.

Results of Experiment I

These figures are admittedly meagre, but they support the contention of previous authors that the metabolic effects of D-thyroxine, judged by clinical means, are very slight, the most responsive patient having an "L:D ratio" of 10:1. In the majority of patients it appears that the ratio is far higher, and may be as high as 50:1 or more. Neither the B.M.R. nor the serum cholesterol was measured consistently in a sufficient number of patients for firm conclusions to be drawn, but in no patient was a rise in the former or a fall in the latter observed with a daily dose of less than 4 mg. In 6 of the 8 cases, 10 mg. or more was needed. The serum cholesterol (*pace* Starr, 1958) appeared to fall when the clinical condition was corrected.

Experiment II: Effect of D-thyroxine on the Immediate Thyroidal Uptake of Radio-iodine

In the earlier cases, numbering 10, the slope "S" of the immediate uptake of ^{127}I (Farran, 1958) was measured before the administration of D-thyroxine and afterwards at fortnightly intervals during its administration in various doses.

(a) Four of the patients were originally euthyroid by all criteria. A suppression of iodine uptake occurred with a dose of 1 mg. daily of D-thyroxine in three cases (two with single "hot" nodules, and one with slight diffuse thyroid enlargement). In one patient with a multinodular goitre no suppression occurred with either D-thyroxine (1 mg.) or L-thyroxine (0.3 mg.). One of the patients with a single "hot" nodule showed suppression of iodine uptake with a dose of 1 mg. of D-thyroxine but no suppression with 0.2 mg. of L-thyroxine.

(b) Six of the patients were thyrotoxic and deserve more detailed consideration.

Case 9.—Severely toxic diffuse goitre with severe exophthalmic ophthalmoplegia. The uptake expressed as "S" on 0.25 mg. daily of D-thyroxine was temporarily suppressed from 3.4 to 0.85; 1 mg. daily of D-thyroxine was needed to maintain it at this level. In 10 months no change in the eyes or in the degree of thyro-

FIG. 1.—Response of Case 9 to varying dosage levels of D-thyroxine. (a) B.M.R. (b) Urinary excretion of ^{127}I during 0-6 hours.

toxicosis occurred, and it was necessary to treat the exophthalmos with x-rays to the orbits and the thyrotoxicosis with carbimazole. L-thyroxine 0.3 mg. daily failed to suppress the uptake (see Fig. 1).

Case 10.—Severely toxic diffuse goitre, with severe exophthalmic ophthalmoplegia, acropachy, and pretibial myxoedema. D-thyroxine 0.5 mg. suppressed S from 2.8 to 1.1, but only temporarily; 1 mg. failed to produce any further depression, and it was necessary to terminate the experiment and give x-rays to the orbits and carbimazole.

Case 11.—Slight thyrotoxicosis with impalpable thyroid and exophthalmos. D-thyroxine 0.5 mg. daily produced suppression of S from 2.8 to 1.1; but an increase in dosage to 1 mg. produced no further depression or clinical change, and the experiment was discontinued after three months.

Case 12.—Slight thyrotoxicosis with slightly enlarged thyroid and exophthalmos and a thyroid index ("T") of 24. D-thyroxine in a dosage of 0.5 mg. daily suppressed S to 0 in four weeks; 1 mg. was required to maintain depression, but on stopping treatment S rose to 1.2. No clinical changes occurred.

Case 13.—This and the next case are worthy of special consideration. Case 13 was a male suffering from severe thyrotoxicosis judged by clinical standards. He had a slightly enlarged diffuse goitre, a severe but stationary degree of exophthalmos, a B.M.R. of +24%, a characteristic E.C.G., and pretibial myxoedema. T was 29. D-thyroxine in a dose of 0.25 mg. daily raised gradually to 1 mg. had no effect, but after a fortnight on 1 mg. a slight suppression of uptake occurred, and after 14 weeks the value of S sank gradually from 1.8 to 0. During this time his clinical condition steadily improved and at the end he was clinically euthyroid. His weight had increased by 12 lb. (5.44 kg.) and his B.M.R. had dropped to +11%. Treatment was stopped without, during nine months of clinical observation, any detriment to his clinical condition. Throughout there was no significant change in his exophthalmos, but his pretibial myxoedema disappeared (Fig. 2).

Case 14.—This case also deserves special consideration. It was that of a young woman with severe recurrent thyrotoxicosis four

FIG. 2.—Response of Case 13 to treatment with D-thyroxine. (a) The effect on the B.M.R. (b) "S."

FIG. 3.—Response of Case 14 to treatment with D-thyroxine. (a) The effect on the B.M.R. (b) "S."

years after thyroidectomy, with severe and recently progressive exophthalmos. The B.M.R. was +21%. D-thyroxine in a daily dosage of 0.5 mg. reduced the value of S from 1.6 to 0.75. The dose was gradually raised to 1 mg. daily and the value of S dropped to 0.2. During five months she steadily improved and became clinically euthyroid, with a B.M.R. of +9%. There was no change in the degree of exophthalmos. When seen six months later she remained well (Fig. 3). It would appear, therefore, that 1 mg. daily of D-thyroxine suppressed the uptake of radio-iodine in all these six thyrotoxic patients, albeit temporarily in two. In two, a complete remission of thyrotoxicosis occurred during treatment with D-thyroxine, but in neither was any improvement in exophthalmos observed.

Summary of Results of Experiment II

Of 10 patients—6 thyrotoxic, 4 euthyroid—9 showed a depression of uptake of radio-iodine, most with doses as low as 0.25 mg. daily of D-thyroxine. However, in the majority a daily dosage of 1 mg. was necessary for suppression to be maintained. The only patient in whom suppression did not occur had a multinodular goitre without evidence of either hyperthyroidism or hypothyroidism. A daily dose of 0.3 mg. of L-thyroxine likewise failed to suppress uptake, though, unlike D-thyroxine, it rendered the patient thyrotoxic.

Two patients are worthy of particular stress. Both were suffering from thyrotoxicosis with exophthalmos. A daily dose of 1 mg. of D-thyroxine apparently rendered them euthyroid but failed to improve their exophthalmos. Though the operation of chance cannot be excluded, it is difficult to escape the conclusion that in these two patients the thyrotoxicosis was due to an excessive production of T.S.H. and that the exophthalmos was not, in the period of observation, relieved by its reduction.

Experiment III: Effect of D-thyroxine on the Discharge of Radio-iodine from the Thyroid

The first experiment having shown that 1 mg. of D-thyroxine was sufficient to produce an effect on the uptake, it was decided that the discharge of radio-iodine from the thyroid would perhaps be a more reliable index of the suppression of T.S.H. production. In 12 cases ^{131}I was given orally, 50 μc to patients under 45 and 200 μc to older patients about to undergo treatment with radioactive iodine. After 48 hours, treatment was begun with carbimazole in a dosage of 20 mg. eight-hourly, given in order to prevent re-use of circulating iodide by the thyroid. This drug was chosen instead of potassium perchlorate, which might from some points of view be considered preferable, because in our clinic it is normally used for the preparation of thyrotoxic patients for thyroidectomy and often for therapy with radioactive iodine. Thenceforward counts over neck and thigh were made twice daily, using a partially collimated, wide-angle scintillation counter with an efficiency of about 10 counts per second per μc in the neck. The counting rate over the thigh, minus that over the neck, was plotted against the time in hours, using over the thigh, was plotted against the time in hours, using the semilogarithmic paper, so that the biological half-life of the radioactive iodine in the thyroid could be plotted as a straight line. The slope of this line could usually be determined after three or four days, though in one or two cases six or seven days were necessary. When the initial slope had been determined, 1 mg. of D-thyroxine was given daily for 5-10 days, counts twice daily continuing.

Results of Experiment III

An immediate effect of D-thyroxine was observed in 5 of the 12 cases. In 5 cases no discernible change in the slope occurred during the succeeding 7 to 14 days (Figs. 4 and 5). In two cases the initial biological half-life was so long that the results could not be assessed.

An analysis of the characteristics of the five "successful" cases gives no indication of any which clearly differentiates them from the "unsuccessful" cases. All patients in both groups were thyrotoxic, most of them severely. Both groups contained examples of diffusely enlarged and nodular goitres with various degrees of enlargement, and

FIG. 4.—Effect of 1 mg. of D-thyroxine daily on the rate of discharge of ^{131}I from the thyroid. Showing suppression of T.S.H.

FIG. 5.—Effect of 1 mg. of D-thyroxine daily on the rate of discharge of ^{131}I from the thyroid. Showing no apparent effect on T.S.H. production.

of exophthalmos. It is clear that if any clinical difference exists between the two groups a larger series must be examined before it becomes manifest.

Discussion

The results of these experiments give support to previous work and strongly suggest that D-thyroxine has a very weak effect upon tissue metabolism. A numerical estimate of the relative potency of D-thyroxine and L-thyroxine cannot be made at present, but it appears that L-thyroxine is at least 10 times as effective as D-thyroxine by any criterion, and the figure may well be higher. On the other hand, small doses of D-thyroxine have, even in thyrotoxicosis, a suppressive effect on the thyroidal uptake and discharge of radio-iodine and, it may be inferred, upon the production of T.S.H. by the anterior pituitary. This finding is surprising. Werner *et al.* (1952) failed to suppress by means of desiccated thyroid the radio-iodine uptake of thyrotoxic patients. Morgans *et al.* (1952) reported a like failure using L-thyroxine, and Werner and Hamilton (1953) using triiodo-L-thyronine. The fact that in two of our patients suppression

was produced by D-thyroxine but not by L-thyroxine might suggest that D-thyroxine has a qualitatively different effect from that of L-thyroxine on the anterior pituitary. This seems highly improbable, and further work with both isomers is necessary to resolve the dilemma.

The expectation that cases of thyrotoxicosis might be found in which it would be possible to reduce the metabolism to normal by means of D-thyroxine has apparently been fulfilled in two of six patients treated for three months. This is not so surprising, for Means (1948) has reported a clinical improvement in cases of Graves's disease treated with desiccated thyroid, and Werner *et al.* (1952) quote a single case personally communicated to them by Greer. Moreover, these authors noted that in several of their patients treatment with thyroid was accompanied by a fall in the level of P.B.I. They advanced three possible causes for this finding—the effects of non-hormonal iodine in the desiccated thyroid, of repeated doses of ^{131}I , or of rest in bed. None of these explanations is applicable in our patients. Moreover, the danger to the patient of using thyroid or L-thyroxine is absent when the relatively non-calorigenic D-thyroxine is used.

Although the output of T.S.H. was inhibited, at least temporarily, in almost every case in our series, in no instance was any change seen in the degree of exophthalmos. This observation cannot be explained by the hypothesis that exophthalmos, originally produced by an excess of T.S.H., has become irreversible, for it is a common observation that exophthalmos may decrease or even disappear spontaneously. The doses of D-thyroxine used, smaller than in the hypothyroid patients, were large enough to depress the uptake of radio-iodine for periods up to 10 months, but not large enough to increase metabolism. Our results give support to those who have long doubted the classical hypothesis that exophthalmos is due to an excessive production of T.S.H. by the pituitary.

Summary

The metabolic effects of D-thyroxine are very slight when compared with those of L-thyroxine, the latter being at least ten times as potent. On the other hand, doses of D-thyroxine too small to effect metabolism directly are capable in most cases, even of thyrotoxicosis, of suppressing the uptake of radio-iodine and, by inference, the production of T.S.H. Suppression of the production of T.S.H. appeared to induce a remission of Graves's disease in two of six patients, but the exophthalmos was not improved.

We are grateful to other members of the staff of the department of endocrinology of New End Hospital for allowing access to their patients, and to Dr. A. W. G. Goolden for much helpful advice. Glaxo Laboratories Ltd. have most generously supplied all the D-thyroxine used.

The fourth annual "Aircen" medical conference, dealing with aviation medicine and the medical aspects of nuclear warfare against air bases, was held at Headquarters, Allied Air Forces Central Europe, Fontainebleau, from October 8 to 10. Group Captain E. S. Sidey, Medical Branch of the R.A.F., presided. Over 50 delegates attended, including senior officers from the Medical Services of the armed Forces of the United Kingdom, the United States, Canada, France, Belgium, the Netherlands, West Germany, and Italy.

THE IMMEDIATE UPTAKE OF RADIOACTIVE IODINE AS A TEST OF THYROID FUNCTION

BY

HELEN E. A. FARRAN, B.Sc.
New End Hospital, London, N.W.3.

The rate of uptake of radioactive iodine by the thyroid has been used as the basis of a number of tests of thyroid function (Myant, Pochin, and Goldie, 1949; Astwood and Stanley, 1947; Goolden, 1958). It is commonly agreed that in about 90% of the cases tested a good separation can be achieved between thyrotoxic and euthyroid patients with an overlap of 5 to 10% whichever method is adopted. The technique reported here has been found of value when an answer is needed immediately or when serial investigations are required on the same person. The radiation dose is extremely small, particularly when ^{132}I is used.

Material and Method

Four scintillation counters with sodium iodide crystals, $1\frac{1}{2}$ in. (3.8 cm.) diameter and 1 in. (2.5 cm.) long, are used. Each crystal is backed by a perspex light guide, $1\frac{1}{2}$ in. (3.8 cm.) in diameter and $\frac{1}{2}$ in. (1.9 cm.) long, which forms the optical connexion to a photomultiplier. The pulses from the four counters are fed into a mixer unit and from there, through an amplifier, to a ratemeter which is connected to a pen recorder (Fig. 1). The counters are mounted in cylindrical lead shields 2 in. (5 cm.) thick, which are positioned so as to form a ring 20 cm. in diameter. The patient is seated in a dental chair, which can be adjusted

FIG. 1.—General view of the equipment.

FIG. 2.—The counters in position round the patient's neck.

so that the counters are at the level of the thyroid (Fig. 2). The pen recorder is started as soon as the patient is comfortably settled and measures the background radiation under the conditions of the test. When serial tests are made this recording can be used to correct for any residual activity in the neck due to previous investigations. Normal saline containing 3–5 μC of either ^{131}I or ^{132}I is injected intravenously, and the uptake of the radioactive iodine is continuously recorded for 30 minutes after the injection is given. The recording is continuous, but, if necessary, intermittent readings made on the recording, which continues to run until the test is finished.

Calculation of Results

The uptake of iodine by the thyroid is dependent partly on renal clearance and partly on the rate of diffusion into the extracellular tissues. Various mathematical expressions have been suggested to fit these conditions (Oddie, 1949; Berson *et al.*, 1954, 1955; Larsson, 1955). Astwood and Stanley (1947) found empirically that the activity in the thyroid plotted against the square root of time resulted in a straight line, and this convention has been adopted here. The counting rate is taken from the recording and re-plotted against the square root of the time in minutes. The resultant straight line is extrapolated back to the time of the injection to find the counting rate at zero time (C_0). The result of the test is then expressed as an arbitrary quantity "S," which is calculated from the formula: $S = \frac{C_{25} - C_0}{C_0}$, where C_{25} is the counting rate 25 minutes after the injection. S is thus independent of the amount of activity given.

C_0 varies slightly with the size and shape of the person being investigated, since it is a measure of the proportion of the activity which is seen by the counters, and is of the order of 80–100 counts per second per μC of ^{131}I injected; 1 μC of ^{132}I gives twice this counting rate. The background counting rate before any activity is given is usually 120–150 counts per second, and the efficiency of the counters is such that 1 μC of ^{131}I gives 800 counts per second and 1 μC of ^{132}I nearly 2,000 counts per second. Small variations in the position of the source make very little difference to the counting rate.

In patients suffering from severe thyrotoxicosis this graph of the uptake does not remain a straight line even for the first 25 minutes, and in these cases C_0 is calculated from the first straight portion of the curve; but the actual value of initial straight portion of the curve; but the actual value of C_{25} is used, so that the value for S is less than would be expected from the initial rate of uptake. C_0 is proportional to the extrathyroidal activity, which decreases during the test owing to clearance of the radioactive iodine by the thyroid and kidneys. In patients whose thyroids concentrate little or no iodine, either because they are hypothyroid or because of the administration of antithyroid drugs, S has a negative value.

Results

Tests of thyroid function have been made on 357 subjects in whom the clinical diagnosis is reasonably certain. The criterion for selection has been the expressed opinion of two independent clinicians, or, when this has not been available, the opinion of one clinician when that opinion has been subsequently confirmed by laboratory tests or by a therapeutic trial of antithyroid drugs, usually carbimazole. In 50 of the patients 10 μC , or more, of ^{131}I has been given and measurements made of the radioactivity in the urine. In Fig. 3 the value for S has been plotted against T (Fraser *et al.*, 1953). It can be seen that, while there is reasonably good correlation for the non-toxic patients, there is a wide scatter in the toxic ranges, although the overall assessment of thyroid state is in good agreement. Of the 357 patients, 100 were thyrotoxic, 136 had non-toxic goitres, and 105 had no thyroid disorder, while 16 patients were clinically hypothyroid. The results in the first three classes are shown in Fig. 4.

This test has proved most useful in investigating the effects of drugs on thyroid function where several tests are often required on the one person (Greene and Farran, 1958; Greene *et al.*, 1958). In these circumstances ^{132}I is preferable to ^{131}I , because of its shorter half-life. Any residual activity due to ^{131}I contamination of the ^{132}I can be corrected for by subtracting the background counting rate before subsequent injections are given.

It is not possible to say whether or not S is of value in the diagnosis of hypothyroidism until more cases of proved hypothyroidism have been tested. Negative values of S probably indicate a hypothyroid state, but many more patients will have to be investigated before a firm conclusion can be reached regarding its suitability or otherwise for this purpose. A limited number of patients have been tested three months after having had treatment with radioactive iodine, but here again the results are inconclusive. It seems, however, that residual thyrotoxicosis can be excluded if S falls within the euthyroid range (0–0.8).

This test has now been in routine use at New End Hospital for over 18 months, and it is felt that its simplicity

FIG. 4.—Histograms of the value of S obtained in (a) thyrotoxic patients, (b) patients having non-toxic goitres, and (c) patients without any apparent thyroid disorder.

and the fact that an answer can be obtained less than an hour after requesting the test make it of considerable value in a busy department. It is merely a simplified version of other tests based on clearance rates, but, particularly if ^{132}I is used, it has the advantage that the radiation received from each test is practically negligible, which enables serial tests to be made safely on the same person over a long period.

Summary

A simple test for thyroid function which consists in measuring the rate of uptake of radioiodine by the thyroid during the first 30 minutes after the intravenous injection of 3–5 μC of radioactive iodine is reported. A good separation between thyrotoxic and euthyroid subjects is obtained in about 90% of the cases tested.

Its main use is in serial measurements to test the response to drugs and other antithyroid substances. Other possible uses are discussed.

I wish to thank my clinical colleagues at New End Hospital for permission to use their material and also Miss E. V. Webb for her technical assistance.

OCCULT BLOOD IN FAECES AFTER ADMINISTRATION OF ASPIRIN

BY

L. Th. F. L. STUBBÉ, M.D.

Department of Rheumatology, University Hospital, Leyden

It is known that aspirin (acetylsalicylic acid) may occasionally cause a gastric haemorrhage due to gastritis or a peptic ulcer (Douthwaite and Lintott, 1938; Hurst and Lintott, 1939; Hurst, 1943; Douthwaite, 1954; Muir and Cossar, 1955; Kelly, 1956; Lange, 1957). Despite the frequent use of this drug such complications have been rare. Moreover, it is difficult if not impossible—certainly in individual cases—to establish a direct proof of an immediate causal connexion. This may be a reason why insufficient thought has been given to this possibility.

In some of our patients, who had been treated with aspirin for rheumatoid arthritis, unexplained occult blood in the stools occurred. This article describes an attempt to determine the possible role of aspirin as a cause of this blood loss. The only paper on this subject was published by Lange in November, 1957, concomitantly with my thesis which recorded the results of our own investigation. Lange came to the conclusion that, even when the most readily soluble salicylic acid preparations were used, irritation to the gastric mucosa, accompanied by an occult loss of blood, could not be avoided. He was of the opinion that this irritation was of a general nature and was not confined to ultrasensitive persons. According to him the frequency of the occult loss of blood could be reduced if the patient took the medicine after meals. He furthermore suggested that the frequency of this blood loss might also be reduced if the tablets were given a good coating.

As Lange himself points out, his tests are open to criticism. He did not ascertain in all his test cases whether the occult loss of blood could not be due to some other cause than the taking of aspirin preparations. Furthermore, he did not prescribe a meat-free diet for his patients, and consequently there was always a possibility of the benzidine reaction in the faeces being influenced by the quantity of meat consumed by the patients prior to the tests. Lange accordingly found a relatively large number of instances in which there were positive benzidine reactions in the cases of patients who had not been treated with aspirin, whereas they should have been negative, provided that there was nothing else to

cause bleeding. Moreover, he does not state the number of patients who had a positive benzidine reaction in the faeces, but only how many positive and negative specimens of faeces had been obtained from a group of patients during a certain period of time. It would have been more valuable if from each of the patients the same number of samples of faeces had been collected. During our tests we eliminated the above-mentioned drawbacks.

Method of Investigation

Since the results of tests for occult blood in the faeces are far from reliable in out-patients, the investigation was carried out only on patients who were hospitalized because of some rheumatic complaint. Those whose histories recorded stomach trouble were excluded from treatment with aspirin. Otherwise no selection was made.

The aspirin was administered in the form of tablets taken with milk or water shortly after a meal. As, according to the literature, a distribution of fine particles is less harmful than concentrated bulk, the patients included in this study were emphatically told not to swallow the tablets whole, but to permit them to disintegrate in the mouth or to chew them. It might have been better to administer the substance in the form of powder; but we gave up this idea, as patients generally object to taking it in this form and would seldom do so at home; it seemed to us that it would be better to carry out our experiments under conditions that were as near as possible to those generally prevailing in actual practice. We did, however, administer the drug in powder form to a small group of persons to determine whether results might be different.

The quantity of aspirin given as a medicine was not changed. In the main the quantity was 750 to 3,000 mg. a day, a few larger amounts being given as an exception. This moderate dosage may be taken as a criterion for the quantities generally administered in practice.

A meat-free diet was prescribed and the patient was not allowed to brush his teeth. In order to obviate possible disturbing factors, green vegetables and preparations containing iron were also forbidden; and, to preclude the possible influence of food consumed previously, no use was made of the first three lots of faeces produced after the diet had begun.

The benzidine reaction test was carried out as follows: Approximately 150 mg. of benzidine was dissolved in 7 ml. of ethyl alcohol 96%; to this was added 7 ml. of glacial acetic acid and 7 ml. of hydrogen peroxide. The strength of the resultant benzidine solution was therefore approximately 0.75%.

Gregersen (1919) showed that the benzidine reaction becomes more rapid in proportion to the concentration of the benzidine solution. He therefore recommended a solution with a strength of 0.5%, while Hulst (1933) obtained good results with a solution of 1%. We therefore certainly did not use too high a concentration of the solution in our experiment. This is proved by the fact that the reaction was always negative in the periods when no aspirin was taken. After the benzidine solution had been prepared we waited a while to make sure that it did not become coloured through the presence of impurities before the faeces were added. Then, using a glass rod, we took a small quantity of faeces from the centre of the mass and mixed it well with the benzidine solution. The following criteria were established:

Strongly positive ..	Deep blue colouring within 20 seconds
Positive ..	Deep blue colouring within 60 seconds
Slightly positive ..	Greenish blue colouring within 60 seconds
A trace positive ..	Green colouring within 60 seconds
Negative ..	No colouring within 60 seconds

In order to ensure the greatest possible uniformity in these observations all benzidine tests were carried out by the same technician.

Only after a positive or a negative reaction had been found in three successive specimens of faeces was the result

recorded as such. A benzidine reaction which showed only a trace (green colouring within 60 seconds) after aspirin had been taken was regarded as negative. As a rule the benzidine diet was prescribed after the patient had been taking aspirin for 14 days. In some cases, however, the diet was prescribed after the patients had been taking the medicine for a much longer period. A patient was said to react to aspirin *negatively* when the benzidine reaction was still not positive after aspirin had been taken for 20 days or longer (the last six days of the period with a diet).

A patient was said to react to aspirin *positively* when the benzidine reaction was positive during the taking of aspirin and became negative when he stopped taking it. The following scheme illustrates this classification.

Aspirin given	{ Benzidine - Benzidine - Benzidine - }	Patient reacting negatively to aspirin.
Aspirin given	{ Benzidine + Benzidine + Benzidine + }	Aspirin stopped
	{ Benzidine - Benzidine - Benzidine - }	Patient reacting positively to aspirin.

As it was found that "entrosalyl" (coated sodium salicylate) never caused a positive benzidine reaction, those patients for whom salicyl therapy was desirable were given this medicine after they had stopped taking aspirin.

The results obtained when aspirin was taken were checked in two ways: (1) By determining the possibility of reproducing the phenomenon during alternating periods with and without administration of aspirin. Here the patient himself serves as a control. (2) By bringing groups of healthy volunteers into the scheme. With these control groups of healthy men and women we followed the same method of testing.

Results

Altogether 144 patients were examined. In four cases an alternating positive and negative benzidine reaction was observed after the patients had taken aspirin, and they could therefore not be designated as reacting positively or negatively. These four cases are left out of further consideration. Of the remaining 140, 95 showed a positive reaction to aspirin. These 140 patients comprised 38 males and 102 females; 23 and 72 respectively showed a positive reaction to aspirin (Table I).

TABLE I

	No.	Positively Reacting
Males ..	38	23 (60.5%)
Females ..	102	72 (70.6%)
Total ..	140	95 (67.9%)

Out of the 95 patients who had reacted positively, 79 who needed further treatment with salicyl were given sodium salicylate instead of aspirin (10 patients were given ordinary tablets and 69 coated tablets). In all these cases the benzidine reaction became negative.

Reproduction of the Phenomenon.—In 27 of the 28 cases in which the possibility of reproducing the phenomenon was examined, we were able to cause a repetition of the positive or negative benzidine reactions by administering or not administering aspirin. Examples are given in the Graph in which it is shown how the benzidine reaction repeatedly became positive after the administration of aspirin and became negative when the drug was discontinued. In one case it was not possible to reproduce this condition. After this patient had taken aspirin for 18 months the benzidine reaction was strongly positive. When entrosalyl was substituted the reaction became negative. When aspirin was administered again the benzidine reaction was still negative after 45 days. It was not possible to ascertain the reaction of this patient again at a later date.

Controls with Groups of Healthy Volunteers

The possibility that rheumatic patients would react to aspirin differently from healthy persons should be con-

sidered. For this reason the same method of testing was applied to a number of men and women who could be assumed to be healthy. If a person was found to have any sort of gastric complaint he was excluded from the experiment.

It was found impossible to take an absolutely random sample from the general population. We had to confine ourselves to persons who took their meals in groups. This made it easier to check whether the diet prescribed was being strictly observed and also whether the tablets were taken as directed.

The control groups consisted of 20 women and 20 men (Table II). The doses prescribed for the 20 women were: 8 women to take 3 g. a day (3×2 tablets); 12 women to take 1.5 g. a day (3×1 tablet). It was our intention to

TABLE II

Quantity of Aspirin (mg. day)	Negatively Reacting	Positively Reacting			
		Total	Slightly Positive	Positive	Strongly Positive
Females					
1,500	3	9	—	3	6
3,000	2	6	1	1	4
Total	5	15	1	4	10
Males					
1,500	4	16	1	7	8

split the group of men in the same way, but when a gastric ulcer was found in one of the women in the 3 g./day group it was decided for safety's sake not to give the dose again, although this isolated case may have been merely coincidental. Consequently each of the 20 men was given 1.5 g. a day.

Table III shows a comparison between the results obtained with the control group and those obtained with the patients.

TABLE III

	No.		Positively Reacting	
	Females	Males	Females	Males
Control group ..	20	20	15 (75%)	16 (80%)
Patients ..	102	38	72 (70.6%)	23 (60.5%)
Total ..	122	58	87 (71.3%)	39 (67.2%)

If we now summarize the results of this experiment we find that after taking aspirin a large proportion of the persons examined (70%) had a positive benzidine reaction in the faeces (Table IV).

TABLE IV

	No.	Positively Reacting
Males ..	58	39 (67.2%)
Females ..	122	87 (71.3%)
Total ..	180	126 (70%)

Influence of Dosage

The quantity of aspirin given to the patients as a part of the medical treatment varied from 750 to 6,000 mg. a day. The customary doses were 1,500 and 3,000 mg. a day to 68 and 30 patients respectively. We did not find that a positive benzidine reaction occurred more often in those larger doses.

When the positive reactions were divided into slightly positive, positive, and strongly positive, we likewise found no distinctive difference between the results from larger or smaller doses.

No association was found between the ages of patients and their reaction to aspirin. The age of the patients was mostly between 40 and 60 years; there were a few younger and older patients—some of 11 and some of 72 years. On the whole, younger adults were taken for the control group.

As stated in the description of the method applied, the benzidine diet was as a rule prescribed after the patient had been taking aspirin for 14 days, and the first three lots of faeces were not examined.

In order to determine how rapidly the benzidine reaction can become positive we examined the stools of four patients from the very first day on which aspirin was taken. In these four cases the change from negative to positive occurred after three, six, four, and three days respectively (see Cases 1 and 2 in Graph).

Nevertheless the change need not always occur in such a short time. For instance, when we tried to reproduce the condition in a female patient who had originally reacted positively we found no clearly positive reaction even after three weeks of aspirin treatment. When the benzidine reaction was checked again after a space of 60 days it was found to be definitely positive (see Case 4 in Graph).

From the examples given it will be seen that among those persons who were recorded as having reacted negatively during our experiments there may have been some who would have shown a positive reaction during a longer period of observation.

In 70 cases we were able to determine in how many days the benzidine reaction became negative after the administration of aspirin was discontinued. The average period was found to be four to five days, but here again there were some exceptions. In three patients the benzidine reaction was still positive after 20, 23, and 31 days respectively. When the examination was repeated after 56, 43, and 53 days respectively the reaction had become negative.

It appears from our experiments that taking aspirin, even in moderate doses, causes a positive benzidine reaction in the faeces in a high percentage of cases.

It was not possible to find any association between the occurrence of this deviation and the occurrence of subjective complaints. Complaints of a slight feeling of fullness and "burn" in the region of the stomach were made by only a few of our patients. Such complaints were, however, made not only by patients who had reacted positively to aspirin but also by those who had shown a negative reaction. In the case of only one patient, to whom a dose of 3 g. of aspirin a day had been administered, the complaints were of such a nature that treatment had to be stopped. In the female control group, for whom 3 g. a day had been prescribed, complaints of stomach trouble were far more frequent than in the patients who had been given the same doses. Five of the 10 women undergoing the experiment complained of nausea and pains in the stomach. In two cases the pains were so violent that the women were unable to continue with the experiment. It is possible that the frequent occurrence of stomach trouble in this control group was due to a considerable extent to psychological factors. The persons concerned knew that they were undergoing a test, and they may have been expecting gastric troubles. On the other hand, the patients were given aspirin as a medicine, and it is therefore likely that although some of them were troubled they did not complain.

Some research workers have attributed stomach troubles when aspirin was administered to an increase in the value of the gastric acids. We did not carry out any systematic

experiments to determine the gastric acidity when aspirin was taken. As, however, we found five positive reacting patients with an achylia that was refractory to histamine, in addition to a few patients with an increase in gastric acid values after taking aspirin, it may be said that the increase in gastric acid values is possibly not the only factor when stomach troubles occur after the taking of the drug. It has been suggested in the literature that no stomach disorders occur when aspirin is administered as a powder. We have already said why we did not regularly give it in this form. We did, however, give a small control group of four patients and six healthy volunteers 500 mg. of aspirin powder suspended in water three times daily after meals. All these persons had previously shown a positive benzidine reaction after one tablet of 500 mg. had been taken three times a day. In all 10 cases there was once again a loss of blood found in the faeces. There was no clear difference in the strength of the reactions compared with those which occurred when tablets had been taken.

It would appear that the ideal substitute for the ordinary tablets would be coated tablets of aspirin, which would not disintegrate until they reached the small intestine. Talkov *et al.* (1950) do mention the disappearance of subjective disorders after patients had taken such tablets, but this does not imply that there was no occult loss of blood. We carried out a tentative experiment with coated tablets, which we gave to 20 patients who were showing a positive benzidine reaction caused by taking ordinary tablets. In 5 of these 20 cases the benzidine reaction became negative within the four to seven days after taking the coated tablets. The reaction of two others became clearly less strongly positive, and in the 13 remaining cases the reaction after an average of 13 days was still unchanged in intensity.

From the data given in the literature it may be concluded that when aspirin is taken in moderation it is highly improbable that hypoprothrombinaemia is the cause of the gastric haemorrhage. Nevertheless, to ascertain whether this was the case four patients with strongly positive benzidine reactions during the administration of aspirin were analysed with regard to their coagulation mechanism. No disorder was found, and notably there was no hypoprothrombinaemia. Time and again normal values for the bleeding-time were found. Therefore in our opinion we need not take into account the possibility of a disorder in the coagulation mechanism of the blood being the cause of the positive benzidine reaction which we had found.

For various reasons we did not carry out a systematic x-ray examination whether or not there was an ulcer in these cases, especially as there were no complaints. The stomach and intestines were radiographed in only four cases in which the patients showed a positive reaction. There was no sign of disorder in any of these x-ray films that would account for the positive benzidine reaction. We did, however, prove by means of x-ray films the presence of a gastric ulcer in a woman in the control group who had been taking 3 g. of aspirin a day for a period of three weeks. This woman had never previously complained of stomach trouble. As she had violent pains coupled with a strongly positive benzidine reaction after taking aspirin we made an x-ray examination of the stomach. Unfortunately we did not have an x-ray film of her stomach taken before she had the aspirin. There is accordingly no proof that the gastric ulcer was brought about by the aspirin. It can be said with greater certainty that the aspirin was the cause of the stomach troubles and of the strongly positive benzidine reaction. For, after the medicine had not been taken for four days the stomach troubles ceased and the benzidine reaction became negative.

We considered the possibility of the positive benzidine reaction, after taking aspirin, being due to a substance other than blood. In order to preclude this possibility the stools of six patients were examined spectroscopically and spectrophotometrically. In cases with a positive benzidine reaction we found a typical blood-absorption curve. The experiment is explained at greater length elsewhere (Stubbs, 1957). Kelly (1956) has stated that the loss of

blood as a consequence of the taking of aspirin may lead to serious anaemia. We on our part found a woman of 23 suffering from extreme anaemia (Hb content 30%), which had been brought about by taking not more than two tablets of 500 mg. of aspirin a day. In the hospital we found the benzidine reaction negative, as no more aspirin was administered after the patient was admitted. When we administered a tablet of 500 mg. of aspirin three times a day during two periods, after we had taken all kinds of precautionary measures, we found signs of melaena after four days and again after seven days, without any complaint on the part of the patient. No disorder could be found when the patient was suffering from melaena, either by x-ray examination or by coagulation tests; the bleeding-time was also normal. After iron had been administered orally it was found that the Hb content had risen to 90% within two months of taking aspirin. These extreme cases are, however, exceptions and are fortunately seldom met with. The occult loss of blood, on the other hand, is a complication very often encountered in aspirin therapy, as we have already said.

To obtain an idea of the amount of blood lost in such cases a few patients were given a small quantity of their own blood to drink 10 times a day. In this way we were able to ascertain with what loss of blood the criteria employed for determining the strength of the benzidine reaction approximately corresponds.* It was found that when 4 ml. of blood was administered there was a strongly positive benzidine reaction.

Although this experiment was carried out with only a few patients one might conclude from the results that a patient with a strongly positive reaction loses about 30 times 4 ml. = 120 ml. of blood a month. Those patients who show a strongly positive reaction within the space of a few seconds will probably lose even more blood.

By way of comparison we might take the average quantity of blood a woman loses a month during the menses. According to Wright (1952) the loss amounts to 40 ml. (varying from 10 to 210 ml.).

Discussion

It is known that bleeding may occur in the stomach after a person has taken aspirin. But, considering the enormous quantities of this drug which are consumed and the frequency with which it is taken, such an occurrence may be regarded as an exception.

Subjective complaints of the stomach are not of rare occurrence, but, so far as we know, no one has ever systematically tried to ascertain whether these coincide with organic disturbances. When there are no subjective complaints at all it is generally supposed that objective disorders are out of the question. From our experiments, however, it appeared that about 70% of the persons who took this medicine, and who mostly had no complaints, lost blood with the faeces. It goes without saying that the observance of a positive benzidine reaction is also dependent on the sensitivity of the reaction. The existence of a physiological blood content of the faeces was established in experiments by Hulst (1933) and others.

From this it would appear desirable not to raise the sensitivity of the reaction too high by making the concentration of the benzidine solution too strong. On the other hand, it is of interest clinically to be able to demonstrate the pathological loss of even small quantities of blood. As already stated, we used a benzidine solution of about 0.75% for our experiment, on the basis of data given in the literature. And it appears, from the fact that the reaction was invariably negative during the control periods without the administration of aspirin, that the reaction in the course of the experiment was not too sensitive.

The observations made by Douthwaite (1938, 1954) and other research workers, who with the aid of the gastro-scope saw rapid changes occur in the mucous membranes only around the particles of aspirin and not at other places

*A detailed description of the method applied was given in our thesis (Stubbs, 1957).

situation on the basis of the number of anginal attacks and the effort required to produce them. It should always be stopped before the patient returns to work.

Because of the danger of masking myocardial ischaemia, the numerous side-effects, and the risk of serious liver damage, iproniazid is not indicated for the patient with mild angina.

Although the drug could theoretically give rise to "silent infarction," this did not happen in any of our patients. Two of them had infarcts while receiving iproniazid. Both were at rest at the time and had typical pain.

The side-effects of iproniazid are described by Robitzek and Selikoff (1952) as, firstly, those referable to autonomic stimulation, including dryness of the mouth, constipation, delayed micturition, and difficulties in visual accommodation; secondly, those referable to central nervous system stimulation, including vertigo, muscle-twitching, hyper-reflexia, excitement, euphoria, somnolence; and, thirdly, those referable to antagonism to vitamin B, including peripheral neuropathy. Unfortunately these and other side-effects limit the usefulness of the drug.

Summary

Iproniazid has been given to 40 patients with severe angina pectoris from occlusive coronary atherosclerosis, and was highly effective in reducing the frequency and severity of anginal attacks. It appears to act by blocking pain and not by improving the coronary circulation. Side-effects are common; many of our patients complained of giddiness and two developed pulmonary oedema, presumably from fluid retention. The blocking of angina may encourage the patient to be more active and may precipitate infarction. Because of this and the side-effects, the drug is not indicated for patients with mild angina pectoris. In the patient with severe and intractable angina it is of great value, especially if anti-coagulant therapy can be given in addition. The patient can often be helped over a prolonged ischaemic episode, the drug being withdrawn when the condition improves.

We are grateful to Dr. Margaret Briggs, of Roche Products Limited, for her help and for supplies of marsilid.

"We have learnt a great deal during the last three years from three reactor accidents which have led to partial melt-out of the reactor fuel elements. Although two of the reactors were put out of commission for a year and one was written off, no one was hurt by these accidents or received an overdose of radiation. The results of the accidents agree in a remarkable way with laboratory experimental work in showing that only a very small fraction of some of the bone-seeking isotopes escaped from the melted fuel. The disturbances due to these accidents were accordingly less than envisaged previously. Later generations of reactors than these early models are much better protected by containment and instrumentation, and some papers have shown considerable progress in advanced designs of containment which are thought to be proof against the maximum credible accident. This gives us considerable confidence in safe operations in the future, and we may, in due course, expect the location of plants in more populated areas. There has also been a growth of national reactor safety and inspection organizations, analogous to those in being for the aircraft industry. They inspect designs and prescribe codes of operation to help to maintain safety."—From a lecture by Sir JOHN COCKCROFT, F.R.S., to the Danish Society of Civil Engineers on October 6.

JAUNDICE ASSOCIATED WITH ADMINISTRATION OF IPRONIAZID

REPORT OF TWO CASES

BY

S. BENAIM, M.B., M.R.C.P., D.P.M.

Iproniazid ("marsilid"; or 1-isonicotinyl-2-isopropylhydrazine phosphate) is a variant of isoniazid, which was first used for its antituberculous properties in 1952. Then described as a drug which made patients "dance and sing in the ward" and as a "fountain of energy," it was discarded by chest physicians as too apt to produce side-effects, including psychotic episodes; it has since been hailed by psychiatrists as a powerful "energizer," and been found useful in the treatment not only of depressive states but also in angina pectoris and collagen diseases, gastro-intestinal conditions, etc. Zeller *et al.* (1952) found that iproniazid was a powerful inhibitor of amine oxidase. Udenfriend *et al.* (1957) were able to demonstrate a rapid and large rise in brain serotonin in animals given the drug. The effect of the drug on mood in humans has been attributed to this increase in serotonin.

In a symposium (1958) in New York in 1957 many preliminary studies were presented, but concluding speakers stressed the need for carefully controlled trials before definite claims for the value of the drug in psychiatric and other conditions could be made. During the course of such a trial in this hospital, two cases of jaundice have occurred. The possibility of this drug being hepatotoxic has recently been raised. In view of the increasing use of iproniazid in psychiatric practice, these cases seem worthy of immediate report.

Case 1

The patient, a 53-year-old working-class widow, had been subject to spells of agitation and depression, with increasing suspiciousness and misinterpretation for three years. She was previously hardworking and loyal, and had struggled to bring up five children, one of whom was diabetic from infancy. She had had no serious illness previously, and had never been jaundiced. She had not received injections and there was no contact with cases of infective hepatitis.

She was admitted to hospital on October 11, 1957, and made a good initial response to hospitalization. Iproniazid was first given at 150 mg. daily on January 11, 1958, and reduced to 100 mg. daily on February 11. During the first week of March she began to feel vaguely unwell, suffered from giddiness and palpitations, and later complained of superficial pains in the limbs and shivering attacks. All but the latter symptoms have been described as side-effects and are often encountered in iproniazid therapy. Our patient minimized these for fear that she might be taken off the drug, which was helping her considerably. On March 24, however, she developed mild anorexia with constipation and took to her bed. Iproniazid was discontinued. Two days later, though subjectively much improved, she was jaundiced and had a pale stool and biluria.

On examination the liver edge, slightly tender, could be palpated two fingerbreadths below the costal margin, but liver dullness was not greatly increased. She was, and remained, apyrexial. (For details of investigations, see Table.) With a low-fat diet, rest, and vitamins her strength and

appetite improved further, though jaundice deepened. On April 6, however, there was a return of anorexia and nausea was persistent. Her clinical condition deteriorated, some petechiae appeared, hepatomegaly was no longer demonstrable, but the spleen was found to be enlarged and easily palpable. Rubefacience, circumoral pallor, with "cherry-red" lips and red palms, were observed. There was no tremor or other signs of encephalopathy. Subacute hepatic necrosis was diagnosed, and our findings were confirmed by Dr. Philip Harvey, who kindly saw the patient and on April 9 arranged her transfer to St. Stephen's Hospital for further investigation and treatment.

Intravenous corticotrophin in dextrose was immediately given, the patient receiving a total of 600 units over a period of three days. Diet was restricted to 1,500 calories (with 35 g. of protein). Neomycin and tetracycline were given orally, together with soluble insulin (5 units before meals) and propyltestosterone, these measures aiming at diminishing protein katabolism. Vitamin K, folic acid, and vitamin B₁₂ completed the regime. Twelve hours after initiation of this therapy icterus had greatly diminished. The serum bilirubin level had fallen from 16.6 to 6.4 mg. at the end of corticotrophin administration; by April 25 this level had fallen to 2.8 mg., and her recovery has since been uninterrupted.

A liver biopsy, performed by Dr. Gordon Signy on April 14 (after completion of the corticotrophin treatment), was reported as follows: "There are widespread fatty changes. There are focal areas of swollen hepatic cells and some bile thrombi, focal areas of infiltration, with small cells, including lymphocytes, polymorphs, and eosinophils, mostly occurring round the central vein. There is some increase of collagen fibres around the central vein and the portal spaces. The picture is one of focal necrosis." An electrocardiogram showed sinus bradycardia only. The white blood count remained within normal limits, and the sedimentation rate was not raised.

Case 2

A 31-year-old single woman, secretary to a business executive, had been admitted for the third time to Bethlem Royal Hospital in September, 1957, on account of severe and disabling neurotic symptoms accompanied by depressive features. After discharge from hospital in January, 1958, she remained apathetic, mildly depressed, and unable to work.

Iproniazid was given on January 31 in doses of 150 mg. daily and continued until April 12. Soon after initiation of this therapy she was able to resume work, and remained so well that she failed to keep her out-patient appointments. At the beginning of May she began to feel ill, nauseated, tense, and depressed, but attributed such symptoms to her anxiety relating to a difficult emotional situation. Nausea had been a frequent feature of her various neurotic illnesses.

When seen in the out-patient department on May 9 she appeared agitated and depressed. Iproniazid was again prescribed in doses of 75 mg. daily, combined with chlorpromazine, 150 mg. daily. Later that day she noticed that her

urine was dark and her stools were pale. On the following day jaundice appeared. Iproniazid and chlorpromazine were discontinued after only a few doses. When she reported sick to her firm's medical officer she was found to be pyrexial, and on examination the liver was palpable and tender. "Toxic jaundice" was diagnosed, and she was sent home to bed and treated with a fat-free diet. She had not received injections and there was no contact with other cases of jaundice. Unfortunately, we were not informed of these events until May 30, by which time the jaundice was resolving. She was visited at her home on June 1. On examination she was still slightly jaundiced, the liver edge was palpable but not tender, there was no splenomegaly, and haemorrhage and other skin manifestations were absent. After this visit she was admitted to St. Stephen's Hospital, and a liver biopsy was carried out by Dr. Gordon Signy on June 6. The tissue obtained proved to be part of a haemangioma, and no information could be obtained from the few liver cells present in the sections. The patient suffered no after-effects and was discharged home.

Laboratory Investigations on June 1.—Serum bilirubin: direct, positive; indirect, 2.3 mg.; thymol turbidity, 3 units; zinc flocculation, 9 units; colloidal gold, 0; alkaline phosphatases, 9.6 units; serum transaminase, 47 units; Total protein, 6.5 g. (albumin 4.2 g., globulin 2.3 g.). Electrophoresis showed that the α_2 pattern was less prominent than usual. Abnormality of gamma-globulin was not found.

Discussion

Jaundice was reported during iproniazid administration in tuberculous patients (Bosworth *et al.*, 1955; Ogilvie, 1955). Although only one more case has been published since then (deVerteuil and Lehmann, 1958), jaundice was referred to by Kline (1958) as the most serious complication of iproniazid treatment. The incidence of this jaundice is estimated to be under 0.05% and to approximate that of infective hepatitis (Marks, personal communication). The mortality rate, however, is higher than that reported in infective hepatitis.

The five cases reported during treatment of tuberculosis recovered, but the case reported by deVerteuil and Lehmann, occurring during a trial of iproniazid on 31 depressed and apathetic patients, was fatal. Necropsy in this case showed a "hepatic necrosis of the type sometimes seen in response to toxic agents."

Scherbel (1957a) has described four cases of jaundice in a trial of isoniazid and iproniazid in rheumatic arthritis. In two of his patients there was evidence of previous liver damage: one patient was alcoholic and had a portal cirrhosis and the other, previously subjected to cholecystectomy, had a biliary cirrhosis. The liver biopsies presented a picture typical of "viral hepatitis." The serum bilirubin was 7.2 mg. in the most severe of his cases. Unfortunately, it is not clear from his report whether the patients were receiving isoniazid or iproniazid when jaundice occurred.

During the course of the above clinical trial Scherbel (1957b) described a state of behavioural hyperactivity in some of his patients who were receiving iproniazid. Labora-

Table of Laboratory Investigations

	March 26	April 2	April 11	April 14	April 25	May 6	May 24

tory investigations showed an increase in gamma-globulin, a decreased pseudo-cholinesterase, and increased bromsulphthalein retention in the absence of a rise in serum bilirubin. These findings were suggestive of hepatic dysfunction.

Pare (personal communication) has studied the effect of iproniazid on the serum transaminase level and found this to be increased in some patients, although other liver-function tests remained normal. This again might suggest some liver dysfunction.

Further evidence of liver involvement is supplied by Fouts and Brodie (1956). These authors discovered that iproniazid inhibited the enzymes in the liver, whose function is to detoxify such drugs as barbiturates, amphetamine, aminopyrine, and acetanilid. Toxic cerebral reactions following injections of pethidine have been reported by Mitchell (1955) and by Papp and Benaim (1958), and can be similarly explained on the basis of potentiation of the drug by iproniazid.

Randall (1958) reports slight parenchymatous degeneration in the liver and kidney, engorgement of the spleen, and bone-marrow hyperplasia in animals receiving large doses of iproniazid. Such changes were dependent on the dosage administered, and all were reversible.

Our two cases of jaundice occurred during a clinical trial of iproniazid on 60 depressed patients. Case 1 had received the drug for 72 days to a total of 8.6 g. when jaundice developed. The course of the disease was unlike that of infective hepatitis. Prodromal symptoms were minimal, asthenia and anorexia becoming marked only when clinical signs of necrosis supervened. Liver enlargement and tenderness were slight. There was no fever, and the E.S.R. remained normal throughout her illness. The initial liver-function tests were in favour of intrahepatic cholestasis. In common with other investigators, we found disturbance of protein metabolism with an increase in globulin. Unfortunately, electrophoretic studies were not carried out. The marked change in condition on the twelfth day of jaundice, with the development of clinical signs of liver failure, pointed to the onset of necrosis. This diagnosis was supported by a high serum transaminase level and by the biopsy findings, which showed evidence of focal necrosis in spite of the administration of corticotrophin for three days beforehand. Moreover, the presence of eosinophilia in the sections is strong evidence of drug-induced jaundice (Hollister, 1957).

Case 2 had received iproniazid for 75 days to a total of 11.25 g. It is unfortunate that the case was not seen until 22 days after the onset of jaundice, by which time she was recovering. No definite conclusions can be reached on the information available.

The hypothesis was originally put forward that jaundice occurring in iproniazid therapy was due to a coincidental occurrence of viral hepatitis and an inhibition of the amine oxidase system by the drug, causing failure of the detoxicating mechanisms of the liver. From the evidence available, however, it is difficult to escape the conclusion that iproniazid may have a direct toxic effect on the liver. The fact that jaundice has occurred in patients receiving as little as 25 mg. daily and that it appears unrelated to the duration of administration (Marks, personal communication) suggests that an element of idiosyncrasy may be present.

While it is difficult to decide at this stage whether iproniazid jaundice is of obstructive or hepatocellular type, the severity of some of the cases reported, including our first case, supports the latter possibility. Moreover, our liver biopsy provided definite evidence of hepatocellular damage. The picture was very different from that encountered in chlorpromazine jaundice, obstructive in type and benign in course, in which one invariably finds bile plugs in biliary canaliculi and minimal inflammatory changes (Movitt *et al.*, 1955).

It is clear that further research is needed to establish beyond doubt the mechanisms whereby iproniazid produces liver damage and jaundice. It is hoped that such risks can

be eliminated and that this very helpful drug can continue to be used by psychiatrists and physicians with a greater degree of safety.

Summary

Two cases of jaundice occurring during a clinical trial of iproniazid in 60 depressed patients are reported. Both patients recovered.

Details of biochemical investigations and of a liver biopsy are given. These, together with the course of the disease, suggest that iproniazid is a hepatotoxic drug. Possible mechanisms of action are discussed and the need for further research is emphasized.

We thank Dr. R. F. Hobson and Dr. J. G. Hamilton, under whose care the patients were admitted, for permission to publish this report, and Dr. Linford Rees for his advice and encouragement. To Dr. Philip Harvey we are indebted for seeing and treating our patients; and to Dr. Gordon Signy for performing the liver biopsies. Dr. J. Marks, of Roche Products Ltd., supplied the marsilid for our clinical investigation and provided us with much unpublished information.

TOXIC EFFECTS OF IPRONIAZID IN A PATIENT WITH ANGINA

BY

CORNELIO PAPP, M.D.

Clinical Assistant, Cardiac Department, London Chest Hospital

AND

S. BENAIM, M.B., M.R.C.P., D.P.M.

Senior Registrar, Bethlem Royal and Maudsley Hospitals

Iproniazid ("marsilid"), closely resembling isoniazid in its chemical structure, was originally planned as an anti-tuberculosis drug. Its use in tuberculosis had to be abandoned because of its unpredictable side-effects on mood, ranging from mental excitement to frank psychoses, when given in doses of 4 mg. per kg. of body weight (200–300 mg. a day) as at first advised (O'Connor, Howlett, and Wagner, 1953). This euphoric effect was recently exploited in psychiatry for the treatment of mental depression, where, with smaller doses (100–150 mg. a day), promising results were obtained (Kline, 1958; Dally, 1958). The use of iproniazid in angina pectoris is based on a chance observation in a patient with mental depression who recovered from incapacitating angina while on the drug. Encouraged by this result, Cesarman (1958) tried iproniazid in 41 patients with moderate to severe angina. He reports "total remission" of anginal pain in all of his patients, with electrocardiographic improvement in some. Cossio (1958) out

of 36 patients found almost complete relief of angina in 15, improvement in 11, and no benefit in 10. The daily dose varied from 100 to 150 mg. (two to three tablets). Side-effects have been minor, such as euphoria, constipation, difficulty of micturition, giddiness caused by orthostatic hypotension, and impotence. Dally in his recent large series of 131 psychiatric patients mentions only two in whom treatment had to be stopped on account of fainting caused by postural hypotension.

We were less fortunate in one patient, out of the few, in whom the drug was given for incapacitating decubital angina by one of us (C. P.). This patient developed a transitory toxic cerebral state while taking iproniazid.

Case Report

A married woman underwent bilateral lumbo-dorsal sympathectomy for severe hereditary hypertension in 1948, when aged 40. There was at the time slight renal involvement and grade II–III retinopathy; but the main indication for operation was disabling angina with attacks refractory to nitrites, lasting for hours, cut short only by injections of morphine. She did not sustain cardiac infarction then or morphine. At any time later, and the electrocardiogram showed extreme left ventricular strain with ischaemic changes only. Surgery proved a great success; she was able to resume an active life, lost the angina, and the electrocardiogram reverted to normal. Now, ten years after the operation, the blood pressure in erect posture is still normal, while in recumbency it varies between 160/100 and 180/120.

During the past four years the cardiac symptoms recurred in the form of increasingly severe decubital angina. It was thought that the raised blood pressure in the lying position was causing the attacks, during which the electrocardiogram showed acute ischaemic changes. Prolonged bed rest with showed acute ischaemic changes. Prolonged bed rest with ganglion-blocking agents and rauwolfia, which effectively lowered the recumbent blood pressure, did not prevent the attacks. Heavy sedation, long-acting nitrites, and various coronary vasodilators were all tried without success. Parenteral pethidine, 100 mg. at first, later 200 mg., suppressed attacks of moderate severity; occasionally she needed morphine in addition. Pethidine never caused any side-effects, and the morning after the injections she was as usual active in her home. In March, 1958, when she had almost daily attacks, left stellate ganglionectomy was performed. After a fortnight the attacks reappeared and within days they became as severe as they were before the operation.

Iproniazid was started on April 26. For the first fortnight she was given 50 mg. twice a day, then three times a day. After a fortnight the attacks became less frequent—about twice weekly, and milder. Trinitrine was effective for the lighter attacks, though for the severe ones she still required pethidine injections. At this stage the only adverse effect was pronounced postural hypotension. On May 27 she complained of difficulty of micturition. At 10 p.m. on May 30, after not having had angina for four days, she had a severe attack. Pethidine, 100 mg. by injection, did not relieve her, and the same dose was repeated half an hour later. Within minutes she became extremely restless and confused, and passed into a state of uncontrollable hyperactivity. She was tossing and turning, flopping her arms aimlessly, and it was difficult to keep her in bed. There was general clonus, tremor, excitation, grinding of teeth, and continuous picking of bedclothes. She was semiconscious, had an anxious expression, and became completely unmanageable.

Paraldehyde, 5 ml., phenobarbitone sodium, 3 gr. (0.2 g.), and promethazine hydrochloride, 50 mg. by injection, and pentobarbitone sodium and quinalbarbitone sodium, 3 gr. (0.2 g.) of each orally, were given with no effect. Finally the chlorpromazine, 50 mg. by injection, two hours after the attack began, quieted her, and she fell asleep within half an hour. Iproniazid was now stopped, she having had a

total of 4,400 mg. in 35 days. Next day she was calm and in a normal mental state; she had impaired memory of the events of the previous night. The next evening (June 1) she had a further bout of angina, suppressed with 200 mg. of pethidine by injection. Again a similar state of agitated hyperactivity developed, which was easily controlled with an injection of 50 mg. of chlorpromazine. Thereafter oral chlorpromazine was given, 50 mg. three times a day. A further attack of angina on June 3, for which 200 mg. of pethidine had to be injected, was not followed by restlessness. One week after iproniazid had been stopped postural hypotension and difficulty of micturition still persisted.

Liver-function Tests.—Serum bilirubin: direct, negative; indirect, 1 mg. per 100 ml.; thymol turbidity, 3 units; zinc flocculation, 9 units; colloidal gold, 0; alkaline phosphatase, 3.9 units; serum transaminase, 30 units per ml. Serum proteins: total, 5.8 g. per 100 ml. (albumin 4 g., globulin 1.8 g.). Electrophoresis of proteins showed no rise of γ -globulin. Urine analysis showed no abnormalities.

Discussion

In a recent symposium on the biochemical and clinical aspects of iproniazid Kline (1958) reported that jaundice was the most serious side-effect of the drug. One of us (S. B.) has studied two cases of iproniazid jaundice; his findings are reported at p. 1068. Hepatic dysfunction in the absence of jaundice has been reported by Scherbel (1958) in the treatment with this drug of patients suffering from rheumatoid arthritis. Four of his cases suddenly developed restlessness and hyperactivity. Laboratory investigations showed an increase in bromsulphthalein retention, a diminution of pseudo-cholinesterase, and a disturbance of proteins with an increase of γ -globulin.

Fouts and Brodie (1956) found that iproniazid inhibits the enzyme system in the liver responsible for detoxication of various drugs—for example, barbiturates, amphetamine, aminopyrine, and acetanilid. This study, together with that of Randall (1958), explains the potentiation of these drugs by iproniazid. He also suggests that the toxicity of iproniazid may result from this enzyme inhibition.

Pethidine is de-esterified and demethylated in the liver (Goodman and Gilman, 1955), and it is now recommended that this drug should not be used in patients suffering from severe liver disease, as exaggerated responses, especially cerebral excitation and confusion, may occur (Dundee and Tinckler, 1952).

There was a clear temporal relationship in our patient between the administration of pethidine and each attack of cerebral excitement. Since pethidine was given in therapeutic doses, such exaggerated response could be interpreted as evidence of interference by iproniazid with the detoxicating mechanism of the liver. Such liver-function tests as were carried out were normal. It is unfortunate, however, that no test of bromsulphthalein retention was performed in our patient, since this is one of the most sensitive tests available (Neeffe *et al.*, 1955).

Randall has shown that iproniazid has a cumulative effect, and this may explain why our patient, who was receiving pethidine frequently, developed signs of central nervous system intoxication only during the fifth week of iproniazid treatment. The slow excretion of iproniazid accounts for the persistence of the ganglion-blocking effect as well as the exaggerated response to pethidine after its withdrawal.

Among the many reports dealing with the toxic effects of iproniazid upon the central nervous system, we found only one other instance where the first signs of toxicity appeared after pethidine (Mitchell, 1955). A patient with tuberculosis who had been taking 250 mg. of iproniazid a day for one month developed nausea and muscle-twitchings 20 minutes after 100 mg. of pethidine, which he used to take without side-effects. He became cyanosed, was sweating, and had a rapid pulse, exaggerated tendon reflexes, ankle clonus, and a bilateral plantar extensor reflex. This condition subsided

within 36 hours. He continued on the same dose of iproniazid for a further five months, during which time he showed signs of increasing restlessness, euphoria, insomnia, and other mild toxic effects. He died in coma after an acute illness characterized by fever, coarse tremor, hallucinations, and "auditory delusions." At necropsy the brain showed that death was due to haemorrhagic encephalitis; since no other cause was apparent this was believed to be due to the toxic effect of iproniazid.

The toxic manifestations of the central nervous system caused by pethidine and iproniazid are similar: cerebral excitation, confusion, restlessness, and muscle twitchings are common to both. It is difficult to decide whether in our own and Mitchell's case cerebral symptoms were caused by the simple additive effect of the two drugs or by a more complex inhibition of the enzyme-detoxifying system in the liver. The problem, however, is of theoretical interest. It is of practical importance that the two drugs become incompatible once a certain level of iproniazid is reached in the tissues. This may take up to four weeks.

The response to chlorpromazine was remarkable and perhaps a life-saving measure in our patient. Barbiturates commonly invoked in the treatment of cerebral excitation did not help, and in larger doses could have done actual harm if, as we have suggested, the liver detoxifying system was affected by iproniazid.

Although the pharmacological action on the heart is not yet clearly established, the improvement in this case and in others still under observation suggests that iproniazid is a promising drug in the treatment of angina. Patients with decubital angina, however, need heavy sedation with morphine analogues and barbiturates; potentiation with iproniazid may give rise to toxic cerebral reactions as in our patient. It is because of such therapeutic implications that this case is reported.

Summary

A case of decubital angina treated with iproniazid is reported. Although the frequency of the attacks diminished, occasional pethidine injections were still needed for the relief of pain. During the fifth week of iproniazid treatment these injections were followed by signs of severe cerebral irritation and excitement which responded dramatically to chlorpromazine. Either the simple additive effect of the two drugs or more complex interference with the normal detoxification of pethidine in the liver by iproniazid is believed to have caused toxic cerebral damage. It is suggested that pethidine should be used with caution in patients on iproniazid treatment.

ADDENDUM.—Since this paper was submitted a different complication of iproniazid treatment has been encountered in a 63-year-old man suffering from incapacitating angina of effort. On a dose of 50 mg. twice daily, much improvement resulted. One month later, while still on the same dose, he complained of difficulty of micturition and giddiness, and his blood pressure had fallen from 140/80 to 110/75. Iproniazid was discontinued, and then resumed after one week. A fortnight later he developed a small cerebral thrombosis, from which he fortunately recovered. Hypotension caused by iproniazid may have precipitated this complication.

TREATMENT OF ULCERATIVE COLITIS WITH LOCAL HYDROCORTISONE HEMISUCCINATE SODIUM

A REPORT ON A CONTROLLED THERAPEUTIC TRIAL

BY

S. C. TRUELOVE, M.D., M.R.C.P.

Nuffield Department of Clinical Medicine, University of Oxford

(From the Radcliffe Infirmary, Oxford)

With an Appendix by M. H. HAMBLING, M.B., B.S.

Two previous studies have dealt with the use of hydrocortisone applied topically to the colon in ulcerative colitis by means of a nightly rectal drip (Truelove, 1956, 1957). In the first study, 21 mild or moderate attacks of the disease were treated with hydrocortisone in the form of the free alcohol, and there were 14 rapid remissions, these remissions usually occurring in the first few days of treatment. However, although the sigmoidoscopic findings showed improvement in parallel with the clinical response, the histological picture as judged by biopsy specimens was little altered. As hydrocortisone itself is poorly soluble in water, the actual solution used for the rectal drip was prepared by diluting hydrocortisone dissolved in 50% ethyl alcohol with 10 times its volume of saline. There was the possibility that the weak alcoholic solution used as the vehicle for the hydrocortisone prevented the mucosa from healing.

In the second study, a compound freely soluble in water, hydrocortisone hemisuccinate sodium, was used. The clinical response was similar to that obtained with hydrocortisone itself in that there were 11 rapid remissions out of 18 courses of treatment. However, the histological picture of the colonic mucosa showed a favourable response in those subjects enjoying clinical remission, and it was therefore decided that the hemisuccinate (or some other water-soluble compound) was the corticoid of choice for this form of treatment.

The view that hydrocortisone applied topically is a useful form of treatment in this disease could be only presumptive on the results so far mentioned. In other words, this view rested solely on a personal clinical judgment that no considerable proportion of patients with an attack of ulcerative colitis would go swiftly into remission unless the treatment was having some strongly positive effect. Any student of ulcerative colitis must view with scepticism the use of a treatment based upon personal impressions, for the history of the disease includes a large variety of treatments which in their turn were introduced with enthusiasm on the strength of a few favourable responses and then slowly abandoned when they were found to be ineffective. The disease is one which manifests itself by exacerbations and remissions which are often unpredictable. Furthermore, a large body of opinion regards it as a psychosomatic disorder, so that a new form of treatment might possibly be beneficial for reasons unconnected with the pharmacological actions of the therapeutic agent. It is therefore essential that new forms of treatment should be put to formal tests so that patients are not exposed unnecessarily to useless methods of treatment.

Objects of the Present Study.—The main object of the present study was to compare the effect of hydro-

cortisone hemisuccinate sodium used topically with an inert preparation which resembled it superficially. The second object was to form an impression whether the combined use of hydrocortisone and antibiotics was better than hydrocortisone used alone. The third object was to determine whether patients who went into remission with local treatment would remain relatively free from relapse if they received maintenance treatment on two nights a week.

Method

The study comprised three parts, corresponding to the three objects of the trial.

Part I. Blind Controlled Trial of Local Treatment Lasting One Week

Patients with active symptoms of ulcerative colitis were allotted in a random order to treatment with either preparation A or preparation B, one of which was actual hydrocortisone hemisuccinate sodium while the other was an inert replica. These preparations were made and labelled by Glaxo Laboratories, and their identity was unknown to all the other persons concerned in the trial until after its conclusion. Treatment was prescribed in the following form:

A. J. Smith
U. C. No. 23

R Special rectal drip nightly for seven nights.

Patients were numbered consecutively as they entered the trial, and the hospital pharmacist entered their names on a prepared list that showed which preparation a patient with any particular serial number was to have. Treatment consisted in dissolving the contents of one ampoule of A or B in 120 ml. of normal saline and dripping the solution into the rectum at night. No other treatment was used.

The inert preparation was made by the manufacturers by freeze-drying concentrated dextran solution put up for intravenous use. The resulting powder closely resembled the preparation of hydrocortisone hemisuccinate sodium used in the trial. Each ampoule of inert preparation consisted of 20–30 mg. of freeze-dried dextran, which corresponded in volume to 100 mg. of hydrocortisone in the form of the hemisuccinate sodium ester. On general principles we should expect this small amount of intravenous dextran in 120 ml. of saline to be harmless to the colonic mucosa, and practical tests on patients with ulcerative colitis immediately after going into remission support this view.

Part II. Open Use of Hydrocortisone and Antibiotics for Two Weeks

At the end of the first week all patients were given nightly rectal drips of known hydrocortisone and antibiotics. Penicillin, 1 mega unit, and streptomycin, 1 g., were added to the hydrocortisone solution, which contained the hemisuccinate in an amount equivalent to 100 mg. of hydrocortisone itself. In 10 instances neomycin in a dose of 250 mg. was used in place of penicillin and streptomycin.

Part III. Blind Controlled Trial of Maintenance Treatment Employing Rectal Drips Twice a Week Over the Course of Six Months

Patients who were in clinical remission at the end of Part II were admitted to the maintenance part of the trial. The practical arrangements were analogous to those used in Part I in that Glaxo Laboratories supplied preparations labelled X and Y, one of which was actual hydrocortisone and the other was inert. In the earlier stages of this part of the trial neomycin or an inert replica, labelled as antibiotic X or antibiotic Y, was used in combination with hydrocortisone or its "dummy," but this was later given up for reasons set out below.

Selection and Assessment of Cases

Only patients with active symptoms from ulcerative colitis were admitted to the trial. As in the previous studies, severe cases with much constitutional disturbance were excluded.

Many of the patients were ambulant and were treated as out-patients, although some were in hospital.

Some patients who went into remission but who relapsed during or after maintenance therapy were readmitted to the trial, once again being allotted to treatment A or B at random.

The clinical condition immediately before treatment was recorded. All patients were examined by sigmoidoscopy on the day when treatment began, and the findings were recorded. During this examination a mucosal biopsy was performed by means of an improved version of an instrument devised for serial biopsy (Truelove *et al.*, 1955) and a swab was taken from the lower colonic mucosa for bacteriological study.

At the end of Part I and of Part II of the trial, exactly similar observations were made. They were also made during Part III (trial of maintenance therapy), although they might be limited to the final attendance six months after the conclusion of Part II.

Barium-enema studies were not made as a routine. In every patient at least one barium-enema examination had previously shown evidence of ulcerative colitis. This examination not infrequently causes an exacerbation of symptoms. The patients are usually young and suffer from a disease from which they are likely to have future attacks in the course of which further x-ray studies may be essential. Many of them are women in the reproductive years of life, and unnecessary gonadal exposure to x-radiation is to be avoided. For all these reasons, the barium enema should be used sparingly in ulcerative colitis.

Forty courses of treatment were given, it being arranged beforehand that 20 would be with preparation A and 20 with preparation B during Part I of the trial. In the interests of brevity, individual case histories are not recorded.

Part I. Controlled Trial of Local Hydrocortisone Treatment

Clinical Response.—The clinical response to the two preparations is given in Table I. It can be seen that there is a striking difference between the clinical response shown with inert treatment and that with actual hydrocortisone, only 1 in 20 treatments with a "dummy" resulting in clinical remission, compared with just over one-half with hydrocortisone. In statistical terms, the difference is highly significant, as it would occur by chance less than 1 in 100 times.

TABLE I.—Clinical Results of One Week's Treatment With Hydrocortisone or an Inert Preparation

Treatment Group	No. of Patients	No. Symptom-free	Test of Significance
A (Inert therapy)	20	1	$\chi^2_c = 9.6$ $n = 1$ $P = 0.01$
B (Hydrocortisone hemisuccinate)	20	11	

* calculated with Yates's correction for continuity in view of the small numbers involved.

Sigmoidoscopic Responses.—The sigmoidoscopic findings resembled the clinical responses in showing a marked preponderance of favourable changes among the group receiving actual hydrocortisone. Once again the results are statistically highly significant (Table II). It is worth mentioning that there was almost perfect agreement between a good clinical response and a clear-cut sigmoidoscopic improvement. All the patients going into clinical remission showed improved sigmoidoscopic appearances. The only discrepancy was that one patient in each treatment group

TABLE II.—Sigmoidoscopic Response to One Week's Treatment With Hydrocortisone or an Inert Preparation

Treatment Group	No. of Patients	No. Showing Definite Improvement	Test of Significance
A (Inert)	20	2	$\chi^2_c = 8.9$ $n = 1$ $P < 0.01$
B (Hydrocortisone)	20	12	

showed improved sigmoidoscopic appearances even though they were not in clinical remission. Both later became symptom-free.

Histological Response.—Before treatment all the biopsy specimens taken at 15–20 cm. from the anal margin showed inflammatory changes of the type associated with ulcerative colitis. They have been classified as showing severe, moderate, or mild inflammation, according to the criteria employed by a pathologist colleague in a previous study (Truelove and Richards, 1956). Table III shows the histo-

TABLE III.—Histological Responses to One Week's Treatment With Hydrocortisone or Inert Preparation

Treatment Group	Degree of Inflammation	Before Treatment	After Treatment	Significance of Differences Before and After Treatment
A (Inert therapy)	Severe	8	7	No significant difference
	Moderate	10	11	
	Mild	2	2	
B (Hydrocortisone hemisuccinate)	Severe	8	4	$\chi^2=8.6$ $n=2$ $P<0.02$
	Moderate	11	7	
	Mild	1	9	
Significance of differences between A and B		No significant difference	$\chi^2=6.2$ $n=2$ $P<0.05$	

logical picture as judged from biopsy specimens in each treatment group before and after the one week's controlled trial. Before treatment the two groups of patients were closely similar in respect of the histological changes. After treatment the histological picture in group A (inert therapy) was for all practical purposes identical with that before treatment. In group B (real therapy) there was a definite swing towards histological mildness. In statistical terms this group was significantly better histologically after treatment than it was before ($P<0.02$) and was also significantly better than group A after treatment ($P<0.05$). We may therefore justifiably conclude that topical hydrocortisone hemisuccinate exerts a favourable influence on the actual pathological picture of the colonic mucosa in ulcerative colitis (Fig. 1).

FIG. 1.—Position at end of Part I of trial, showing the differences in the clinical, sigmoidoscopic, and histological pictures after one week of treatment with either an inert preparation or real therapy. (A=Inert preparation. B=Hydrocortisone hemisuccinate sodium.)

Part II. Two Weeks' Treatment with Known Hydrocortisone and Antibiotics

Clinical Response.—At the end of another two weeks, when all patients had been treated with known hydrocortisone hemisuccinate and antibiotics used locally, the two treatment groups were closely similar in respect of their clinical state. In treatment group A, which began with only one patient in clinical remission, 12 patients went into remission during this period, making a total of 13 for the group. In treatment group B, which began this part of the trial with 11 patients in remission, another 5 became symptom-free, making a total of 16. The final difference between the two treatment groups is small, and would be expected to occur frequently by chance alone (Table IV).

TABLE IV.—Clinical State at End of Part II of Trial, When All Patients Had Completed Two Weeks' Treatment With Known Hydrocortisone and Antibiotics

Treatment Group	No. of Patients	No. Symptom-free	Test of Significance
A	20	13	$\chi^2=1.1$ $n=1$ $P>0.05$
B	20	16	

Sigmoidoscopic Response.—Once again the sigmoidoscopic appearances moved in parallel with the clinical response. All of the 29 patients who were free of symptoms at the end of the third week showed sigmoidoscopic appearances which were decisively better than when they began treatment. Some residual inflammation (as judged by gross appearances) was present in a number of these 29 patients, but in 18 the appearances were judged to be "normal" or "near-normal," the latter term implying that the only abnormality was a fine pin-point granularity not accompanied by hyperaemia or by increased mucosal fragility. Three of the 11 patients still having bowel symptoms at the end of three weeks' treatment showed sigmoidoscopic improvement, and in all three there had been lessening of the bowel symptoms, although they were not yet symptom-free. Table V shows that the two treatment groups A and B were closely similar at the end of the second part of the trial.

TABLE V.—Sigmoidoscopic Appearances at End of Three Weeks' Treatment, the Last Two Weeks Having Been With Known Hydrocortisone and Antibiotics

Treatment Group	No. of Patients	No. with Normal or Improved Sigmoidoscopic Appearances	Test of Significance
A	20	15	$\chi^2=0.5$ $n=1$ $P>0.05$
B	20	17	

Histological Response.—The histological responses likewise showed improvement in both treatment groups after known therapy, and there was little difference between them at the end of this part of the trial. The small advantage maintained by group B is not statistically significant (Table VI, Fig. 2).

TABLE VI.—Histological Picture at End of Part II of the Trial

Treatment Group	Degree of Inflammation	No. of Patients	Test of Significance
A	Severe	3	$\chi^2=1.2$ $n=2$ $P>0.05$
	Moderate	6	
	Mild	11	
B	Severe	1	
	Moderate	6	
	Mild	13	

FIG. 2.—Position at end of Part II of trial, showing the similar clinical, sigmoidoscopic, and histological pictures after both treatment groups had received topical treatment with known hydrocortisone hemisuccinate sodium.

Action of Antibiotics Added to the Rectal Drip

The effect of antibiotics is not straightforward. The first thing to note is that in a few patients their use was attended by a sharp exacerbation of symptoms. In two of these cases it was known that the patients had previously had sensitivity reactions to penicillin given by injection, so that no great surprise was aroused when immediate symptomatic deterioration occurred. Both these patients had colonic biopsy specimens taken in the phase of flare-up, but the specimens showed only those changes which we associate with active ulcerative colitis; in other words, there was no specific recognizable change to be attributed to the penicillin. The antibiotics were stopped in these two patients, and they continued on the second part of the trial with hydrocortisone hemisuccinate alone; both went into clinical remission in this period. There were three other patients without known sensitivity reactions to any antibiotic who behaved in a similar manner. Two of these were among the 10 patients who were treated with neomycin in the drip instead of penicillin and streptomycin. One of them was already in remission when going into this second part of the trial, but she promptly relapsed on going on to known hydrocortisone and neomycin. On stopping the neomycin she rapidly became symptom-free, and remained so for some months. For this reason neomycin was discontinued for the remainder of the study.

On the other hand, there were some patients in whom it has been found that hydrocortisone alone did not have any appreciable effect during the first week of therapy but who improved rapidly when antibiotics were added to their treatment. (That such patients were on actual hydrocortisone during the first week has, of course, been known only since the study ended.) In parenthesis, it may also be added that the study ended.) In parenthesis, it may also be added that the study ended.) In parenthesis, it may also be added that the study ended.) In parenthesis, it may also be added that the study ended.)

Consequently, there appear to be two conflicting factors at work. On the one hand, the inflamed colonic mucosa may sometimes react badly to the topical application of antibiotics in high concentration. On the other hand, some patients who are not responding to local hydrocortisone alone appear to do so promptly when antibiotics are added to the rectal drip. The net effect of these two opposing influences seems to be a small gain in the number of remissions achieved, if one can go on a comparison of the results obtained in the present study with those of the two previous studies of local hydrocortisone in ulcerative colitis (Table VII). The differences are not statistically significant, and

TABLE VII.—Comparison of Results Obtained When Antibiotics are Added to the Rectal Drip of Hydrocortisone with Those Obtained with Hydrocortisone Alone

	No. of Patients	Remissions		Test of Significance
		No.	%	
(I) Hydrocortisone (free alcohol) for 2–3 weeks (Truelove, 1956)	12	14	66.6	$\chi^2=0.8$ $n=2$ $P>0.05$
(II) Hydrocortisone hemisuccinate sodium for 2 weeks (Truelove, 1957)	18	11	61.1	
(III) Hydrocortisone hemisuccinate sodium plus antibiotics (present study)	40	29	72.5	

inspection of the figures is sufficient to discount any idea that the addition of antibiotics makes any major difference to the success of this form of treatment. Nevertheless, one can tentatively suggest the following working rules: (1) Antibiotics should not be used as a routine addition to a rectal drip of hydrocortisone hemisuccinate. (2) If no response is obtained with hydrocortisone alone in one week, it is worth trying the effect of adding antibiotics, and a mixture of penicillin and streptomycin seems preferable to neomycin. If the addition of antibiotics causes symptomatic exacerbation they should be stopped immediately. If the response is good, antibiotics can be continued for a week or 10 days, being then discontinued even if treatment with local hydrocortisone is to be maintained.

Of course, this opinion refers only to the use of high concentrations of antibiotics. It is possible that the use of lower concentrations might not cause exacerbations, but further work will be necessary to decide this.

Bacteriological Findings

Colonic swabs taken serially from the patients were examined bacteriologically by Dr. M. H. Hambling, who has summarized his findings in an Appendix to this article. The main object of this part of the study was to see whether the use of antibiotics frequently gave rise to colonic organisms insensitive to the antibiotics used, and, if so, whether this circumstance influenced the response to treatment. In brief, it can be said that resistant organisms sometimes appeared in the bowel, but their presence seemed to have no influence on the clinical response to local hydrocortisone.

Part III. Controlled Trial of Week-end Maintenance Therapy with Local Hydrocortisone for a Period of Six Months

Twenty-six of the patients who were symptom-free at the end of Part II of the trial were put on to maintenance treatment consisting of a rectal drip on two consecutive nights each week (week-end maintenance therapy). Of these, 13 received treatment with hydrocortisone hemisuccinate sodium (preparation Y) and 13 with the inert preparation (preparation X).

These two treatment groups did not differ in their liability to clinical relapse during the six months covered by this part of the trial. In each group of 13 patients there were five who suffered from clinical relapse accompanied by sigmoidoscopic and histological deterioration (Fig. 3). It has therefore been shown that week-end maintenance therapy with local hydrocortisone does not protect against relapse occurring.

However, it must be mentioned that among the 10 patients who relapsed during the maintenance part of the trial 9 rapidly became symptom-free with nightly rectal drips of hydrocortisone; the tenth did not respond to topical hydrocortisone alone, but did so promptly when oral prednisolone, 5 mg. four times a day, was given in addition.

Discussion

The present study has shown beyond all reasonable doubt that hydrocortisone hemisuccinate sodium administered in a rectal drip produces rapid clinical remissions in a considerable proportion of patients with mild to moderate attacks of ulcerative colitis. These clinical remissions are accompanied by improvement in the sigmoidoscopic appearances and by lessening of the inflammatory changes seen in colonic biopsy specimens. The experimental design of the trial permits the conclusion that the beneficial effect is a pharmacological one, because a control group receiving a placebo given under identical conditions showed a negligible number of favourable responses.

It is probable that the hydrocortisone hemisuccinate sodium acts chiefly by some direct effect upon the actual mucosa of the colon. In the first place, the beneficial effect commonly appears to be much more rapid than that observed with cortisone and its analogues used systemically. Secondly, some patients outside the present study have been maintained on nightly rectal drips of hydrocortisone hemisuccinate sodium for periods of several months without any clinical evidence of cortisonism. Thirdly, the preliminary

FIG. 3.—Position at end of Part III of trial, showing the similar state of patients given week-end maintenance therapy with either an inert preparation or real therapy. (X=Inert preparation. Y=Hydrocortisone hemisuccinate sodium.)

results of my colleague Dr. I. E. Bush suggest that only a comparatively small fraction of the hydrocortisone hemisuccinate sodium reaches the systemic circulation. Finally, and perhaps most convincingly, favourable clinical, sigmoidoscopic, and histological responses have been observed in patients with ulcerative colitis limited to the rectum and recto-sigmoid region by the use, once or twice a day, of suppositories containing only 10 mg. of hydrocortisone as the hemisuccinate. As some of these patients had previously suffered from attacks of classical ulcerative colitis involving a substantial part or the whole of the colon, there is no need to consider the possibility that they were not true examples of ulcerative colitis.

The therapeutic action would appear to resemble what happens in those skin diseases, such as atopic dermatitis, which respond favourably to topical application of hydrocortisone in a lotion or ointment. Absorption through the skin is very small, being of the order of 2%, so that the systemic effect is negligible, but the favourable results can be impressive, and have been shown by properly controlled studies (Sulzberger and Witten, 1954) to be directly due to the hydrocortisone. An analogous improvement of the buccal mucosa has been observed in patients with severe recurrent aphthous stomatitis who were receiving amounts of hydrocortisone hemisuccinate sodium too small to have any appreciable systemic effects (Truelove and Morris-Owen, 1958).

The addition of antibiotics to the rectal drip has turned out on balance to be beneficial in only a small proportion of patients. Although the weight of evidence is heavily against ulcerative colitis being a bacterial disease, there is little doubt that secondary bacterial infection is responsible for many of its most unpleasant complications. It seemed possible that the presence of bacterial infection might be the reason for some patients failing to respond to local hydrocortisone treatment. As it has been shown by elegant experiments that an infected atopic dermatitis may respond neither to local hydrocortisone alone nor to local antibiotics alone but will respond when the two are used together (Robinson *et al.*, 1956), it was hoped that an analogous response might be obtained in ulcerative colitis. In the event, the gain from adding antibiotics to the rectal drip of hydrocortisone has appeared to be small, and sharp exacerbations have occurred in a few patients from the direct application of antibiotics to the inflamed colon.

Although some patients enjoy a prolonged remission after a short course of local hydrocortisone, about two-fifths of the patients have a recurrence of symptoms in the course of the next six months and require further treatment. This fact illustrates the major problem in the management of ulcerative colitis to-day. By one method or another most attacks of ulcerative colitis can be brought under control by medical methods and the patient rendered symptom-free. However, once a patient has suffered from an attack of ulcerative colitis he is extremely liable to have subsequent attacks, and we know of no method to prevent them. The part of the present study which concerned maintenance therapy was designed to see whether, once a patient had been brought into clinical remission with local hydrocortisone, he could be held in remission by means of local treatment given on two consecutive nights a week only (week-end maintenance treatment). The answer is a decisive "No." A more fruitful approach to the problem may be to give a much more prolonged initial course of local treatment in those patients who respond well to it, in the hope that the colon will become more permanently improved by this means.

Outside the present study, a number of patients have been on prolonged treatment with nightly rectal drips of hydrocortisone, and the results so far appear to be very favourable, not only as regards the immediate benefits but also with respect to the production of a long-lasting remission. However, more patients need to be treated and to be observed for longer periods before this important question can be answered with any degree of assurance. Alternatively, the liability to recurrent attacks can be accepted and each one

can be treated as it arises. When a patient has once responded well to local hydrocortisone it is likely that he will do so in subsequent attacks, and a number of patients have now been kept free of any major disability by intermittent courses of treatment given whenever clinical relapse occurred.

Although the present study has shown topical hydrocortisone hemisuccinate sodium to have a genuinely favourable effect in ulcerative colitis, it remains to be seen whether this form of treatment is superior to others which have been shown to be of value in cutting short attacks of the disease, such as corticoids used systemically. My impression is that local hydrocortisone hemisuccinate sodium scores over corticoids used systemically by the rapidity with which favourable responses are obtained and by the absence of any evidence of systemic side-effects of therapy. At present, my experience of this form of treatment extends to its use in about 100 patients, a number of whom have had more than one course of treatment, while some others have been on treatment for periods of several months consecutively. There have been no side-effects discernible clinically and no complications. In my own experience, therefore, the method has proved entirely safe.

Although this and the two previously published studies have been concerned with the less severe attacks of ulcerative colitis, it should not be thought that local hydrocortisone hemisuccinate sodium is valueless in the severe attacks. A number have been treated, and the results have been most encouraging. However, the local treatment of severe attacks raises certain problems, one of which concerns methods of ensuring that the therapeutic agent is retained in the colon. Propantheline bromide, given intravenously, is one agent which has been used to assist in retention. Heavy sedation of the patient and elevation of the foot of the bed also help. But these are issues which lie outside the province of the present study, which is concerned mainly with a formal demonstration that topical hydrocortisone hemisuccinate sodium is an effective form of treatment for a large proportion of patients with mild or moderate attacks of ulcerative colitis.

Summary

A formal therapeutic trial has been conducted to show whether topical hydrocortisone hemisuccinate sodium has a genuinely beneficial action in ulcerative colitis.

In the first part of the trial a controlled comparison was made of hydrocortisone and an inert preparation which resembled it in appearance. At the end of one week of treatment the patients receiving hydrocortisone therapy showed a striking advantage over those on the inert preparation, not only in respect of the clinical state but also as regards the sigmoidoscopic appearances and the histological appearances of colonic biopsy specimens.

All patients were then given open therapy with topical hydrocortisone and antibiotics used in conjunction for two weeks. About three-quarters of the patients were in clinical remission at the end of this period. By comparison with other studies in which antibiotics were not used, the addition of antibiotics seems to confer a small gain in the number of successes with topical hydrocortisone therapy, although at the price of a few patients developing exacerbation of symptoms.

Twenty-six of the patients who were in clinical remission after open therapy were entered for a trial week-end maintenance therapy lasting six months. Thirteen of the patients received hydrocortisone and the other 13 an inert preparation. The clinical course of the two groups was identical, each having five patients who relapsed during the six-months period. Week-end main-

tenance therapy with local hydrocortisone is therefore ineffective in reducing the chance of relapse.

The implications of these various findings are briefly discussed.

I am indebted to Glaxo Laboratories, who not only made a gift of the hydrocortisone hemisuccinate sodium and the inert preparation, but also packed and labelled them ready for use in this trial. I am also indebted to the Medical Research Council for a grant for technical assistance. I wish to thank the following colleagues: Dr. M. H. Hambling for conducting the bacteriological studies; Dr. R. L. Vollum and Dr. W. H. H. Jebb for advice on antibiotics and bacteriology; Miss H. Enser, who assisted me in the sigmoidoscopic examinations and prepared the histological specimens; Miss M. G. Craig and Miss S. V. James, who issued the various therapeutic agents according to the prepared plan; and Miss M. C. McLarty, who made the Charts.

APPENDIX: BACTERIOLOGY OF THE COLONIC SWABS

BY

M. H. HAMBLING, M.B., B.S.

Department of Bacteriology, the Radcliffe Infirmary, Oxford

Methods

At each examination the pelvic colon was swabbed through the sigmoidoscope. Bacteriological examination of the swab was made: (1) to exclude intestinal pathogens of the Salmonella and Shigella groups; and (2) to determine the antibiotic sensitivities of the predominant organisms in order to detect any marked increase of resistant strains following rectal antibiotic therapy.

Each swab was shaken with 5 ml. of digest heart broth, and a loopful of the broth was inoculated to each of the following media:—*Solid media*: Two blood-agar plates (one for anaerobic incubation), a deoxycholate citrate agar plate and a MacConkey agar plate. *Fluid media*: A Robertson's cooked-meat medium, and a Robertson's cooked-meat medium to which 10% NaCl had been added.

Finally 5 ml. of selenite F (Leifson, 1936) was added to the remainder of the broth and all cultures were incubated at 37° C. overnight.

The following day the plates were examined. The Robertson's cooked-meat medium was plated to two blood-agar plates (one for anaerobic incubation), one deoxycholate citrate agar plate, and one MacConkey agar plate; the Robertson's cooked-meat medium containing salt was subcultured to a plate of nutrient agar containing 7% salt and cultured to a blood-agar plate (for aerobic incubation). The selenite F broth was plated to a deoxycholate citrate agar plate. All the plates were then incubated overnight at 37° C.

No special media were used in an attempt to isolate yeasts, lactobacilli, or anaerobic Gram-negative rods.

The organisms most frequently isolated were lactose-fermenting Gram-negative rods (L.F.s), *Streptococcus faecalis*, *Clostridium welchii*, *Staphylococcus aureus*, micrococci, Proteus, and paracolon organisms; and of these, L.F.s and *str. faecalis* were the most common.

The Gram-negative rods were examined for sensitivity to streptomycin and neomycin, while the Gram-positive organisms were tested against penicillin and neomycin.

Findings

1. No member of the Salmonella or Shigella groups was isolated from any of the 137 specimens examined.
2. Lactose-fermenting Gram-negative rods isolated from the 30 patients treated with rectal penicillin and streptomycin tended to show an increased resistance to streptomycin.

Before treatment, 34 strains of L.F.s were isolated of which 4 were sensitive to 25 units of streptomycin per ml., and 30 sensitive to 12 or less units of streptomycin per ml.; whereas after treatment 24 strains were isolated, of which 7 were resistant to 100 units of streptomycin per ml., 1 was sensitive to 50 units of streptomycin per ml., 3 were sensitive to 25 units of streptomycin per ml., and the remaining 13 strains were sensitive to 12 or less units of streptomycin per ml. Strains of *Str. faecalis* isolated before and after treatment showed no increased resistance to penicillin.

3. Strains of *Staph. aureus* were isolated from eight patients, but in no case was a penicillin-sensitive strain replaced by a penicillin-resistant strain, and in only one patient (an in-patient) was *Staph. aureus* isolated from every specimen.

Colonic swabs from the smaller series of patients who were given neomycin rectally were subjected to the same culture routine as above, but in no case were neomycin-resistant organisms isolated.

Summary

Bacteriological examination of 137 colonic swabs failed to isolate any member of the salmonella or shigella groups.

Following rectal administration of streptomycin, penicillin, and neomycin it appeared that a few strains of lactose-fermenting Gram-negative rods showed increased resistance to streptomycin, but no Gram-positive organisms showed increased resistance to penicillin or neomycin.

TREATMENT OF ULCERATIVE COLITIS WITH TOPICAL HYDROCORTISONE HEMISUCCINATE SODIUM

A CONTROLLED TRIAL EMPLOYING RESTRICTED SEQUENTIAL ANALYSIS

BY

GEOFFREY WATKINSON, M.D., M.R.C.P.

Senior Lecturer in Medicine, Department of Medicine, University of Leeds

The many reports indicating that systemic corticoid therapy was of value in the treatment of ulcerative colitis, and the fact that topical hydrocortisone had been used successfully in various eye, joint, and skin diseases, made it possible that mild cases of colitis would respond to this method of treatment.

Favourable reports of the use of topical hydrocortisone in colitis have already appeared (Truelove, 1956, 1957). These results were considered by him to be encouraging enough to merit a controlled trial of this form of treatment of colitis.

A controlled trial has therefore been undertaken where the relative merits of solutions of hydrocortisone hemisuccinate sodium and an inert preparation administered rectally to patients with haemorrhagic proctocolitis and ulcerative colitis have been assessed in a blind controlled trial. In order to obtain a significant answer as rapidly as possible a method of restricted sequential analysis devised by Dr. Peter Armitage has been used in the planning and control of the trial. A significant advantage in favour of the potent hydrocortisone has been demonstrated by 19 treatments in 16 patients with colitis where symptomatic remissions and sigmoidoscopic improvement occurred significantly more commonly in those receiving potent therapy. The

responses of patients receiving potent and dummy treatments are first contrasted and later the method of sequential analysis of the results obtained is detailed.

Method of Administration

Glaxo Laboratories were kind enough to provide potent and inert agents for the trial, labelled Y and X respectively. Treatment was administered to patients as follows: 100 mg. of hydrocortisone hemisuccinate sodium or the dummy preparation was dissolved in 100 ml. of normal saline. It is important that the solution be freshly prepared before use, as slow hydrolysis occurs and causes some of the hydrocortisone to precipitate out of the solution on standing. The patient lies on his left side, and the solution is then administered through an intravenous drip set attached to a rectal catheter at a fairly rapid drip rate of one to two drops per second over a period of 15 to 30 minutes. The rectal infusion is retained overnight and is repeated on 15 successive evenings. Usually the technique was rapidly mastered by the patients receiving it, and after two to three nights of

treatment in hospital they returned home and continued nightly infusions there.

In more severely affected patients in whom nocturnal diarrhoea might prevent the retention of the infusion an intravenous injection of propantheline, 15–30 mg. half an hour before the infusion, was given to aid retention overnight.

Patients Treated

Sixteen patients with haemorrhagic proctocolitis or colitis were treated on 10 occasions with potent therapy and on nine with an inert preparation, three patients being treated twice. Treatments were allocated in random fashion to both groups, as is described later. All patients gave typical histories of recurrent diarrhoea and blood-stained stools, and showed mucosal changes on sigmoidoscopy which were consistent with the diagnosis. Barium-enema examinations were undertaken in each patient to assess the extent of colonic involvement. Precise clinical information on the age and sex, duration of history, and extent and severity of the disease is given in Tables I and II, and is summarized

Ulcerative lesions	2	1

patients treated are surprisingly similar in age, sex distribution, extent of disease, and duration of history. Two patients with more severe ulcerative lesions were treated with potent therapy and one with inert drug.

Method of Investigation

In all cases a clinical assessment of the patient's condition was made personally by an inquiry into the severity of diarrhoea and the blood content of the stools, the observer being unaware of the treatment given. A haemoglobin and an erythrocyte sedimentation rate were determined before and after treatment. Sigmoidoscopic examinations were performed before treatment and within two or three weeks of completion of the course of infusions. These examinations were made by an independent observer (Professor J. C. Goligher), who was also unaware whether potent or dummy treatment was being given. As will be seen, the clinical response of the patients receiving hydrocortisone (Table I) was strikingly better than those receiving inert therapy (Table II). In most patients receiving hydrocortisone the stools rapidly became normal; usually within two to three days of starting treatment blood disappeared from the stools and an improvement in the patient's general condition was shown by increased well-being and a rise in haemoglobin level and reduction in the erythrocyte sedimentation rates. The sigmoidoscopic appearances often returned to normal, but were improved in most of the cases going into clinical remission. Table II shows that inert therapy was strikingly ineffective: diarrhoea, if anything, was worse after treatment; haemoglobin and E.S.R. levels were unchanged or rather worse; and sigmoidoscopic appearances showed no change or a deterioration.

The overall results obtained in 19 treatment periods are summarized in Table IV. Of 10 patients receiving potent therapy all but one went into clinical remission as compared with only one out of nine patients receiving inert treatment. Two, however, showed slight improvement after inert

TABLE IV.—Topical Hydrocortisone in Ulcerative Colitis. Results of Treatment

therapy. Mucosal appearances became normal in 3 and improved in 6 of the 10 patients receiving the potent agent, and contrasted markedly with those receiving the dummy treatment, where only three showed slight improvement. It

has not been definitely established how long remission will be maintained after an initial course of treatment, but 4 of the 10 patients treated with hydrocortisone have remained in clinical remission for six to nine months. Three relapses have already occurred but have responded to further courses of treatment. The one patient showing remission on dummy therapy relapsed within a month of stopping treatment.

The response of three patients who were treated in the trial by both agents is of interest.

Case A: Courses 5 and 10.—A woman aged 25 gave a history of rectal bleeding, diarrhoea, and mucus discharge for one year, and sigmoidoscopy confirmed the presence of a haemorrhagic proctosigmoiditis. An initial course of dummy treatment effected a slight improvement with a reduction of the frequency of diarrhoea from ten to five stools daily and a lessening of rectal bleeding. Relapse occurred within one month and the patient re-entered the trial. She was unfortunate enough to be allocated a further course of dummy treatment, which had no effect upon her diarrhoea. She continued to pass six loose stools daily which contained more blood than before treatment was given. Mucosal appearances also worsened. Potent therapy was given outside the trial and induced a rapid clinical remission, with a reduction of stool frequency from six to two daily, a disappearance of blood from the stools, and an improvement in the mucosal appearance. A mild relapse has occurred in this patient after two months.

Case B: Courses 14 and 15.—A woman aged 53 gave a history of recurrent rectal bleeding, mucus discharge, and diarrhoea for 25 years. Sigmoidoscopy again confirmed the presence of a haemorrhagic proctosigmoiditis. An initial course of dummy treatment effected a slight improvement in the character of the stools and mucosal appearance, but relapse occurred within two months. A course of potent drug caused a striking clinical remission with a reduction of stool frequency from six to one daily and a disappearance of rectal bleeding. Mucosal appearances were improved.

Case C: Courses 9 and 19.—A woman aged 48 gave a history of ulcerative colitis for one year and severe mucosal inflammation, and ulceration was confirmed sigmoidoscopically. Treatment with the potent drug initially induced a slight improvement, with a reduction of bowel action from eight to five stools daily and a lessening of rectal bleeding. Mucosal inflammation was less marked after treatment. A severe relapse, however, occurred after one month, and treatment on a second occasion by dummy therapy considerably worsened the patient's diarrhoea and the appearances sigmoidoscopically. This patient showed some improvement with systemic corticotrophin, but required surgery to control her symptoms.

It will be seen that two of these patients serving as their own controls showed appreciable advantages in favour of potent therapy. The third patient did not seem particularly responsive to any form of corticoid treatment, but certainly fared better with potent than with dummy treatment. The successful outcome of potent therapy in the majority of patients treated is therefore clearly apparent. A method of sequential analysis used to demonstrate significant differences between the forms of treatment is now detailed.

Sequential Analysis

The statistical technique of restricted sequential analysis has been developed in particular relation to therapeutic trials by Dr. Peter Armitage, and formerly has been used to establish the relative merits of analgesics and cough-suppressive agents (Armitage, 1954, 1957; Newton and Tanner, 1956; Snell and Armitage, 1957). Treatments are allocated to pairs of patients in a random order, and the course of the trial is followed by accumulating the qualitative comparisons between treatments which are provided by each pair of patients. Results are recorded on a chart while the trial is in progress, the boundaries of which determine the minimum number of observations necessary to establish a significant advantage in favour of one treatment. Alternatively, other specified limits indicate that if no significant difference emerges when a certain number of pairs of patients have been treated the trial should be abandoned.

Sequential analysis is therefore the method most economical of patients and of time in the comparison of two treatments, and seemed admirably suited to compare the relative merits of hydrocortisone and a dummy prepara-

tion in the treatment of colitis. By this method the significant advantage of potent treatment has been established in the strikingly small number of 19 treatment periods. Dr. Peter Armitage was kind enough to devise a chart suitable for the trial and to suggest the method of random allocation of the treatments given. Without his generous help the trial could not have been undertaken in this particular form.

Method of Random Allocation

A master sheet was prepared and held by the pharmacist dispensing the two forms of treatment. Pairs of patients, one receiving potent and one receiving dummy preparations, were first paired by the system of random numbers shown below, which is seen to be different for each group of 10 patients studied. The order of treatments given to each pair was determined by the spin of a coin, the next patient entering the trial receiving the alternative treatment and completing each pair. In this way a doubly randomized method of selection was ensured. Pairs of randomized treatments were as follows:

Patient's No.:	1	2	3	4	5	6	7	8	9	10
P	P	D	P	D	P	D	D	P	D	
11	12	13	14	15	16	17	18	19	20	
P	D	P	D	P	P	D	P	D	D	

P=Potent. D=Dummy treatments.

Both patient and physician were unaware of the nature of the treatments given until the course had been completed. Patients told that the relative merits of two unproved therapeutic agents in colitis were being compared, and that they stood even chances of receiving either, agreed willingly to participate in the trial.

Method of Sequential Analysis

The outcome of treatment in the pairs of patients studied is one of the four types indicated in Table V. Potent or inert therapy might be equally successful or ineffective; these are termed "tied" pairs and show no particular advantage for one agent and are not recorded on the chart. Pairs of subjects, where potent or inert therapy is effective in one instance and fails in the other, are termed "untied" pairs, and are recorded on the control chart as a point in favour of one form of treatment. The comparative frequencies of symptomatic remission and mucosal improvement assessed sigmoidoscopically are summarized in Table V, and provided information for separate control charts.

TABLE V

	"Tied" Pairs		"Untied" Pairs	
	+	-	+	-
Potent ..	..	..	..	..
Dummy ..	..	..	..	..
Symptomatic remission ..	2	1	6	—
Sigmoidoscopic improvement	—	2	7	—
Method of recording on chart	Not used in investigation	Plot as point in favour of potent drug	Plot as point in favour of dummy preparation	

Similar success or failure occurred in five pairs of patients which were not used in the investigation. The number of "tied" pairs is the only factor which cannot be predicted in advance in this type of trial. The frequency of "tied" pairs in this trial is remarkably small, as it might have been expected that similar numbers of pairs of patients might be "tied" or "untied." In six pairs of patients symptomatic remissions were induced by hydrocortisone, while in seven pairs mucosal appearances improved with the

potent drug. Inert therapy in each pair of patients was uniformly unsuccessful. The number of untied pairs in favour of hydrocortisone was sufficient to establish a significant advantage when recorded on the control charts.

The outcome of treatment in each untied pair was completed on the chart shown in Fig. 1. Information is entered

FIG. 1.—Sequential analysis chart comparing treatment of granular proctitis with dummy and that with hydrocortisone. Outcome of treatments in untied pairs, starting at point O. For each untied pair favouring hydrocortisone a point is drawn diagonally upwards towards the upper limit of the chart, XX, and for each untied pair favouring inert therapy diagonally downwards towards the lower limit, YY. As soon as one of these limits is intersected the significant advantage of one form of therapy is established. This will occur if 6 of 6, 10 of 11, or 11 of 13 untied pairs favoured one agent. If no significant differences are demonstrated between treatments the control line will oscillate up and down and eventually intersect the inner limits of the chart, ZZ, which might occur after as few as 6 or as many as 13 pairs of dissimilar responses had been entered on the chart. Intersection of these inner limits, ZZ, would indicate that the trial should be abandoned, as no significant advantage for a particular treatment would emerge.

on the chart starting at point O. For each untied pair showing an advantage in favour of hydrocortisone a line is drawn one point diagonally upwards towards the upper limit of the chart XX and for each untied pair in favour of the dummy therapy one point diagonally downwards towards the lower limit YY. If the differences between treatment are great, successive points in favour of the potent remedy rapidly approach the upper limit XX, and once this margin is intersected a significant advantage for potent therapy to the 5% level has been demonstrated.

As will be seen from Fig. 1, this might be possible if six out of six untied pairs favour hydrocortisone when significant differences could be shown after 12 patients had been treated. If one untied pair of patients favoured inert therapy in the course of the investigation the outcome of the trial would be delayed until 10 or 11 untied pairs had favoured hydrocortisone and the upper margin of the chart had been intersected. Finally, if two pairs of patients favoured dummy preparation the outcome of the trial would be delayed until at least 13 untied pairs of patients had been obtained. A similar outcome would occur if dummy treatment was better than potent, when the progression of the line would be downwards to intersect the lower limit YY on the chart. If no significant difference existed between treatments the line would oscillate backwards and forwards and eventually intersect the inner limits of the chart labelled ZZ, which would indicate that even if the maximum number of 13 untied pairs were obtained no significant difference would emerge, indicating the limit to which the trial should be pursued.

The disadvantages of this type of analysis are that the number of tied pairs cannot be predicted precisely and that unless the difference between the agents compared is a great one a significant result will not emerge.

Special charts were used to record the frequency of symptomatic remission and sigmoidoscopic improvement.

The chart illustrating the occurrence of symptomatic remission in the pairs of patients treated is shown in Fig. 2, where it will be seen that remissions were induced in six of six untied pairs treated with hydrocortisone and that the control line favouring this agent rapidly approached the upper limit of the chart, demonstrating a significant advantage in favour of this agent.

FIG. 2.—Sequential analysis chart illustrating the frequency of symptomatic remission in pairs of patients treated is here shown. As remissions were induced in six or six untied pairs treated with hydrocortisone the control line passed rapidly upwards and intersected the upper limit of the chart, demonstrating a significant advantage for hydrocortisone.

An almost exactly similar chart is shown in Fig. 3, where improvement in mucosal appearance assessed sigmoidoscopically has been recorded. Here again seven of seven untied pairs favoured hydrocortisone, and the control line uninterruptedly approached and intersected the upper limit of the chart, demonstrating again a significant advantage for the potent drug.

Hydrocortisone hemisuccinate sodium therefore was shown to be more effective than a dummy preparation after the

FIG. 3.—The frequency with which mucosal appearances improved sigmoidoscopically is entered on this chart, where again the significant advantage of potent therapy is demonstrated by an uninterrupted progression of the control line upwards to intersect the upper limit of the chart after seven pairs of patients had been treated.

small number of 19 treatments had been given and seems a valuable form of therapy for ulcerative colitis, particularly in mild cases where the inflammatory process is confined to the rectum and sigmoid colon. Its use in more severe cases of colitis is being further investigated. In these patients the intravenous administration of 15–30 mg. of propantheline half an hour before the rectal infusion reduces colonic motility overnight and enables the patients with nocturnal diarrhoea to retain the agent overnight. It might also be possible to incorporate the hydrocortisone hemisuccinate sodium in a suppository for use in patients with proctitis. This, too, is being investigated, as this method would prove far more convenient to patients with this disease.

Discussion

The favourable results reported by Truelove in 1956 and 1957 on the treatment of mild cases of colitis by the topical administration of hydrocortisone seemed to merit further inquiry, and for this reason the controlled trial into the value of this mode of treatment was undertaken and has been detailed above.

Truelove in 1956 treated a group of 17 patients with ulcerative colitis on 21 occasions by rectal infusions of a solution of hydrocortisone-free alcohol administered by slow rectal drip, and induced rapid clinical remissions in 14, accompanied in most instances by an improvement in the sigmoidoscopic appearances. A year later he reported a second series of 15 patients with colitis treated on 18 occasions by rectal injection of a solution of the more soluble derivative, hydrocortisone hemisuccinate sodium. Rapid clinical remissions were induced in 11 patients; sigmoidoscopic improvement was observed in every case in remission, accompanied in this instance by reductions in the severity of the inflammatory process judged histologically by serial colonic biopsies and by an improvement in cell morphology as judged by exfoliative studies.

The advantage of potent over dummy therapy has been demonstrated in three ways. Firstly, in the contrasting responses of patients treated in the two ways, where the majority of patients receiving hydrocortisone improved and those receiving dummy treatment worsened. Secondly, in the responses of two patients, serving as their own controls, who received both forms of treatment and who in both cases failed to respond to inert treatment and to undergo remission when potent therapy was given. Finally, by the use of sequential analysis, by which potent therapy was shown to induce symptomatic remission and sigmoidoscopic improvement significantly more commonly than the other form of treatment, the value of the rectal instillation of hydrocortisone hemisuccinate sodium was definitely established.

The new method of restricted sequential analysis designed by Armitage in 1957, modified from the method described by Bross in 1952, proved an extremely satisfactory method of demonstrating the differences, and a significant answer was obtained after 19 treatments had been administered.

Summary

An assessment of the value of rectal instillations of topical hydrocortisone hemisuccinate sodium in patients with ulcerative colitis has been undertaken.

The frequency with which symptomatic remission and sigmoidoscopic improvement were induced has been compared in pairs of patients receiving potent or dummy treatments.

The responses of the groups of patients receiving potent and inert therapy are contrasted. The majority of patients receiving potent hydrocortisone improved and those receiving inert therapy worsened.

In two patients serving as their own controls, dummy treatment failed to induce improvement while hydrocortisone caused a remission to occur.

Finally, comparison by sequential analysis showed that symptomatic remission and improvement in mucosal appearances were significantly more often induced by potent than by inert treatment.

My thanks are due to Glaxo Laboratories, who provided supplies of both potent and inert hydrocortisone for the trial; to Dr. P. Armitage, who designed the sequential analysis chart; and to Professor J. C. Goligher, who performed sigmoidoscopic examinations. I am grateful also to Professor J. C. Goligher, Mr. A. V. Pollock, Mr. G. Smiddy, Mr. E. T. McCartney, Dr. W. S. Suffern, Dr. M. Atkinson, and Mr. D. B. Feather, who referred patients for treatment.

ANKYLOSING SPONDYLITIS

BY

F. DUDLEY HART, M.D., F.R.C.P.

Westminster Hospital, London

In the spring of 1958 a questionnaire was sent to 343 patients with ankylosing spondylitis who had been seen, and the majority treated, at Westminster Hospital since the war. Answers were received from 209; most of the rest were returned by the Post Office, the present address of those patients being unknown. Many of the patients had been seen and treated while in the armed Forces, and the difficulty in tracing many lay in this fact. In the vast majority of cases, however, where the questionnaire was sent to the correct address an answer was received within three weeks, demonstrating once again the high degree of co-operation found in our previous study with this group of patients (Hart, Robinson, Allchin, and MacLagan, 1949). Questions were related particularly to the effects of treatment as assessed by the patient himself and the ability to do his work and earn his own living.

Duration of Disease.—Of the 209 who returned their questionnaires, 23 had suffered from ankylosing spondylitis since before the onset of the second world war, in 58 the onset lay during 1940–4, in 75 during 1945–9, in 44 during 1950–4; in only 9 had it developed since that date.

Results

Work Capacity.—200 question sheets were returned fully completed. Of these, 21 were from women, 179 from men. This 8.5:1 ratio is an artificial one owing to the high number of Service men seen; it therefore does not reflect the true sex ratio in this disease. Of this number, 160 were working full time, and, if housewives, were doing their full duties in the home. Many stated that in addition to their ordinary duties they worked voluntarily in the evenings, and others did gardening and played games. 40 stated that they were incapable of full duties, but only 9 were incapable of any duties whatsoever. 19 were capable of modified duties and 12 of light or occasional duties. In addition the questionnaire had been returned by relatives of four patients, all male, who had died: one of amyloidosis, one of coronary thrombosis, one of carcinoma of the pancreas, and one of a neoplasm of uncertain nature. These figures—160 at full work, 19 at modified work, and only 21 capable of little or no duties—are typical of the group as a whole, and similar figures have been reported by Blumberg and Ragan (1956). Although working full time, many commented that the duties

in their particular post were not physically hard and some that the post had been selected because of their disability. In four instances a regular paid post had been given up for full-time independent work where self-imposed duties could be varied to avoid the stiffness and discomfort attendant on too little mobility at work. Once again the well-known fact became evident that a stiff spine alone does not cripple, though stiff hips and peripheral joint involvement may.

General Health.—Of 191 patients who answered questions relating to their general health, 36 stated it was excellent, 74 good, 71 "fairly good," and 10 poor. Asked specifically about indigestion, 11 complained of severe recurrent or chronic dyspepsia, 38 of more moderate but annoying symptoms. Radiological investigation in 37 cases had revealed peptic ulcers in 10. Of these 191 cases, therefore, 49, or roughly 25%, have dyspepsia to the point of being a definite and occasionally a major complaint. Although some symptoms were obviously related to or aggravated by therapy, this was clearly not so in all cases. This group of spondylitic dyspeptic patients remains a major therapeutic hazard, for almost all current forms of therapy may aggravate gastro-duodenal symptoms or cause complications. Of other disabilities, the next most common was iritis. Although no specific question was asked and although the eye was not mentioned on the questionnaire, 36 patients mentioned iridocyclitis when asked for general comments about their health. One was registered as a blind person from this disability. Three patients were under treatment for pulmonary tuberculosis; one had had a thoracoplasty. Vertigo was mentioned by 7, headaches by 4, anaemia by 4, and recurrent bronchitis by only 4, although 8 made major complaints regarding stiffness of the chest wall and inability to breathe deeply.

Analgesics.—To the question, "What medicines have you found to be most helpful for your spondylitis?" 43 answered none, 49 aspirin in some form, 54 compound codeine tablets, 56 phenylbutazone, and 9 steroid therapy. This last is a small group, as only a small minority had been offered steroid therapy. No other drug was mentioned more than once.

Radiotherapy

One of the main reasons for the follow-up was to learn what the patients thought of the long-term results of deep x-ray therapy and to find out what blood disorders had occurred, if any. The large majority of these patients were treated at Westminster Hospital by Dr. F. M. Allchin, Mr. Tom Prosser, and Dr. Kenneth Newton in the conservative dosage reported by us previously (Hart *et al.*, 1949); only a few treated elsewhere received a total dosage above 1,500 r to any part of the spine, and the majority received under 1,200 r. Of 143 patients who had received therapy to the spine, 114 (80%) stated they had received some benefit, 29 (20%) that they had not. Of those who stated that they had received benefit, 41 (28.7% of all patients treated with deep x rays) stated that some benefit still persisted, after follow-up periods varying from 2 months to 17 years since therapy was given; 27 of these 41 patients had received therapy more than four years previously. 30 patients had had symptomatic relief for six months or less, 18 for seven months to five years, 3 for periods over five years, the effect then completely wearing off. In 22 cases details of duration of relief were not adequately given.

While some of this improvement may be psychogenic and reflect the high optimism of the patients as a group, the stories given fall into fairly regular patterns, and suggest more than "therapeutic persuasion." In some cases the question of introduction of a natural remission has to be considered where for many years after therapy the condition appears to have remained largely or completely quiescent. On these figures it seems that 20% of irradiated spondylitics will derive no benefit whatsoever, 20% a temporary symptomatic improvement for a period of up to six months, the remaining 60% some degree of relief for periods varying from seven months to many years.

Discussion

With so many missing returns no conclusions could be drawn as regards mortality and morbidity, though the main reason for failure to return the questionnaire was the migratory nature of these patients and frequent change of addresses. Nevertheless, of the returns received 80% of the patients were at full work and only 5% capable of no work whatsoever of any sort, the remaining 15% being capable of modified, light, or occasional duties. These figures are the most encouraging we have in the rheumatism unit—far better than those for rheumatoid arthritis. 110 of 191 patients considered their general health good or excellent and only 10 poor.

As regards the most popular of the drugs used it is of interest that aspirin in some form, compound codeine tablets, and phenylbutazone were quoted in almost identical numbers, the last-named coming top in this poll by the narrow margin of two votes. It has been our impression in the unit for some time that, if tolerated, this drug is the single most useful one for spondylitics at all stages of their painful disease, and Bauer and Ropes (1956) found it more useful in this disease than in rheumatoid arthritis.

The effect of any drug, however, depends on its regular daily administration; its beneficial effects rapidly disappear on stopping it. In contrast, deep x rays appear, on this survey, to give some degree of lasting relief in many cases, for 32 of 114 patients (28%) obtained some amelioration of symptoms for over four years. Caution is necessary, however, in interpreting these figures, for a course of deep x-ray therapy, like a surgical operation, sticks in the memory as a landmark in the disease course, and subsequent improvement may falsely be attributed to it when, in fact, natural remission has occurred. Improvement, also, is as compared by the patient with pre-treatment symptoms which were severe enough to bring the patient to hospital. One may therefore be comparing symptoms of exacerbation with symptoms of remission, and the therapy given between the two may have been unrelated. A second point to emphasize is that it is impossible on the returns to tell whether symptomatic improvement was great or small; all that can be said is that some measure of symptomatic improvement occurred after therapy.

Wilkinson and Bywaters (1958) found that 43% of 200 irradiated patients required no regular analgesics within a year of completion of therapy, this figure dropping to 22% after a ten-year follow-up. These figures, obtained by clinicians from assessment of analgesic consumption, do not differ very greatly from those obtained by us from an assessment of our patients' own statements.

While I have hitherto been doubtful about the induction of natural remission in this disorder by this form of therapy, there is some indication on these figures that it may occur. The hazards of irradiation are well known, and have latterly received much attention; it is as well to record the reverse side of the coin.

Summary and Conclusions

Question sheets were sent to 343 patients with ankylosing spondylitis, and 209 answers were received. Of these returns, four were from relatives of deceased patients, and five were incomplete. Of the 200 fully completed returns, 179 were from men, 21 from women.

160 (80%) stated that they were working full time; 19 were capable of modified duties, 12 of light or occasional duties; and only 9 were permanently incapable of any work whatsoever.

Of 191 patients who answered questions relating to their general health, 36 stated that it was excellent, 74 good, 71 fairly good, and 10 poor. 11 complained of severe, 38 of moderate but annoying dyspepsia. X-ray examination in 37 cases revealed peptic ulcers in 10.

Of 143 patients given deep x-ray therapy to the spine, 114 (80%) derived some benefit; 41 (28.7%) claimed some measure of lasting relief, which still continues 2 months to 17 years after treatment. Of these 41 patients 27 were irradiated over four years previously. 30 claimed transient improvement lasting six months or less, 18 improvement for periods of seven months to five years, 3 for more than five years. 32 of 114 (28%) of these patients derived some measure of symptomatic relief for periods exceeding four years.

These results once again emphasize the relatively good prognosis as regards work capabilities in this group of patients and a reasonably satisfactory response to existing forms of therapy.

My thanks are due to Professor J. H. Kellgren and Dr. J. Sharp, of the Rheumatism Research Centre, Manchester University, for their helpful and constructive comments.

VALUE OF AZACYCLONOL ON
CHRONIC SCHIZOPHRENIC PATIENTS

PRELIMINARY OBSERVATIONS

BY

SYLVIA REID, B.A., M.B., D.P.M.

Consultant Psychiatrist, Carlton Hayes Hospital,
Narborough, near Leicester

Azacyclonol hydrochloride ("frenquel") is the gamma isomer of pipradrol hydrochloride ("meratran"), the latter drug being used in this country as an antidepressant agent. Chemically, azacyclonol is α -(4-piperidyl) benzhydrol hydrochloride. Despite its structural resemblance to pipradrol, azacyclonol has been reported to possess different clinical properties inasmuch as it exerts a tranquillizing effect.

Both mescaline and L.S.D.25 have been reported to produce states resembling schizophrenia. Fabing (1955a, 1955b, 1955c), working in the United States, has reported a series of controlled experiments on "normal" volunteers who were each given L.S.D.25. This dose produced a characteristic psychosis with symptoms resembling schizophrenia. The experiment was then repeated, but some of the volunteers were given a course of azacyclonol prior to the administration of the L.S.D.25 and the other volunteers were given control tablets. It was observed that, although the effects of L.S.D.25 began as usual, the more acute symptoms were inhibited in the patients who had been pretreated with azacyclonol. The vivid hallucinatory experiences were absent and some of the group even succeeded in carrying out their normal duties. It would appear from this work that azacyclonol has some blocking effect in experimental psychosis or clinical conditions of disorientation.

The nature of this neurochemical effect is not yet fully understood.

Fabing and Hawkins (1955) have reported on clinical trials with azacyclonol in a series of acute and chronic schizophrenic patients. It appears that azacyclonol affords schizophrenic patients some amelioration of

their symptoms and that it might be a useful addition to the ataractic group of drugs. It was therefore decided to attempt a controlled study of the value of azacyclonol in a group of chronic schizophrenic patients.

Method

Twelve female patients were selected. Their ages varied from 19 to 54 years, with an average of 36.9. The 12 patients were then divided equally into groups known as A and B. The total period of the trial was to be 12 weeks. For the first six weeks the six patients in group A received azacyclonol and the remainder (group B) received identical placebo tablets. The converse of this arrangement was used for the second six weeks.

The experiment was conducted by the usual "double blind" technique. The issue of the tablets was controlled by a member of the male nursing administrative staff who did not know the patients concerned in the trial, and selected the patients for the two groups in a random manner. Until the period of the trial was complete no one else knew which patients were receiving active and which inert material, and all observations were made before the key was broken. During this time none of the patients selected received any other forms of medication, with the exception of one patient, a chronic asthmatic, whose ephedrine, ½ gr. (32 mg.) daily, was continued.

All patients were interviewed prior to the beginning of the trial and their type of schizophrenia was classified as follows: simple, 1; katatonic, 2; hebephrenic, 3; paranoid, 6 (see Table).

The following adjustments were made in ward routine to facilitate observation of the patients. Nurses were instructed to make notes on their patients' behaviour in a special book, with emphasis on the following points: (1) hallucinations, commenting whether patients behaved as if hallucinated or admitted to hallucinatory experiences; (2) degrees of accessibility of patients to friendly approaches by staff or whether hostile, aggressive, or asocial; (3) helpfulness in ward; willingness to partake in household duties and to show initiative with regard to these; (4) response to efforts of staff to keep them tidy in dress and clean in habit; and (5) whether interested in hair styles and responsive to normal use of cosmetics.

Handicraft classes took place in the ward and not in the occupational therapy centre, to maintain continuity in the observation of the patients. The nursing staff assisted at the occupational therapy and accompanied the patients when they were engaged in activities outside the ward—for example, dancing classes, P.T. classes, and walks.

M. B.	"	"	Deteriorated	Much improved
M. Bu.	Katatonic	"	Improved	Improvement maintained
J. K.	Paranoid	"	Deteriorated	Much improved

Results

Three patients were much improved when receiving azacyclonol. These three patients had several features in common. They were all paranoid schizophrenics, hallucinated, and hostile. They were also asocial, with a tendency

to be aggressive if disturbed. Here are summaries of their case histories.

J. K., aged 29. She was suspicious and at times violent, responding to auditory hallucinations and delusions of persecution. On placebo (phase 1) she deteriorated. On azacyclonol she improved and became more accessible. She did not appear so distressed by hallucinations and co-operated in various occupational activities. Her condition deteriorated again after cessation of the trial.

K. B., aged 49. She was sullen, asocial, and suspicious, with no insight. She experienced auditory hallucinations, during which she heard voices of men planning sexual assaults. She had occasional outbursts of physical violence. Her behaviour improved with azacyclonol. She became friendly, co-operative, and helpful with regard to domestic duties. She did not appear to be hallucinated, and denied hallucinatory experiences. Previously she had freely admitted these. Her behaviour deteriorated steadily throughout the placebo phase and the subsequent period after the trial.

M. B., aged 54. At the time chosen for this trial this patient was almost constantly hallucinated. All day long she carried on noisy and interminable conversations with hallucinatory voices. These outbursts often continued far into the night. It was with considerable fortitude that the nursing staff bore with her behaviour and adhered to the rule that nothing other than azacyclonol or placebo should be used during the trial. On azacyclonol her behaviour improved and she became much quieter. She took part in occupational therapy and her hallucinations appeared to diminish in force and intensity.

It will be observed also that two other paranoid schizophrenics displayed no appreciable change throughout the course of the trial. Both of these patients (K. G. and T. S.) had histories of being hallucinated, but did not appear to be so at the time of the trial. Both had well-preserved personalities despite the chronicity of their illnesses, and both had delusions of the paranoid type. It will be appreciated that it is more difficult to observe changes in this type of patient than in the more grossly disintegrated personalities of K. B., M. B., and J. K.

Five further patients showed some improvement in the azacyclonol phase. One of these maintained her improvement later on placebo, but two deteriorated in the placebo phase.

O. R. showed some improvement on placebo in phase 2 but deteriorated after cessation of all tablets.

Discussion

The number of patients selected for this trial was small because it was felt that it would be difficult to assess accurately a larger number of patients. It must be remembered that the nursing staff conducting this trial also had the responsibilities of their routine ward duties.

Conflicting reports have been published referring to the use of azacyclonol. It has been suggested that its major use is for hallucinated patients where the hallucinations are of either schizophrenic or toxic origin (Fabing and Hawkins, 1955).

Later publications, such as reports by Ferguson (1956) and Cohen and Parlour (1956), have shown that higher doses than those used in the trial may be more effective. Recent work with azacyclonol in this hospital has confirmed these observations. It is possible that the principal use of this drug lies as an adjunct to other forms of therapy, when quite noticeable improvement may sometimes be obtained. Fortunately, even in combination, high doses of azacyclonol can be given, as it appears to be completely free from all forms of toxicity and side-effects.

During the early part of the trial detailed blood tests were carried out on all patients, but as no change could be detected this procedure was considered unnecessary and deleted from the programme.

Summary

A study of the effect of azacyclonol on 12 schizophrenic female patients is reported.

The double blind technique was used throughout with the dose standardized at two tablets three times a day (120 mg. daily). In every case all other psychiatric treatment was withdrawn for the duration of the trial.

Substantial improvement was noticed in three patients and some improvement in a further five.

No side-effects were noted.

It would appear that further trials with this drug in disturbed hallucinated patients would be justified and possibly very helpful.

I should like to thank Dr. D. F. Macgregor, medical superintendent of Carlton Hayes Hospital, for his co-operation and assistance with the trial. Also Mr. Mills, senior technician, Mr. Cannings, and other members of the nursing staff. My thanks are also due to Mr. B. A. Weightman, of Riker Laboratories Ltd., who kindly supplied the azacyclonol used in the trial.

AN AFRICAN'S MENTAL OUTLOOK IN BRITAIN

BY

W. I. B. ONUIGBO, M.B., Ch.B., B.Sc.
House-physician, General Hospital, Enugu, Nigeria.
W. Africa; Lately Nigeria (Eastern Region)
Government Scholar, Glasgow University

"Were all the circumstances, internal and external, scanned closely and weighed accurately it would be seen that there is no accident in madness" (Maudsley, 1879).

To-day, considerable effort is being expended on establishing "scientifically attested knowledge" about how to keep normal persons mentally healthy (Bartlett, 1949). How to maintain the mental health of university students is a serious problem (Parnell, 1951; Gibson, 1953). Indeed, tuberculosis and mental diseases are "the two major medical problems among undergraduates" (Practitioner, 1957).

Immigrants suffer mental ill-health more commonly than do the indigenes (Hill, 1943; Crew, 1955). It stands to reason that the mental health of foreign students must be an even graver problem than that of the British-born.

Otis (1955), of Illinois University, has discussed the mental-health problems of foreign students in America. He recommended that "in order to better prepare future students" there was need to analyse problems "met by one's countrymen who have been students abroad." I wish, therefore, to report my own experiences while studying in Britain. It is hoped that this may be of some help to those who are in a position to counsel foreign students.

Writing on colour prejudice in Britain, Richmond (1954) stated that "examples can be cited of psychotic individuals whose behaviour is clearly conditioned by the conflicts that they have experienced through racial prejudice in this country." Sclaire (1953) also drew attention to the effect that racial discrimination has on the neurotic pattern seen among American negroes.

If colour prejudice can thus undermine mental health, in what way may the negro student be safeguarded? In presenting my own solution I have in mind what Max-

well (1871) told a meeting of the British Association for the Advancement of Science in 1870: "It was a great step in science when men became convinced that, in order to understand the nature of things, they must begin by asking, not whether a thing is good or bad, noxious or beneficial, but of what kind is it? and how much is there of it?"

Present Investigation

Human beings are "notoriously elusive subjects for objective study and quantitative measurement" (McCalman, 1953). An objective assessment of discriminatory trends in a British city has been made, using a simple, measurable, behavioural quantity—namely, the presence or absence of courtesy in a public utility.

Between November 22, 1954, and November 8, 1955, whenever I paid my fare in any Glasgow Corporation transport I took careful note of whether my fare was accepted with thanks or not with thanks. As a control, I observed whether a European passenger, whose fare was taken just before, or, failing that, just after mine, was thanked or not.

In all, 500 journeys were made. Three types of data were obtained and entered in my diary, each record being made soon after the journey.

Type I—408 cases in which a European fellow passenger and I were both courteously thanked; type II—73 cases in which neither of us was thanked; type III—19 cases in which a European was thanked but I was not. In no case was I thanked but not a near-by Caucasian.

Discussion

It was Lord Lytton (1956) who said that "courtesy is a duty public servants owe to the humblest member of the public." Indeed, the General Manager of Glasgow Corporation Transport Department (1955) reported that his "greatest difficulty is to inculcate amongst the staff a spirit of courtesy and pride of service." Since courtesy is valued so highly in Britain, this social grace is a dependable criterion for a scientific analysis of discriminatory behaviour in this country.

From the above analysis we see that in only 19 cases out of 500 was there acceptable evidence of discrimination. This finding is not statistically significant ($\chi^2=0.72$, $P<0.05$).

The 73 type II cases are noteworthy. Each is potentially fraught with the danger that the negro might think that there was discrimination. If he is not to think so, then comparable discourtesy to Europeans travelling with him has first to be observed. How often, we may well wonder, would such a controlled observation be made in everyday life? Kenneth Little (1947) has said that the negro in Britain may often suspect discrimination and aloofness "where they were never intended." I think that this is true.

What clinical clue, if any, does this conclusion contribute? Weinberg (1955) found that "too frequent and embarrassing uncertainties may lead to inner insecurity, or cause a latent insecurity to become overt." Or, as Hume (1947) put it, sociological factors may undermine mental health by "multiplying precipitating situations." Consequently, the negro student who overestimates prejudice multiplies psycho-social trauma and runs a graver risk of mental breakdown. It is in his own interest that he does not make this mistake.

Admittedly, other investigations may yield a different result; for example, if a criterion other than courtesy is employed. Nevertheless, we may conclude that if there is insight into the difference between real and imagined prejudice the probability is that the threshold of what is unbearable will not be approached. Mental hygiene requires that "environmental difficulties should not be excessive" (Stevenson, 1945). As Bartlett (1949) also said, "there are limits of toleration, both environmental and internal, the persistent passing of which leads to mental trouble."

In education for mental health, correct perception of reality is important (Florence Clothier, 1951). If other

essentials such as financial backing and academic background are satisfactory, a correctly oriented negro student will, like Richmond's (1954) ideal, "not be unaware of the frustrations and tensions which negroes experience, but he will be able to face up to such conflicts, precisely because he has succeeded in achieving, for himself, a measure of status and security. He is less bound by the personal anxiety and inner conflicts which besiege so many of his fellows."

Conclusion and Summary

In Britain to-day the mental health of undergraduates is receiving considerable attention. Since immigrants and those open to racial discrimination are prone to suffer mental ill-health, the mental health of the negro student must be an even graver problem than that of the British-born.

Courtesy shown to me and to European fellow passengers by Glasgow Corporation transport workers has been scientifically analysed. The survey suggests that the negro student may easily overestimate the incidence of racial prejudice.

Now, unfavourable sociological attitudes such as prejudice tend to precipitate mental breakdowns, particularly when they are recurrent. Consequently, adequate insight into the racial environment in Britain will, by ruling out instances of imagined rather than real discrimination, help the African student or a student of other lands to maintain a healthy mental outlook while in this country.

Medical Memorandum

Congenital Reduplication of Ileo-caecal Valve Presenting as an Acute Intussusception

The presence of two separate openings in an intussusception protruding from the anus is unusual enough to be worthy of record. Kolb *et al.* (1956) reported a case of intussusception presenting at the anus with duplication of the caecum, but not of the ileo-caecal valve.

CASE REPORT

A male child aged 19 months was admitted to hospital on July 1, 1955, with a diagnosis of intussusception. He was a firstborn, and was quite well until a week before admission, when he developed abdominal pain and looked ill. Forty-eight hours before admission this pain seemed to become worse, and on the next day he vomited four times and passed loose stools. No blood was seen. On the day of admission he vomited three times, and the mother noticed "that something was protruding from the back passage."

On examination he was a well-nourished but very ill boy, being pale and listless, with a temperature of 99.4° F. (37.4° C.) and a pulse rate of 130. A sausage-shaped tumour was felt in the left iliac fossa and a portion of bowel 5 cm. long was protruding at the anus. On closer examination this was found to have two separate openings, one at the tip and one on the left side. A catheter could be passed into each opening separately for a distance of 15 cm. without difficulty.

At operation the prolapsed bowel was reduced inside the rectum. Laparotomy through a left lower paramedian incision showed a little blood-stained fluid in the peritoneal cavity. The intussusception was felt at the level of the pelvic floor and reduced without difficulty. The appendix and caecum were congested but viable. The terminal ileum was adherent to the ascending colon for 5 cm. above the ileo-caecal valve. As the child was very ill the abdomen was closed rapidly, but, despite emergency measures, he died a few minutes later.

Necropsy (Dr. J. B. Enticknap).—The terminal ileum and lower right colon were congested. The last 4 cm. of the former was firmly attached to the caecum and opened into it at both ends of this length (see Diagram). The lower opening was a normal valve in position and form. At the upper one the ileum entered the caecal lumen and almost immediately left it again. Histological section at this point showed the muscular walls of caecum and ileum to be continuous and regular, about 6 mm. of the ileum in the fixed and paraffin-embedded specimen forming part of the caecal wall. There was moderately advanced bronchopneumonia of the right upper lobe and an acute tracheobronchitis causing partial collapse of the periphery of both lungs.

COMMENT

The necropsy findings suggest that the two openings in the bowel prolapsing at the anus were separate ileo-caecal valves, and the regularity of the continuous smooth-muscle layer surrounding them makes it probable that this was a congenital reduplication and not an acquired internal fistula. Gross (1953) reported that 3 out of 702 intussusceptions were due to duplication of the terminal ileum, but neither in his report nor elsewhere have any instances of two valves on a single terminal ileal tube been found.

I thank Mr. R. Parkinson for his help and permission to publish this case.

The Government is prepared to consider proposals for individual colours to be added to or removed from the permitted list now embodied in the *Colouring Matter in Food Regulations, 1957* (S.I. No. 1066), and the *Colouring Matter in Food (Scotland) Regulations, 1957* (S.I. No. 1123). The list as a whole is likely to be reviewed in less than five years, but interim modifications to the list are envisaged should new developments in colour manufacture or food processing, or fresh evidence relating to the safety or otherwise of colours, make this desirable. All such proposals should be addressed in the first instance to the assistant secretary, Food Standards, Hygiene, and Slaughterhouse Policy Division, Ministry of Agriculture, Fisheries, and Food, London, S.W.1.

Reviews

INTERNATIONAL OPHTHALMOLOGY

A Century of International Ophthalmology (1857-1957): Written at the request of the International Council of Ophthalmology. By Sir Stewart Duke-Elder. (Pp. 91; illustrated. 12s. 6d.) London: Henry Kimpton. 1958.

It is indeed appropriate that the task of writing this interesting historical record should have been undertaken by Sir Stewart Duke-Elder, president of the International Council of Ophthalmology, for no one has done more to further the international life of ophthalmology than he. The oldest international medical congress that survives to-day is the International Congress of Ophthalmology, the first meeting of which took place in 1857 in Brussels, the eighteenth meeting being due to take place in the same city in September of this year. If, however, the projected sequence of four-yearly meetings had not been disturbed by wars this year's meeting should have been the twenty-sixth.

This little book of praiseworthy brevity is fascinating to read. The list of chief topics for discussion at each congress shows the trend of ophthalmic thought over the years. The photographs of each successive president add to the attraction. Not the least interesting part of this book is concerned with the reflections of Sir Stewart on international congresses in general. He rightly emphasizes their value, but expresses some dismay at the increasing size of the congresses, which tends to replace the informal give-and-take argument, so valuable from the scientific point of view, by a purely formal discussion or even no discussion at all. He also deplores the increasing cost of the congress, which raises the subscriptions and thus tends to exclude the young ophthalmologist—indeed, the very man who will probably profit most from such meetings.

In Part II of the book Sir Stewart describes the activities of the International Council of Ophthalmology (formed in 1927) and its relation to other sponsored international ophthalmological bodies, and refers briefly to some of its future problems.

This book (as its author suggests) should inspire future generations to maintain the unity and brotherhood of ophthalmologists throughout the world.

T. KEITH LYLE.

INTRODUCTION TO PSYCHOLOGY

Introduction to Psychology. By Ernest R. Hilgard. Under the general editorship of Claude E. Buxton. Second edition. (Pp. 653+xv; illustrated. 55s.) New York: Harcourt, Brace and Co. London: Methuen and Co., Ltd. 1958.

This is the second edition of a very well known and widely used introduction to psychology. There can be no doubt about its excellence, and, though one may upon occasion disagree on points of detail, Hilgard has certainly succeeded in the main in his endeavour to present a fair and widely acceptable review of modern psychology. The new edition has been completely rewritten, and is an improvement on the first in that it sheds to a large extent the slight traces of dogmatism which were so characteristic of the earlier work.

The book is well produced and extremely well illustrated by photographs and diagrams. Indeed, if one were to make a criticism one might say that it is too well produced. The constant changes in size of type, cross-headings, etc., while obviously meant to help the reader, may be found rather distracting. Furthermore, many of the pictures seem quite unnecessary; the fact that Mozart revealed his talent for music at the age of 3 can surely be put over without including a badly reproduced picture of the infant prodigy. This American habit of making learning painless by "visual aids" assumes a level of willingness to learn rather lower than is likely to be found in Great Britain. If half the pictures had been omitted the volume could have been produced much more cheaply; it would also have gained in

dignity. However, these criticisms do not alter the fact that this is among the three best introductions to psychology available at the present moment. It will undoubtedly have a wide sale in Britain also.

H. J. EYSENCK.

MEDICAL ANNUAL

The Medical Annual, 1958. A Year Book of Treatment and Practitioners' Index. Edited by Sir Henry Tidy, K.B.E., M.A., M.D.(Oxon.), F.R.C.P., and R. Milnes Walker, M.S.(Lond.), F.R.C.S. (Pp. 580+x1; illustrated. 42s.) Bristol: John Wright and Sons Ltd. Toronto: The Macmillan Company of Canada Ltd. 1958.

Slight changes have been made in this 76th issue of the *Medical Annual*. Hitherto the articles have been arranged in alphabetical order. Now the year's work is reviewed in subsections complete in themselves, which run from Alimentary Diseases to Vital Statistics. This method encourages browsing, which is the attraction of a work of this kind, and there is an excellent index which makes it easy to look up a particular topic. The special articles at the beginning of the review deal with intersexuality, wound infection in operating theatres, dangers arising from the medical use of x rays, and the changing emphasis in paediatrics. There are the usual indexes of pharmaceutical and dietetic preparations, surgical appliances, and books of the year. The contributors all seem to be reporting from the active front of medical progress, and the reader of this volume will have a sound idea of recent advances in medicine. The *Medical Annual* is designed to appeal to medical practitioners throughout the Commonwealth, and it seems likely to continue to do so. It is not afraid of describing not merely the useful, as in the reagent strips for urine testing, but the dramatic, as in the extracorporeal circulation whereby the heart can be arrested and laid open for cardiac surgery, and also the bizarre, as in the series of lesions of the male urinary tract. It is something to have learnt that the erythroplasia of Queyrat is not a blood disorder but a lesion of the penis.

L. J. WITTS.

CORONARY HEART DISEASE

Coronary Heart Disease: Angina Pectoris; Myocardial Infarction. By Milton Plotz, M.D., F.A.C.P. Foreword by William Dock, M.D. (Pp. 353+x; illustrated. 90s.) London, Toronto, Melbourne, Sydney, and Wellington: Cassell and Co., Ltd. 1957.

Coronary heart disease, in spite of the intensity of clinical and metabolic and other investigations into its aetiology and natural history, remains one of the obdurate challenges in clinical medicine to-day. As the last important study of these diseases was published eight years ago, the appearance of *Coronary Heart Disease* by Dr. Milton Plotz is of particular interest. He approaches this problem with the concept that this disease is not an inevitable part of senescence, but a malady in which pathogenesis and treatment and prevention have to be studied. The author's interest is so great and his scope so wide that it is hard to find any aspect of coronary heart disease not touched upon and illuminated. The aim of presenting conflicting views in a fair and impartial way has been achieved, but Dr. Plotz has rightly stated his own opinions and practices, which are obviously founded upon a very great experience. To indicate the diversity of themes dealt with in these pages the following among the chapter headings are quoted: geographic and ethnic factors, lipid metabolism, tobacco, ballistocardiography, differential diagnosis, anticoagulant therapy, and surgical and preventive and medico-legal aspects, though this last relates to American law, which differs in material respects from the English.

Any physician who wishes to know the current outlook on any problem relating to coronary disease would be well advised to look herein and, if need be, amplify by study of the bibliography, which is well chosen but derived very largely from North American and British sources.

K. SHIRLEY SMITH.

SYSTEMIC PATHOLOGY

A Text on Systemic Pathology. Volume I. Edited by Otto Saphir, M.D. (Pp. 865+xv; illustrated, \$32.00.) New York and London: Grune and Stratton. 1958.

This volume, the first of two, departs from the conventional textbook in its restriction to systemic pathology. Its aim is to provide a work of reference for students and hospital pathologists. Though eleven contributors are listed, Dr. Saphir is personally responsible for most of the book, which includes the cardiovascular, respiratory, urino-genital, and haemopoietic systems. The treatment of these is in general comprehensive and up-to-date, and the text is generously illustrated in black-and-white. Bibliographies are provided at the end of each section.

The success of so ambitious a venture must rest largely upon comprehensiveness and ease of reference, and in these respects it is not above some criticism. For example (p. 460), "Hydronephrosis, Pyelitis and Destructive Pyelonephritis" heads a section in which these conditions are inextricably mixed. It includes, moreover, an illustration of necrotizing papillitis, but the description of the latter appears elsewhere (p. 398) under the main heading of "Nephrosis," without cross-reference to the illustration. If this arrangement is odd, it is even odder to find (p. 169) a note of the endocardial changes found in malignant argentaffinomas in the chapter on congenital heart disease. It seems disproportionate to allocate 28 pages to the subject of hermaphroditism and pseudo-hermaphroditism, interestingly though this is presented, while only 37 pages go to the diseases of arteries, 15 to the testis, and 12 to the spleen. The account given of the last of these omits mention of the storage of cystine in the splenic pulp and other parts of the reticulo-endothelial system in cystinosis. It is also surprising that no distinction is drawn between normocholesterolaemia and hypercholesterolaemia in describing the related storage phenomena in the section on lipidoses. The thymus is ignored both in the chapter on mediastinal pathology and in the treatment of the reticulo-endothelial system. This organ is doubtless relegated to the second volume, but it would seem to deserve some attention in the places indicated.

Despite these criticisms this is a book which can be fruitfully explored upon a wide range of topics, and it can only be regretted that the high and rising prices of this type of work inhibit a wide circulation on our side of the Atlantic.

DOROTHY S. RUSSELL.

CHOOSING DRUGS

Drugs of Choice, 1958-1959. Edited by Walter Modell, M.D. (Pp. 931. 95s.) London: Henry Kimpton. 1958.

There are numerous American textbooks of therapeutics, nearly all written by a team of authorities. Most of them are excellent, their only drawback being their size and price, since it may be doubted whether it is justifiable to purchase such sumptuous volumes on a subject undergoing such continuous and rapid metamorphosis. There are also several American textbooks of applied pharmacology, including Goodman and Gillman, which must be regarded as one of the medical classics of the century. The collaborative work under review is not strictly a textbook of therapeutics nor one of applied pharmacology, but something between the two. It seeks to supply the physician with information about the drug of choice for each therapeutic problem with which he may be confronted. The 35 chapters are concerned with the choice of a diuretic, the choice of an anti-infective agent, the choice of drugs for gastrointestinal disturbances, and so forth. Each section contains a short discussion of the clinical condition for which the drugs under consideration are used, an account of the several agents commonly employed in its treatment, and the nature of the available data which make one or another the more desirable. At the end of each chapter there is an extensive, but not necessarily complete, alphabetically

arranged drug index of the agents commonly used for the disorders under consideration, their dosage, and their proprietary names.

There is a great deal of valuable and wise information in this volume, but it is probable that more conventional textbooks on therapeutics are preferable. There are so many conditions in the treatment of which drugs play little or no part—hyperparathyroidism, for example—which cannot be dealt with satisfactorily by the method adopted, and the treatment of diabetes takes only one and a half of the 931 pages of the book; indeed, the choice of the insulins and hypoglycaemic agents is very inadequately discussed. It is always difficult to obtain a uniform method of presentation in 35 chapters written by 37 contributors, and it must be confessed that the editor of this work has not been entirely successful in this respect.

D. M. DUNLOP.

MODERN DEVELOPMENT OF SURGERY

The Surgeon's Tale. A Story of Modern Surgery. By Robert G. Richardson. (Pp. 256. 25s.) London: George Allen and Unwin Ltd. 1958.

In a modest preface the author of this book tells us that it was written "primarily for the reader with no medical background." He has actually done better than this. He has produced a readable, up-to-date account of the development of surgery during the past hundred years which can be read with advantage by readers who do possess such a background.

Recent books on the subject written for laymen have lacked balance and have over-dramatized certain parts of the subject. Here the writing is conscientious, factual, moderate in tone, and more detailed. Though the headings of the chapters may seem popular—"Bugs and Carbolec," "Mainly a Matter of Guts," "Into the Unknown"—the writing is serious and sensible. Yet even with the aid of a glossary (which is provided) it would be difficult for the uninitiated to understand the many operations for hernia or for hydrocephalus which are here described. If, then, we are not certain whether it will appeal to laymen, we have no doubt that medical students and practitioners will alike benefit by reading it, and every surgeon under the age of 50 (and many over that age) will find in it many facts which are new to him. There are some minor errors, but as a whole the book is reliable and accurate and is to be recommended.

ZACHARY COPE.

Volume XXII of the *Cold Spring Harbor Symposia on Quantitative Biology* is devoted to "Population Studies: Animal Ecology and Demography." Subjects discussed include the history of human populations, demographic theory, experimental and theoretical studies of animal populations, the growth of human populations, the ecology of natural populations, the structure of communities, and the population as a unit of evolution. The volume is available from the Biological Laboratory, Cold Spring Harbor, L.I., New York, price \$8.

The third edition of *Recent Advances in Oto-laryngology* (438 pp.; J. and A. Churchill, Ltd., 60s.) is the work of F. Boyes Korkis. Previous editions were by R. Scott Stevenson, who contributes a foreword to the present edition. The book has been entirely recast, rewritten, and enlarged. With the exception of some important historical references, the author has confined himself to an evaluation of work published mostly during the last five years. Many useful illustrations are included.

In the second edition of Dr. Sheila Sherlock's *Diseases of the Liver and Biliary System* (pp. 719+xvi; Blackwell Scientific Publications, 57s. 6d.) some careful pruning has made it possible to include new material without adding to the bulk of the book. A chapter has been devoted to jaundice, and the section on jaundice in infancy has been expanded into a more general account of hepatic disease in infancy and childhood. A new classification of hepatic cirrhosis has been included; a number of other additions reflect the advances made in the knowledge of the subject since the first edition appeared in 1955.

LONDON

SATURDAY NOVEMBER 1 1958

ALLERGIC ENCEPHALOMYELITIS

Myelinated brain tissue contains some so far unidentified chemical substance which, by subcutaneous injection, can cause severe lesions in the central nervous system. Another component of the nervous tissue can produce polyneuritis and polyradiculitis in experimental animals.¹ The first indication of this phenomenon, and of its relevance to human pathology, was provided by the neuroparalytic accidents of anti-rabic treatment. The use of Freund's adjuvants (paraffin, lanolin, and heat-killed *Mycobacteria*)—which enhance antibody production in known immunological systems—along with the sterile brain tissue, regularly resulted in acute disseminated encephalomyelitis in a wide variety of species. The process is organ-specific but not species-specific. Moreover, since intramuscular injection of the animal's own sterile brain tissue, removed by lobotomy,² also caused the disease, experimental support was provided for the postulate of a morbid autoimmunity mechanism.

Perivenous inflammatory infiltrates with a variable degree of perivenous parenchymatous necrosis or demyelination are seen, and histologically the appearances are like those of the human post-exanthematous and post-infectious "myelinoclasts." Because of the curious uniformity in the character, and in the time of onset, of human post-infectious encephalomyelitis, independent of the nature of the primary infection, it had earlier been postulated that post-infectious "myelinoclasts" might be a specific disease process,³ possibly involving sensitization of the nervous tissue.⁴ The discovery of experimental allergic encephalomyelitis has therefore suggested

strongly that this may be the counterpart of this group of human encephalomyelitides. However, a connexion between exanthematous infections and encephalomyelitis has not yet been successfully shown experimentally.⁵ Furthermore, since some workers on human demyelinating disease see no hard-and-fast distinction between acute disseminated encephalomyelitis and multiple sclerosis, it has seriously been postulated that the latter disease also may belong to a group of immunopathological diseases of the nervous system. This thesis was warmly received by many neurologists at the International Congress of Neurological Sciences in Brussels in 1957 in view of the demonstration there, by Y. Uchimura and H. Shiraki,⁶ of the striking similarity of human post-rabic vaccinal encephalomyelitis to multiple sclerosis in Japan, where the latter disease is considered to be rare.

The fact that this experimental disease is a non-infective process has been established beyond doubt. For histopathologists it is an education to reflect that this "allergic" encephalomyelitis often far exceeds the most severe of known infective processes in the extent of the visible structural changes which it causes. And in this respect it can be said that the detection of this purely immunopathological process, along with its close counterpart, iso- and auto-allergic thyroiditis, opens up an entirely new field of structural pathology.

Whereas allergic encephalitis was primarily an empirical discovery in experimental pathology and its immunological background remains to be elucidated, experimental allergic thyroiditis is a discovery directly derived from systematic studies in the immunology of tissue substances. E. Witebsky and N. R. Rose⁷ found that antisera both to purified thyroglobulin and to unfractionated extracts of thyroid gland contained antibodies which were thyroid-specific and not species-specific. Quantitative studies indicated that the thyroid specific antigens, though closely related, were not identical in all species. When, following partial thyroidectomy, an animal was injected with extracts of its own thyroid tissue along with adjuvants, similar antibodies could be shown to appear in its serum. Witebsky and Rose⁸ have shown that these are true antibodies to thyroid protein. Thus, a specific antibody-globulin was produced autogenously in response to an identifiable protein identical with, or very closely related to, the animal's own thyroglobulin. As there was the possibility that denaturation in extraction had rendered thyroglobulin antigenic, the next step was to determine if the circulating antibody had affected the natural substance in the animal's own gland. This led to the discovery of

gross histological changes accompanying the rise of anti-thyroglobulin titre in the circulating blood. The circle of evidence establishing the authenticity of auto-antibodies and of auto-antibody disease would seem to have been successfully closed, and the thyroiditis system must serve as a model for studies of diseases where auto-immunization is postulated.

The present state of the immunology of experimental allergic encephalitis, reviewed recently,⁹ is by comparison still unsatisfactory, and there are important differences in detail from thyroiditis. Immunologically, Witebsky's species-nonspecific neural antigen,¹⁰ a lipopolysaccharide, is not itself the encephalitogenic factor. The brain disease occurs much more quickly than the thyroid disease. The antigen seems to be related to the myelin, and each of three types of chemical substance—certain proteolipids, certain proteins, and a phospholipid (? impure)—has encephalitogenic properties, though together they do not account for the total activity of crude brain tissue. Pending identification and purification of an encephalitogenic antigen, studies of the antibodies produced by the injections have been limited to complement-fixing antibodies (tested with crude extracts), and these have shown no clear relation to the disease in the brain^{11 12}; nor has either humoral or cellular passive transfer of disease been proved possible.¹³ Delayed skin reactions are the only immunological reaction yet found¹⁴ which show any correlation with the development of the disease, and this evidence is so far probably the best favouring the hypothesis of a delayed sensitivity of the tuberculin type as the probable immunological mechanism whereby the brain lesions are produced. The proliferation of the reticular cells in the brain and their maturation to plasma cells strongly support the idea that there is local formation of antibody in the brain itself—though for the same reason it seems this must also occur in the thyroiditis system. Lumsden^{15 16} has drawn attention to the localization of the reactive process to the venules in the brain, and has suggested this is due to a combination of a reticular sheath round post-capillary vessels, high permeability of the walls of these vessels, and relative stasis at this level of the brain circulation. The possibility of local liberation of pharmacologically active substances as a secondary phenomenon responsible for the demyelination has been suggested^{15 16} as consistent with what is known of other aspects of the pharmacology of the inflammatory response. Further work is therefore needed not only on the immunology but also on the pharmacology and cytology of experimental allergic encephalomyelitis.

UNMARRIED PARENTHOOD

The problems associated with unmarried parenthood have for long vexed administrators and perplexed ecologists. The prevalence of illegitimacy has for many years been greater in Scotland than in England, though the proportion of illegitimate births has fallen in both countries; in 1866, 10.27% of all the children born alive in Scotland were registered as illegitimate, the highest figure ever recorded since the inception of national statistics. The Scottish Registrar-General, in his early reports, was at pains to point out that the causes of illegitimacy in Scotland were essentially different from those prevailing in other European countries and had their origin in different social relationships. He returned to the subject in 1874, finding no correlation between the weight of illegitimacy and the extent of "ignorance or want of instruction" among the people.¹ There were wide variations in incidence from one part of the country to another, and the Registrar thought that the explanation for these must be sought in the habits of the people, their greater or less addiction to "night courtships," the want of moral training, "and to the incontinence of youth, which in some countries, particularly those in which the demand for labourers and workers is great, finds its legitimate channel in marriage, though it may be improvident marriage; while in others prudential check operates so strongly that it leads to that form of non-resident concubinage which results in illegitimate births." G. Seton,² writing some ten years later, reiterated that every statistician was "aware that the unrestrained passions which in rural districts result in illegitimate births are in large towns diverted into the channel of barren prostitution." It is certain that illegitimacy was, in general, more prevalent in the rural parts of the Scottish mainland than in other districts; the blackest areas of all were the counties of Banff and Wigtown. In the ten years following 1866 fully 25% of the 1,080 births registered in one Banffshire parish were illegitimate: 59 mothers gave birth to 153 illegitimate children in the course of these ten years, accounting for more than half of the total illegitimacy—2 produced 5 children each; 6, 4 children each; 11, 3 children

¹ Annual Report of the Registrar-General, Scotland, 1874.

⁸ *The Law in Relation to the Illegitimate Child*, 1958, British Medical Association, London.

each; and 40, 2 children each. A local clergyman who studied the subject about that time came to the conclusion that both religion and education had failed to tackle the problems of illegitimacy: among the causes, he listed drink, seduction under promise of marriage (rarely fulfilled), insufficient supervision of servants, inadequate house accommodation, concubinage, the tolerance of public opinion, and the protection of the "male offender," to some extent, by the existing law.

The matter has continued to command attention in more recent times. J. Spence and his co-workers³ found that less than half of the illegitimate children in their Newcastle series were first babies; many of the second and third infants were born to parents living in established, if unofficial, families. In Kilmarnock, B. Nisbet⁴ found that 30% of the mothers of illegitimate children were cohabiting. Many of these families are living under extremely bad environmental conditions, often in condemned property, with little prospect of getting a better house—cohabitators do not rank high in official housing lists. In recent studies of unmarried parenthood, based largely on the case records of the National Council for the Unmarried Mother and Her Child (rather biased and incomplete material, as he points out), C. Greenland⁵ concluded that a combination of factors, such as residence away from home, and certain types of employment, particularly domestic and clerical work and nursing, appear to be associated with an increased risk of conception in young unmarried women. In many cases the mother had applied to the Council for general information and advice; in 13% she wanted advice about an affiliation order; in 9% she was seeking employment and a home; while in 8% she was concerned primarily with ways and means of keeping the child. Greenland found that men under 20 years of age, married men, or members of armed Forces were often the fathers of illegitimate babies, but his findings did not lend support to "theories which regard putative fathers as a homogeneous group having certain psychological features in common."

The welfare of the illegitimate child has long given cause for anxiety. At one time the official attitude to illegitimacy was more concerned with possible repercussions on the poor rate than with the welfare of the child. From 1868 onwards the officers of the Board of Supervision urged parochial boards in Scotland to offer only indoor relief to the mothers of illegitimate children, hoping by this course of action to reduce the burden of pauper illegitimacy, though the refusal of outdoor relief in these cases often led to the death

of the children. It has been the general experience that the prospects of survival of the illegitimate child are much less favourable than those of the legitimate. Recently the Registrar-General⁶ has pointed out that the mortality rates of illegitimate infants are much less accurate than those of the legitimate infants, partly because a proportion of the infants who are registered at birth as illegitimate and subsequently die are not recorded as illegitimate at death registration: it is probable that this has the effect of under-estimating the infant mortality of illegitimate children by about 16%. In 1930-2 the calculated illegitimate infant mortality rate was 79% higher than the legitimate rate; by 1949-53 the excess had fallen to 36% and there had been as well a substantial decline over that period in the mortality of infants in each social class. But, apart from considerations of mortality, the illegitimate child usually starts life with serious handicaps, social, emotional, moral, and legal. The League of Nations study⁷ of the legal position of the illegitimate child and, more recently, the joint report of the British Medical Association and the Magistrates' Association⁸ were agreed that changes in the law were urgently necessary to protect the unmarried mother and her child, and the time seems to be ripe for further action.

BLOOD GROUPS OF MUMMIES

The considerable success achieved by blood-grouping methods in the classification of living human populations has led from time to time to attempts to determine the blood groups of human bones and other tissues obtained from archaeological excavations. Most of the experiments have been limited to the antigens of the ABO system, and it is still exceedingly doubtful whether it will ever be possible to detect the antigens of the other systems in post-mortem material which has not been specially preserved. It is of course impossible to obtain intact red cells from archaeological material, and tests must therefore depend on the inhibition of the grouping sera by samples of the tissues or by extracts or preparations from them. The earliest experiments were those of W. C. Boyd and L. G. Boyd,¹ who performed inhibition tests with muscle tissues from Egyptian and American Indian mummies. Since then methods have been somewhat refined, though no great advances have been made; P. B. Candela² appears to have been the first to carry out tests on ground samples of bone, a substance much more widely available than muscle tissue. The literature of archaeological blood grouping up to 1953 has been reviewed by A. E. Mourant.³

¹ Boyd, W. C., and Boyd, Lyle G., *Proc. Soc. exp. Biol. (N.Y.)*, 1934, 31, 671.

² Candela, P. B., *Amer. J. Phys. Anthropol.*, 1936, 21, 429.

³ Mourant, A. E., *The Distribution of the Human Blood Groups*, 1954, Oxford.

The results of tests on series of ancient remains have proved generally consistent with those on the corresponding living populations, but have often shown an excess frequency of group AB above that required for genetical equilibrium. It thus appears probable that while, taken on a population basis, the results do give some indication of genetical constitution, most if not all series include some false positives. This is not surprising, since all the specimens tested must contain bacteria. Bacterial contamination is already known to give rise for various reasons to errors in the testing even of red cells only a few days or weeks old. Some such results depend upon the Thomsen phenomenon, which is due to the development of an antigen not closely related to the blood groups. This causes "false" positive agglutination and hence would give rise to false results in the detection of blood-group antigens by inhibition methods. On the other hand some bacterial polysaccharides are closely related biochemically and even immunologically to the blood-group substances and so might be expected to cause inhibition simulating that due to the blood-group antigens.

If blood-group tests are to be used for archaeological purposes, and if the results are to command any confidence, it is clear that existing techniques need to be refined considerably, or new methods developed. In either case the methods, before being applied to ancient specimens, must be shown to give correct results with recent cadaver material of which the blood group is known. It may be that the blood-group antigens are too unstable on the one hand or too similar to bacterial polysaccharides on the other for a standard of accuracy ever to be reached comparable with that attained in the testing of living persons; but if reliable results could be obtained they would be of such great value to archaeologists that it is important that renewed efforts should be made to improve the methods of testing.

The news is therefore welcome that a blood-grouping laboratory for these purposes has been set up at the British Museum (Natural History). Work is being carried out by Mrs. Madeleine Smith in the Anthropology Section, of which Dr. K. P. Oakley has charge. The first object of the laboratory is the development and critical assessment of new and more accurate testing methods. It is proposed, however, to undertake almost immediately the testing both of a certain amount of "mummified" material (for example, from the dry soils of Peru) and of a selection of bones of ancient Etruscans, which have been preserved under damper and presumably less favourable conditions. In the long run there is little doubt that mummified material will yield valuable if not completely accurate results; such results would of themselves fully justify the establishment of the laboratory. If in addition reliable methods can be developed for the testing of bones preserved under moist conditions a most important addition will have been made to the scope of archaeology, and a great contribution to the possibility of correlating ancient populations with those of the present day.

GOITROUS HYPOTHYROIDISM

Recent advances in knowledge of thyroid function have emphasized the diagnostic significance of a palpable thyroid gland in a hypothyroid subject, whether baby, child, or adult. The gland itself may be soft or hard, smooth or nodular, small or large, but from its enlargement certain conclusions may be drawn: that the thyroid is subject to some difficulty in producing thyroxine and triiodothyronine, that this difficulty has been present for some time, and that the deficient output of thyroid hormones has resulted not only in the clinical state of hypothyroidism but also in an increased production of the thyrotrophic hormone T.S.H. in the endeavour to stimulate output of thyroxine. This attempt is unsuccessful, and the best that T.S.H. can achieve in this situation is an enlargement of the gland due to hyperplasia.

The thyroid gland is not as a rule well palpated by medical students or by young clinicians. The correct method of examination remains a matter of opinion, but the method usually taught of standing behind the sitting patient and blindly palpating with both hands has little but custom to commend it. Few right-handed clinicians have a left hand as sensitive as the right (the trouble, as Trotter used to explain, with some of us is that we have two left hands), and everyone uses either hand more expertly when aided by direct vision. The methods of standing alongside (to the right if right-handed) the sitting patient and palpating with one hand appears to achieve better results when used by those clinicians not yet wedded to the older method. In hypothyroid children in whom no gland can be palpated in the usual situation the possibility of dysgenesis¹ (imperfect descent) is worth remembering, and the examining fingers should explore the neck on both sides below the jaw.

Further conclusions can be drawn from the nature of the enlarged gland in hypothyroid subjects when the patient and his environment are considered. The discovery of a small, even tiny, gland in a baby with cretinism or in a child with hypothyroidism suggests an inborn defect of thyroxine synthesis; this is even more firmly indicated when the gland is large and nodular and the patient older. The enlarging gland in the thyrotoxic patient treated by antithyroid drugs shows that the patient is moving over to hypothyroidism. The hard and enlarged gland of autoimmunizing thyroiditis is often associated with myxoedema in women.

But in the present state of our knowledge we must not conclude that, because the thyroid gland is atrophic and impalpable in the presence of hypothyroidism, the gland has therefore not been the seat of similar inborn defects or of pathological processes. It is easy to conceive that

a gland destroyed by chronic thyroiditis is incapable of response to T.S.H., and remains shrunken and atrophic; and there is now good evidence that myxoedema is often, if not always, the result of such a process. It is also possible that the foetal thyroid gland, as the result of some inborn enzymatic defect, may also fail to respond to T.S.H.

One group of antithyroid drugs such as potassium perchlorate and thiocyanate act by preventing the uptake of iodide by the gland,² and they are used also in the investigation of thyroid function to procure the discharge of iodine unbound to tyrosine from the gland. Another group, the thiocarbamides such as methyl thiouracil and carbimazole, prevent the iodination of tyrosine³ (the second step in the synthesis of thyroxine). Three types of congenital defect in the synthesis of thyroxine have now been identified.⁴ The first defect occurs at the stage of iodination of tyrosine⁵ (the stage at which the thiocarbamides have their action). The second defect is due to a failure of deiodination of the iodotyrosines, presumably associated with a failure of the enzyme dehalogenase.⁶ And the third is a partial inability to form thyroxine and triiodothyronine from the iodotyrosines.⁷ No drugs are known to interfere with the late stages of thyroxine synthesis at which the second and third of these congenital defects declare themselves. Hypothyroidism which is due to the use of antithyroid drugs requires the temporary cessation of therapy. Hypothyroidism which is due either to congenital defects in thyroxine synthesis or to chronic thyroiditis requires lifelong thyroid therapy—sufficient for the needs of the body, sufficient to suppress the formation of T.S.H., and sufficient to put the overactive or pathological gland at rest.

IMMUNIZATION AGAINST DIPHTHERIA

The proportion of children in different parts of the country immunized against diphtheria varies widely. Though precise figures are not readily available, it seems to range from under 30% to over 70% in England and Wales, and to average about 70% in Scotland. The present outbreaks in Essex and London,¹ though small by the standards of 20 years ago, are a reminder that a high state of immunization is the surest barrier to the epidemic spread of the disease. The number of children immunized in England and Wales against diphtheria in the three years 1955–7 was 525,125, 567,989, and 546,776, respectively. The percentage of children who may be regarded as remaining protected—that is, children who had a course of immunization, primary or booster, during the preceding five years—for the years 1953–7 was 48, 48, 49, 49, and 48. In Scotland it was about 70%. Though the percentage throughout the country varies from place to place, it varies only slightly from year to year in any area. In a speech he made last week Dr. J. A. Stirling, the new president of the Society of Medical Officers of Health, wisely urged his colleagues to keep parents well informed about the necessity of having their children immunized.

¹ *Brit. med. J.*, 1958, **2**, 1051.

In England and Wales in 1956 there were 11 cases of diphtheria among the immunized with 1 death, and 40 cases among the non-immunized with 2 deaths. In 1955 there were 34 cases among the immunized with no deaths, and 120 among the non-immunized with 13 deaths. In Scotland, during the nine years 1949–57 there were 151 confirmed cases of diphtheria among the immunized children, with no deaths; among the non-immunized children there were 665 confirmed cases, with 35 deaths.

The number of notifications of diphtheria fell rapidly after the widespread introduction of immunization, from an annual average of about 55,000 in 1933–42 to 40 in 1957, while the number of deaths fell from an annual average of 2,783 in 1933–42 to six in 1957. The distribution of cases was sporadic, and the largest annual number of cases in local authority areas in 1955 was 19 in Uttroter R.D., 17 in Kingston-upon-Hull C.B., and 14 in West Ham C.B. Kingston-upon-Hull had the largest annual total in 1956 and 1957, with 7 and 6 cases respectively. It is interesting to note that, though full swabbing of family, school, and other contacts was performed in most areas where cases occurred, in only a few instances were carriers revealed; the source of infection usually remained unknown. Past experience has shown that in school communities where immunization rates are low diphtheria has only to be introduced to spread rapidly. It is at school entry that an opportunity exists to raise the number of immunized children in the community.

B₁₂ ASSAYS IN MEGALOBlastic ANAEMIA

Uncomplicated vitamin-B₁₂ deficiency in man frequently gives rise to megaloblastic anaemia, which can be differentiated from that seen in folic-acid deficiency or in scurvy^{1,2} by the fact that it is cured by treatment with vitamin B₁₂. However, the lingual and neurological lesions caused by deficiency of vitamin B₁₂ are sometimes found in patients who are not anaemic,^{3,4,5} and deficiency of B₁₂ and folic acid may occur together in patients with intestinal malabsorption syndrome. In such patients it may be impossible to diagnose deficiency of vitamin B₁₂ by clinical and haematological methods alone.

However, deficiency of B₁₂ can be detected in these patients by assaying the amount of it in the serum by the use of micro-organisms, of which *Euglena gracilis*^{6,7}

and *Lactobacillus leichmannii*⁹ are the best known. Measured in this way, the B₁₂ concentration in the serum of patients with Addisonian pernicious anaemia¹⁰⁻¹⁵ is always lower than in normal subjects. While the B₁₂ concentration in the serum of normal subjects ranges from 140 to 900 µg. per ml., most patients with Addisonian pernicious anaemia have levels of less than 80 µg. per ml. However, some control subjects may have levels as low as 100 µg. per ml. and a few non-anaemic patients with Addisonian pernicious anaemia have levels up to 110 µg. per ml. On the other hand, all patients with subacute combined degeneration of the cord, even when they have no anaemia, have little or no measurable B₁₂ in their serum with the Euglena assay.¹⁰⁻¹¹ The diagnostic value of such an estimation is clear. In addition, this observation suggests that subacute combined degeneration does not develop until the tissues are almost completely depleted of B₁₂, and furthermore that the megaloblastic anaemia in pernicious anaemia may not be due solely to deficiency of B₁₂.

The incidence of B₁₂ deficiency may also be accurately assessed in other megaloblastic anaemias by this method. For instance, in patients with megaloblastic anaemia associated with gastrectomy and with anatomical lesions of the small intestine the B₁₂ concentrations in the serum are almost always subnormal, the levels being similar to those seen in Addisonian pernicious anaemia. Deficiency of folic acid rarely occurs in these patients, for they usually respond completely to treatment with vitamin B₁₂. Subnormal levels of B₁₂ in the serum are also common in tropical sprue¹⁶ and in "tropical megaloblastic anaemia,"¹⁷ but in these conditions they are more frequently associated with deficiency of folic acid, for the haematological responses to treatment with B₁₂ are slower and less complete. Subnormal levels are also found in about 50% of the patients with idiopathic steatorrhoea,¹⁰⁻¹⁴ and in one-third of these patients the levels are as low as in pernicious anaemia, being less than 100 µg. per ml. However, in such patients the B₁₂ deficiency is invariably associated with folic-acid deficiency, for none of these patients appear to respond completely to treatment with B₁₂ alone. Subnormal levels of B₁₂ in the serum are less frequent in megaloblastic anaemia of pregnancy,¹¹⁻¹⁵ and in most patients the concentrations are normal.

While the evidence suggests that a B₁₂ concentration in the serum of less than 80 µg. per ml. indicates clinical B₁₂ deficiency, serum levels between 80 and 120 µg. per ml. have been found occasionally in patients whose tissue stores of B₁₂ were normal.¹¹ Though such findings are very rare, they suggest that borderline levels of serum B₁₂ should be interpreted with caution.

ADVERTISING DRUGS

"You can count the number of useful drugs on the fingers of your two hands" one well-known physician used to say to his students little more than thirty years ago. Since then there has been a revolution in the drug treatment of disease. The revolution is still on. The brilliance of the bacteriologist, chemist, and pharmaco-

logist, combined with the energy and resourcefulness of the pharmaceutical industry, has let loose a flood of new and powerful remedies to be used by doctors for the benefit of patients. Politicians and administrators moan about the cost of this to the National Health Service. At one time the size of the national drug bill was attributed to unrestricted and free access to the simple remedies and dressings in the chemist's shop. Then the blame fell on the pharmaceutical industry for high-pressure salesmanship of remedies, and combinations of remedies, the cost of which was regarded as excessive. No one has been entirely free from blame, least of all the politicians who encouraged the whole population of the United Kingdom in the belief they could take what they wanted out of the chemist's shop without having to pay for it. But without the pharmaceutical industry modern medicine would be powerless to do good with the drugs modern science provides for it, drugs discovered often enough in the laboratories of the industry itself. Information about these drugs reaches the practising doctor in a number of ways, and elsewhere in this issue Dr. Audrey Baker describes the results of her inquiry into the value set by doctors on the information given by pharmaceutical houses through the post, by medical representatives, and in the advertisement columns of medical journals. Some 90% read the advertisements for drugs in medical journals—64% often or always, and 26% seldom. That 80% preferred to get their information on drugs by discussion with firms' representatives suggests that the industry as a whole might look more critically at the type of copy their agents send to the medical press.

What is of special interest to us is Dr. Baker's conclusion that there is "a *British Medical Journal* readership of between 80% and 90%," throughout Great Britain, a record far outstripping that of all other medical periodicals. This is gratifying to us and, we may assume, to the growing number of firms aware of the value of advertising their wares to the *B.M.J.*'s readers.

NOBEL PRIZE FOR CAMBRIDGE BIOCHEMIST

The award of the Nobel Prize for Chemistry to Dr. F. Sanger, F.R.S., is in recognition of his outstanding work in analysing the structure of the insulin molecule. The work took about ten years to complete and was carried out with his colleagues in the Biochemistry Department at Cambridge University during 1945-55. Now aged 40, Dr. Sanger was elected a Fellow of the Royal Society four years ago. At the time this work was completed the insulin molecule was the largest protein molecule to have had its chemical structure elucidated. This great achievement was an essential preliminary to any chemical synthesis of insulin as well as of analogues which may be easier to administer in clinical practice.

We record with regret the death on October 24 of Sir John Megaw, formerly professor of tropical medicine at the Calcutta School of Tropical Medicine and Director-General of the Indian Medical Service from 1930-33.

Drug Treatment of Disease

SEDATIVES AND TRANQUILLIZERS: PART II*

BY

WILLIAM SARGANT, F.R.C.P.

Physician in Charge of the Department of Psychological Medicine, St. Thomas's Hospital

Tranquillizers

In recent years over twenty so-called tranquillizers have been marketed by drug manufacturers to replace or to reinforce the older types of sedatives already discussed. Unfortunately some of these drugs have been offered to general practitioners long before they have been properly tested in Great Britain, and false claims and even some disasters have occurred. We have seen, for instance, the spate of suicides by depressive patients following the unwise advocacy of reserpine as a tranquillizer for general use and in the treatment of hypertension before this fatal complication of treatment had been fully realized. Many cases of jaundice likewise followed the enthusiastic claims made for chlorpromazine long before most British psychiatrists had had any real opportunity to test it out and to find its potential advantages and dangers. Again, it is now known that chlorpromazine can greatly increase depression in an already depressed person (though perhaps not to the same extent as reserpine), with the consequent risk of suicide. It is thus inadvisable to try out new tranquillizers in general practice until they have been thoroughly tested in Great Britain, and tested in circumstances which will prevent the disasters that have happened in recent years.

The writer has, so far, been able to try out only some of these new tranquillizers in a way which justifies their detailed discussion in an article of this nature. Others may be useful, but some have proved of little use at all, and should never have been put on the market or advertised for general use.

Chlorpromazine

This drug unfortunately produces jaundice in some patients, but the benefit it gives often makes this a worthwhile risk if the patients are properly selected for it. It is of far greater value in the sedative treatment of the psychotic patient in hospital than the neurotic patient out-patient. But there is now some evidence that chlorpromazine, if given in sufficiently large doses (200-400 mg. a day), may abort the development of acute schizophrenic illnesses in some of those persons predisposed to them. General practitioners may find it advisable to give this drug immediately to patients in the very earliest phases of the illness and to patients while awaiting, for instance, the taking of further expert advice on future treatment. Since its introduction in psychiatry, this drug has also enabled many schizophrenic patients to be treated much more speedily than previously, and some can now stay on as out-patients instead of having to go into hospital for insulin-coma and other treatments. Even when other treatments, such as full or modified insulin, E.C.T., and leucotomy also have to be used, chlorpromazine seems to be a drug of considerable value as a maintenance treatment, tending to prevent relapses. However, quite large doses are generally necessary, doses which can, in fact, markedly aggravate other neurotic and psychotic conditions. Indeed, schizophrenics may need to be given initially up to 1,000 mg. a day, and maintenance doses of 150-400 mg. a day may also be necessary later on. At present we do not yet know

how long these large doses have to be kept up; but relapses often occur within a month of the patient being taken off the drug even after prolonged use.

There are also many elderly senile patients, suffering particularly from agitation, in whom ordinary sedatives produce confusion and increasing upset of memory. Such patients are often greatly helped by the use of chlorpromazine in lower doses—say, 100-200 mg. a day. By damping down their agitation it may enable them to be nursed at home rather than in hospital. In ordinary neuroses chlorpromazine should be given much more hesitantly. Doses in the region of 100 mg. a day can help some patients with anxiety and depression, but the administering of this drug alone in cases of depression can increase the symptoms, sometimes to the point of suicide, and general practitioners must always be on their guard against this. Anxiety states, anxiety hysteria, and obsessional states are really little helped by this drug, and the barbiturates will be found much cheaper and much more effective. Chlorpromazine, however, may be used to reinforce small doses of barbiturates, and to prevent larger doses producing undesirable states of barbiturate addiction.

Several substitutes and equivalents have been produced for chlorpromazine, some of them claiming that jaundice is avoided as a complication of their use. These may be tried where jaundice has occurred, but whether they are as effective as chlorpromazine is as yet far from certain.

Reserpine

This drug has also had a recent vogue in the sedative treatment of anxiety states and in schizophrenia. Some excellent results have been reported in schizophrenic illnesses when the dose is pushed to as high as 8-10 mg. a day, and a maintenance dose of around 3-6 mg. a day is used later. But there are many undesirable features attaching to the use of this drug. Suicidal depressions are very common, and it is doubtful whether much better results are obtained with reserpine than with the skilled use of chlorpromazine in a proper high dosage. Smaller doses of reserpine (1-2 mg. a day) can, however, be given to supplement larger doses of chlorpromazine.

Some tension states are also undoubtedly helped by much smaller doses of reserpine—about 0.25 mg. three times a day. But it is difficult to delimit these, and one should try to use every other drug first, because of the drug's liability to produce such severe depressive reactions. The physician should be especially careful in treating anyone who has a prior history of a neurotic or psychotic attack of depression.

Meprobamate

This expensive sedative has had a great vogue in the U.S.A. But testing in Great Britain indicates that it has only limited uses as compared to, say, the much cheaper barbiturates. It is helpful in treating withdrawal states in the alcoholic. It relaxes muscle tension, and some patients with reactive tension depressions do seem to be helped by it; these patients may put on weight while on this drug.

Another group of patients which meprobamate helps are those who show mixed hysterical and obsessive phobic symptoms. These patients, when taking short-acting barbiturates, become easily addicted to them; they may also become addicted to meprobamate, and withdrawal symptoms have been reported; but so far this has not yet proved too serious a complication. Meprobamate does not help patients

*Part I of this article was published last week at p. 1031.

with pure obsessional states or deep endogenous depressions. Only 1-2 400-mg. tablets three times a day, and not more, should be prescribed where indicated.

Conclusions

Clearly sedation should not be given to patients without attempts also being made to deal with environmental and other stresses that may be a cause of the anxiety and tension. But it is a commonplace in general practice that the giving of judicious rest to the nervous system by sedation can often make problems which had temporarily seemed insuperable to a patient become quite easy to handle again. It is worth bearing in mind that the normal brain generally

adjusts to its environment, and, as was very obvious during the last war, the normal brain can tolerate very bad environments indeed for very long periods of time. Likewise the last war also showed in a most convincing manner what is just as true in peacetime—namely, that once breakdown happens it is comparatively easy to abort acute neurotic reactions if only proper sedative treatment is given in time. But neurotic reactions are much less easy to treat when new abnormal patterns of behaviour and thought have been allowed to become thoroughly ingrained in brain function through the lack of adequate sedation early on in the illness. It may truly be said that a grain of sedative in time saves nine.

THE PHARMACEUTICAL HOUSE AND THE DOCTOR

BY

AUDREY Z. BAKER, B.Sc., M.R.C.S.

Medical Research Department, Vitamins Ltd., London

Recent correspondence in this and other journals has included statements that doctors are inundated by literature from pharmaceutical houses and that visits from representatives of these firms are not only unnecessary and time-consuming but contribute to the cost of drugs and the expense of the National Health Service.

The Survey

It was decided to ascertain the opinion of doctors themselves on this matter, knowing that only the few who feel strongly on the subject tend to write to the press; it was realized, however, that it would be difficult to obtain a true picture. Surveys are notoriously liable to error, whether in design, method of procedure, or interpretation, but a survey seemed to be the only practicable means.

It was considered that the effectiveness of the survey would depend on two factors: (1) the form of the questions, and (2) the way in which they were presented to the doctor.

The Questions.—(1) These must take only a very short time to answer. (2) They must be such that the answer would be unequivocal.

The Presentation.—(1) The doctor must be assured of his anonymity. (2) He must be asked but not pressed to answer.

Bearing these points in mind, a punch-card was designed with all the questions on one side, so arranged that only a tick or cross was needed in the appropriate spaces.

Knowing the almost universal distaste for questionnaires arriving by post, we gave supplies of blank cards to our representatives and instructed them as follows: "Carry out an interview in the usual way, and, when you are about to leave, ask a doctor politely for his co-operation in filling in the answers to some questions which are of interest to us—pointing out that this will take only about a minute. If any doctor prefers not to do so, do not press him, but record the number of such refusals each day." The representatives were further instructed to complete the back of the card themselves but not to enter the doctor's name anywhere.

All doctors visited were to be presented with cards, and all completed cards were to be returned to us each day.

Classification of Responses.—Cards were appropriately punched on receipt and were filed until enough had been received. The number used in the survey represents 10% of the total number in the National Health Service.

Results

The results are shown in the Table, from which the following observations can be made:

1. Less than 3.5% of the doctors interviewed failed to reply. This figure may be misleading because it takes no count of doctors with whom the representative failed to obtain an interview; but of those who replied, more than 80% said that they almost always see medical representatives.

2. Percentage variations in the replies to certain questions were so slight even in widely separated areas that a strong presumption seems justified that the answers are a true representation of medical opinion and not due to the influence

Table Showing Area Distribution

	Scotland	N. Ireland	N. England	W. England	East and Home Counties	London	Total All Areas

Hardly ever	62	24	76	85	77	21	896
4. Which journal?							
B.M.J.	513	273	773	665	523	226	4,952
Lancet	57	28	115	81	126	82	2,973
Other*	323	146	360	311	251	99	1,490
5. Do you prefer information on preparations?							
As advts. in journals	122	51	300	175	164	111	4,155
Discussed with reps.	525	304	646	602	513	212	923
Sent in post	55	22	139	114	72	79	2,802
6. Would you be willing to co-operate in any future survey of this kind?							
Total replies							3,394
Yes							3,207
By interview							1,344
By post							260
No							187
Not stated							1,603

More than one reply was given on some cards to questions 4 and 5. Some cards omitted replies to questions 2, 3, and 6. It is a coincidence that the numbers of omitted replies to questions 3 and 6 were the same, for a check has shown that they were not necessarily omitted from the same cards.

* Many filled in *Practitioner*.

of the interviewer; for example, in areas as far removed as Scotland and the West of England the answers to question 1 show the following sequences respectively: 91%, 8%, 1% (Scotland); 87%, 11%, 1% (West of England). Similarly, answers to question 4 indicate a *British Medical Journal* readership of between 80 and 90% throughout all areas, and answers to question 5 show that nowhere do more than 16% of doctors prefer obtaining information through the post. Such widespread lack of variation points to a greater significance where variation does occur.

3. Examples of Area Differences in Pattern.—In both Northern Ireland and Scotland the preference is for visits from representatives three times a year. In all areas in England the preference is for twice a year. There is a higher readership of the *Lancet* in the London area and the area including the Home Counties than elsewhere.

4. Other Observations.—Except in the London area, over one-third of all the doctors interviewed seldom or hardly ever read advertisements in journals. Approximately 80% prefer information from discussion with medical representatives. Only about 12% prefer information sent in the post. Classification according to the type of professions practised does not bring to light new facts, but data reveal the known link between consultant physicians and residence in the London area. Further analysis into counties and some of the larger conurbations provides numbers too small for conclusions to be drawn from them. Over 90% of the doctors interviewed expressed willingness to co-operate in a future survey. Among these five times as many preferred an interview to a postal request. Four doctors asked for copies of the survey. Reprints of this paper will be sent to them when available.

I am grateful to the medical representatives who collected the cards and to my assistant, Mrs. I. Winckler, who assembled the data.

TOOLS OF BIOLOGICAL RESEARCH SYMPOSIUM AT GUY'S HOSPITAL

[FROM A SPECIAL CORRESPONDENT]

The Surgical Research Society held a very successful symposium on the "Tools of Biological Research" at Guy's Hospital on October 10 and 11. Mr. H. J. B. ATKINS was responsible for the arrangements. Although the different communications covered an almost bewildering range of subjects, unity was achieved because every speaker first described a technique, its physical principles and limitations, and then showed how it had contributed to knowledge. The detailed proceedings are to be published by Messrs. Blackwells Scientific Publications Ltd.

Strategy and Tactics

In an introductory address, Sir CYRIL HINSHELWOOD, President of the Royal Society, said that the most economical campaign in research usually employed the newest methods. But it was successful only if it had a well-conceived master-plan. Any individual worker might be a specialist in his technical methods, but he should not be so in his thinking and knowledge; the more he was called upon to supervise the work of others, the more he must know what techniques were available and so avoid the tendency common to most of us, to continue to fight the last war. To neglect modern techniques was to be amateurish. They were highly complex and often demanded team-work, but collective action to be its most beneficial must provide opportunities without imposing restrictions.

Dr. PETER ARMITAGE said the original expansion of statistical technique owed much to Carl Pearson, but it was after

To-day's Drugs

In this column we publish from time to time authoritative notes on a selection of drugs in current use.

Predsol and Predsol-N (Glaxo Laboratories Ltd.).—Ointments and lotions containing 0.25 or 0.5% prednisolone disodium phosphate, with the addition in predsol-N of neomycin.

Deltacortril DA (Pfizer Ltd.).—Prednisolone diethylaminoacetate hydrochloride 0.25% in an ointment with a greasy base.

Precortisyl (Roussel Laboratories Ltd.).—Prednisolone in a 0.5% cream or 0.25% lotion.

The value of hydrocortisone and of combinations of hydrocortisone with neomycin in the treatment of various skin diseases has been well established by clinical use in the course of the last two years or so. It is natural that prednisolone should be put to the same purpose in preparations such as these. They seem to be of a suitable strength, and their clinical effectiveness is very difficult to distinguish from the corresponding hydrocortisone applications. There will be little to choose between these preparations and those containing hydrocortisone, but individual patients may do better with one or the other. As with hydrocortisone, systemic absorption is minimal, and even when large areas are being treated the mildest systemic effects are most unlikely.

N.H.S. basic price: predsol lotion 0.1%, 20 ml., 5s.; 0.25%, 20 ml., 9s.; predsol ointment 0.25%, 5 g., 3s.; 0.5%, 5 g., 5s. 6d.; predsol-N ointment 0.25%, 5 g., 3s. 9d.; 0.5%, 5 g., 5s. 7½d.; deltacortril DA ointment, 5 g., 4s. 6d.; precortisyl cream, 5 g., 5s.; precortisyl lotion, 20 ml., 9s.

Aturbane (Ciba Laboratories Ltd.).—This product has, under the title Ciba 10870, been tested as a palliative measure in cases of Parkinsonism, whether idiopathic or post-encephalitic. It comprises an α -phenyl- α -(diethylaminoethyl) glutarimide hydrochloride, and is parasympatholytic in action. Pharmacologically it is capable of relieving spasm induced by acetylcholine. Clinically it has been found helpful in relieving the excessive salivation and the muscular rigidity of Parkinsonism. Any effect upon tremor and upon oculogyric crises is not usually obvious. Side-effects that have been observed include mental confusion, euphoria, dryness of the mouth, nausea, and vomiting, but all apparently slight in degree with ordinary therapeutic dosages. Glaucoma contraindicates the use of this drug. The drug is a white crystalline powder, soluble in water, dispensed in 5-mg. tablets. The suggested dosage is 10 to 20 mg. daily, though in exceptional cases as much as 50 mg. a day may be given.

N.H.S. basic price: 100 tabs., 17s. 4d.

(Continued from previous page)

a single expiration provided a practicable routine means of measuring the balance between gas and blood distribution in the lungs, so vital to the understanding of the functional pathology of many forms of respiratory disease; while sampling from different lobes or segments of the bronchial tree during diagnostic bronchoscopy had opened an entirely new field. Animal experiments showed that specific changes in gas-concentration patterns were associated with reduction of the air-flow or blood-flow within a lobe. It now seemed likely that the ventilation, blood-flow, and some mechanical properties of diseased lobes or segments of the human lung could be measured before surgery. The technique had also enabled the patterns of gas-flow within the bronchial tree to be measured, and a number of future applications in medicine, surgery, and paediatrics were envisaged.

Addiction to Unrestricted Drugs

SIR,—I think Drs. C. P. Seager and A. R. Foster (*Journal*, October 18, p. 950) have not considered the problem of carbromal addiction adequately. According to them an addictive drug should show one or more of the following properties—viz., craving, tolerance, dependence. One other characteristic could be added—i.e., the recipient should either derive pleasure or prevent distress. The morphine (or heroin) addict takes the drugs either for euphoria or to prevent withdrawal symptoms. Whilst under the influence of the drug he is normal physically and mentally. The three cases of carbromal overdosage described by Dr. Seager resulted in most disagreeable symptoms. No addict would have put up with such discomfort for one moment, neither would a normal person. The authors admit that these cases were psychopathic. They certainly exhibited masochism to a marked degree. It is because the normal person is neither psychopathic nor masochistic that such cases, due to carbromal, are almost non-existent. I cannot, therefore, agree with the authors' conclusion that the open chain ureides should be restricted. The mild insomniac should be able to obtain his sedative without hindrance; the presence of a few psychopaths in the community is insufficient warrant for alteration of the schedules.—I am, etc.,

Melbourne.

F. H. SHAW.

SIR,—In their article on addiction to unrestricted drugs (*Journal*, October 18, p. 950) Drs. C. P. Seager and A. R. Foster draw attention to the risks of habituation and addiction attending the unrestricted sale of certain non-barbiturate drugs. All the drugs they mentioned have been noted in our experience, too, to give occasionally rise to habitual abuse in large, often increasing, doses by unstable people, chiefly alcoholics of a hysterical, immature, and inadequate, or psychopathic, personality-type, who in the past often had also taken to excess barbiturates and amphetamines. Most frequent was the misuse of "persomnia" (a finding confirmed by several doctors in this country with experience in the treatment of alcoholics), and there were occasional cases of habitual excess of carbromal itself and "relaxa-tabs" (another carbromal-bromvalerone preparation), chlorodyne, and the stimulant "preludin." One alcoholic took large, increasing doses of meprobamate. Two cases were seen of habituation to glutethimide, one to methypylone (two non-barbiturate hypnotics which otherwise were found to be safe and effective in several hundreds of patients). Sometimes these people drank to excess simultaneously with taking excessive doses of the drugs, but in general the picture was similar: confusion, incoordination, and slight slurring of speech. There seemed to be a great desire to take large doses of the drugs in increasing amounts, but there was no real evidence of "compulsive craving" or of physical dependency in the form of a withdrawal syndrome.

Warnings against the risk of habit formation arising out of the indiscriminate use of such drugs have of course also been raised in other countries. Thus an American study¹ reports 72 cases of habituation and one of addiction following the use of tranquillizing drugs among 8,200 patients suffering from an anxiety state. In the case of meprobamate several observers noted the occurrence of withdrawal symptoms when the drug was discontinued.^{2,3} The W.H.O. Expert Committee on Addiction-producing Drugs states that "cases of misuse (of tranquillizing drugs) are being reported with increasing frequency," and believes that tranquillizers "must be classed as potentially habit-forming." German authorities have reported cases of habituation and addiction to meprobamate,⁴ 1-ethinyl-cyclohexyl-carbamate (a non-barbiturate hypnotic),⁵ and preludin.^{6,7} Swiss doctors

describe the abuse and addiction to "so-called harmless" analgesics (sometimes containing phenacetin)—not affected by the "Betäubungsmittelgesetz"—leading on sudden withdrawal to severe abstinence symptoms, with epileptiform fits, deliria, and hallucinosis.^{8,9}

Apparently among certain unstable, predisposed personalities any drug producing a feeling of improved well-being—perhaps by helping them "to get rid of something" (such as tension and anxiety) or "to get hold of something" (euphoria)—can lead to abuse and, at least, habituation. It therefore seems regrettable that again and again new drugs (as, e.g., a recently introduced non-barbiturate hypnotic) are described and advertised as not giving rise to habituation or addiction.—I am, etc.,

Oesophageal Stricture

SIR,—The papers by Mr. J. A. W. Bingham (*Journal*, October 4, p. 817) and Mr. K. C. McKeown (*Journal*, October 4, p. 819) draw attention to oesophageal stricture as a complication to the surgical treatment of peptic ulceration of the stomach and duodenum, and the authors put forward a number of possible causes. A study of their case records shows that 5 of the 6 patients had hiatus hernia, with a short oesophagus to a marked degree, and that, although this condition certainly existed prior to operation, it was not recognized clinically or radiologically. The sixth patient (McKeown's Case 2) had the symptoms of a reflux oesophagitis, and the operative findings were suggestive of oesophagitis, and the lower oesophagus. The type of gastric mucosa lining the lower oesophagus, is one hernia found, with shortening of the oesophagus, and it thus very commonly associated with oesophagitis, and it thus appears that all these patients had oesophagitis prior to their operative treatment for peptic ulceration of the stomach or duodenum.

The moral is that the symptoms of hiatus hernia and oesophagitis are overshadowed by the more severe symptoms of gastric or duodenal ulceration, until these latter symptoms are relieved by gastrectomy, whereupon they become noticeable. In many cases the removal of acid or pepsin secretion may well lead to the oesophagitis subsiding and giving no further trouble, but in some cases the oesophagitis will have been of such severity that it will heal by fibrosis and stricture formation, leading to more severe symptoms such as those described by the authors in their papers.—I am, etc.,

Hiatal Herniorrhaphy

SIR,—In your issue of September 20 (p. 728) Mr. J. Borrie describes the right-sided approach for hiatal herniorrhaphy. He says "to date no record has been encountered of a right-sided approach for repairing such hernias." I repaired a hiatus hernia in Lewisham Hospital with Mr. J. Jemson on April 11, 1951, using the right-sided thoracic approach. I did this under the mistaken impression that Russell Brock, who to me represents the law and the prophets in all things surgical, recommended it. I found it very difficult and very unsatisfactory, and I vowed never to try it again and never have.

I waited to comment till I had traced the patient. I find that, after being free from symptoms for eighteen months, he returned to Guy's with dysphagia, and x-ray showed that his hernia had recurred. Robert Brain did a re-repair through the left chest in September, 1953, and the patient has since remained well. This 100% recurrence in a solitary

venture compared with more than twenty repairs done through the left chest at the Royal Masonic Hospital, Guy's, and Machynlleth, none of which has as yet recurred, so far as I have been able to discover.—I am, etc.,

London, W.1.

HENEAGE OGILVIE.

Mass Casualties from Nuclear War

SIR,—The paper¹ criticized by Dr. M. C. Berenbaum (*Journal*, September 27, p. 800) is very far from preaching complacency in face of nuclear attack: it is equally far from proclaiming a policy of inactivity and despair. He has not made himself familiar with the premises of the argument he opposes. Briefly, they are that in a mass casualty situation there can never be enough doctors or nurses on site to attend to all the injured: that, in consequence, non-professional men and women must be trained to accept responsibilities that up to now have rested entirely on doctors and nurses. Also that, since casualty sorting is the key to effective management of large numbers of casualties, a filter organization must be created, to prevent the hospitals further back from being overwhelmed either by the lightly injured or by those the hospitals will be unable to help.

We set out to estimate the greatest number of casualties which a given group of medical personnel forming a filter unit could effectively sort and treat in 24 hours. It was thought that this number might be in the region of 6,000. Experiments and time-and-motion studies have been made, to estimate whether a filter unit of the size described could deal with this task. Obviously there is a theoretical element to such tests, but the conclusion reached by the great majority of those to whom the problem has been demonstrated is that suitably trained personnel should be able to do so.

The paper in question, with the hand-out which accompanied it, gives a staffing list of the various departments of a filter unit and also shows among other definitions that the urgent surgery envisaged is limited to simple procedures such as control of bleeding, dealing with rapidly correctable respiratory defects, completion of incomplete amputations, and splinting of compound fractures of major bones. Many such cases will not need a doctor's attention but can be dealt with by others. From these documents, which I now quote because they had a limited circulation, it can be seen that in fact each of 1,200 patients to pass through the immediate treatment (urgent surgery) department would indeed have 9.6 minutes under active team treatment, or a total of 28.2 minutes of nurses' or nursing auxiliaries' time plus 3.6 minutes "doctor's time." This would be achieved by a staff of three doctors and eight teams each consisting of three nurses or nursing orderlies.

Effective casualty sorting, the key function of a filter unit, is a problem that can be tackled, but not by one surgeon as Dr. Berenbaum assumes. To sort 3,600 cases in 24 hours would be the work of two surgeons plus at least two other doctors, working as a team with 12 nursing orderlies to help them. The plan would be for the two doctors to decide upon the disposal of the more obvious cases, and call in the surgeons only when in doubt. The surgeons and doctors have 1.6 minutes to examine the cases referred to them—and by this time the injured will have had clothing removed and their injuries exposed. Experienced surgeons who have witnessed trials have said that casualty sorting of the kind needed in a situation such as this can be performed within this time.

I sincerely trust that readers of this correspondence will feel able, conscientiously, to join in a plan which, in our opinion, can help the victims if we should ever be faced with this kind of disaster.—I am, etc.,

Farnborough, Hants.

T. M. R. AHERN.

REFERENCE

1. Ahern, T. M. R., *Proc. roy. Soc. Med.*, 1957, 50, 968.

SIR,—Many of us interested in the medical aspects of civil defence may possibly agree that Dr. G. D. Kersley's paper (*Journal*, August 9, p. 379) may not produce the effect he desires, but the effects will be much more useful than the suggestions of Dr. M. C. Berenbaum in his letter (*Journal*, September 27, p. 800). Some of the most severe critics of the present civil defence arrangements and of their presentation to the community are themselves in civil

defence. It is only by propaganda directed at the Home Office and by energetic local action that the present inadequacies can be met, but we must never allow the statesmen to have their heads as suggested in the last paragraph of Dr. Berenbaum's letter. Even if they take responsibility for it, the medical profession will still be left to clear up the mess the politicians have created. We must tell the public the truth now and induce the Home Office to do the same. After a fairly extensive association with all workers in civil defence, I am convinced that there is not one who has any illusions about the appalling effects of nuclear warfare.

Dr. Berenbaum maintains that the medical services will be disrupted if a scheme on the scale suggested by Colonel Ahern is put into action. If the country is to survive at all this scheme will be the minimum we require. Other medical services, except those of the most urgent and vital character, will have to cease even before the shooting starts. This disruption will be but one part of the total survival plan which will have to be put into operation. If we are to face annihilation and to save anything from it, every man, woman, and child and every possible activity in which they engage will have to be subordinated to this provision. Even though millions are killed and much of this country and Western Europe are destroyed, we, who believe in ourselves, must have faith that our essential values are worth saving and that this saving can be effected.

In the past the Home Office were not planning on a large enough scale. There are signs now that they are getting away from the last war mentality, and this new approach is the result of the work of knowledgeable and imaginative members of the armed Services and civil defence organizations. There are plenty of memorials in the Health Service already to the work of politicians. A vital matter like this must not be left to their unaided efforts. The medical profession has taken too little interest in civil defence, but we must now play our proper part, and make our voices heard. We cannot avoid taking responsibility for the medical services in the defence of the nation.

—I am, etc.,
Shrewsbury.

E. N. OWEN.

Treatment of Asthma

SIR,—The article on the drug treatment of asthma by Dr. R. S. Bruce Pearson (*Journal*, October 11, p. 905) was both welcome and timely. It deals comprehensively and lucidly with a clinical problem which is becoming increasingly difficult in general practice, owing to the many diverse preparations which are now available, each understandably but none the less confusingly extolled by its manufacturer. May I, however, be permitted to offer some comments which arise from experience in a fairly typical general practice? The treatment of acute cases is not easy outside hospital, and I am chary of employing relatively large doses of corticosteroids on patients whom I cannot keep under continuous surveillance; in the few cases where I have tried it, I have found that corticotrophin has secured better results than the corticosteroids. Indispensable as these drugs now are in status asthmaticus, prophylactic measures outside hospital cannot usually include them, and in my view intravenous aminophylline remains the general practitioner's best standby in acute adult cases.

In less serious cases, and especially in early cases, I would suggest that sedatives can play an even more important part than Dr. Bruce Pearson suggests. I submit that all asthmatics are suffering from anxiety, and that the anxiety may be a primary cause of the asthma. In any event, anxiety predisposes to attacks, and the attacks induce more anxiety; this vicious circle can sometimes be broken by the use of suitable sedatives alone, or preferably in conjunction with antispasmodics to reduce the frequency and severity of attacks. I thus entirely concur with Dr. Bruce Pearson that a combination of sympathomimetic and xanthine substances with a sedative is most suitable in these cases, but disagree with his advocacy of keratin coating to delay absorption for prevention of nocturnal attacks.

In my experience the resin-ephedrine complex which he dismisses earlier is the most effective method of securing both sustained action for prophylaxis of day or night attacks

and reduction of the side-effects of ephedrine. This preparation (I believe "asmapax" is the only one of this kind on the market) contains theophylline and sedatives as well as the resin-ephedrine complex, and thus answers both Dr. Bruce Pearson's prescription and his comment on the high price; it is difficult to compare the cost of a medicament used 12-hourly, and combining several drugs, with the several components used at shorter intervals. Upon investigation I find that asmapax treatment costs the N.H.S. an average of 2s. 4d. weekly, surely a modest sum when compared either with the cost of corticosteroids or with the saving in suffering, working hours, and night visits which I find can be effected with this preparation.—I am, etc.,

London, N.W.2.

H. MARGULIES.

SIR,—As a psychiatrist treating a small but steady flow of asthmatic children and adults I wish to thank Dr. R. S. Bruce Pearson for his admirable article on the drug treatment of asthma (*Journal*, October 11, p. 905). While undoubtedly a large number of these patients have to receive palliative treatment only, and the best one can hope for is to make their lives a little more tolerable to them than it was before, there is no doubt at all that it is possible to cure a few of those that have been resistant to the orthodox management or derived only partial benefit, by the simple means of hypnosis and, especially, autohypnosis.¹

This is not a panacea, but is, with the necessary persistence, learnable; it is not time-consuming, and has few if any absolute contraindications. Apart from the important fact that it seems to help when nothing else does in the case of some patients, many have undoubtedly the capacity for profiting to some extent; it has especially often been remarked to me that "hangover" from drugs and other side-effects are completely absent. This particular technique can be easily acquired and has been used widely in Germany. There are literally dozens if not hundreds of publications in the German language on the matter.—I am, etc.,

Derby.

Malaria and Anaemia in Infancy

SIR,—Drs. R. G. Hendrickse and M. A. R. King (*Journal*, September 13, p. 662) have made an important contribution to the practice of paediatrics in West Africa by showing the relationship between malaria and the anaemia that is so frequent in infants here. An early verbal report of their findings had led us in this hospital to use routine suppressives on all Welfare infants. There are about 900 Welfare attendances at the hospital each week, and anaemia amongst these infants was at one time quite common. Over the last year it has been our practice to give a monthly tablet of pyrimethamine. This costs the hospital only 1.1d. per tablet. Since introducing this measure severe anaemia has become unknown amongst these children, and palpable spleens are uncommon.

Drs. Hendrickse and King offer no explanation for the frequency of negative blood-films. I should like to suggest that this may be due to small doses of quinine. The local mothers in this area are familiar with patent medicines containing quinine, and it is my experience that they may visit a local medicine stall for a dose of this before bringing their child to hospital. This small dose may temporarily clear the blood of parasites.—I am, etc.,

Wesley Guild Hospital,
Ilesha, Nigeria.

D. C. MORLEY.

Congenital Deaf-mutism

SIR,—Dr. L. Fisch (*Journal*, September 13, p. 692) finds it difficult to accept the evidence set out in my article (*Journal*, July 26, p. 201) on congenital deaf-mutism and criticizes the results of audiometry. I realized only too well the pitfalls associated with this method of examination, but, so far, there is no objective vibration. Awkward and

frustrating though it be, we still depend entirely on what the patient tells us.

For record purposes the audiometer used is a Peters fitted with its standard oscillator and providing in the cases noted an interrupted signal. The children mentioned in the article had experienced the sensations of hearing by earphones and therefore had a basis from which to work. With the oscillator applied to the mastoid region by an assistant, the child was repeatedly asked to differentiate between hearing and feeling, and, at the frequencies and intensities indicated, the answers were definite. In every case the signals were gradually increased from the minimal intensity up to the point of hearing.

Concerning the identical appearances of the audiograms noted by Dr. Fisch, it should be pointed out that since the original tests in May, 1957, repeat examinations have shown distinct variations in the curves although there remains in each the general pattern of bone conduction readings at lower intensities than air conduction.

The fact that the inner ear of the congenital deaf-mute is defective on histological examination may suggest that the initial lesion was in the cochlea, but tacit acceptance of this ignores (a) the association of deaf-mutism with congenital defects of the first visceral arch, (b) the complete absence of any recorded instance of other labyrinthine disorders in the deaf-mute child, and (c) the normal radiological appearance of the bony cochlea in deaf-mutism.

Mr. Bauer, who also finds my arguments unconvincing (*Journal*, October 4, p. 588), quotes the condition of bilateral congenital atresia of the auditory meatus with malformation of the incus to show that excellent inner-ear function may exist with an abnormality of the middle ear, but this does not mean that all middle-ear anomalies will allow of excellent cochlear function. His suggestion that the surgeon should examine the middle ear in the congenital deaf-mute through the operating microscope is an excellent one, and, so far as I am aware, has not yet been done. Undoubtedly it is the most direct method of proving or disproving my theory of the cause of congenital deaf-mutism, and I look forward to learning the results of such an investigation.—I am, etc.,

Aberdeen.

JOHN MCKENZIE.

Imbecile Children

SIR,—Dr. C. Guy Millman (*Journal*, October 4, p. 859) suggests that mentally defective children may die just as readily at home as in an institution, and that the high death rate which we reported in the post-admission period may therefore not be significant. He adds that one would not expect skilled nursing and medical attention to hasten the death of the children.

We do know that children on our waiting-list sometimes die at home. We wished, however, to draw attention to the very high death rate in the post-admission period. The figures which we reported provide an internal control, since they show that the death rate is related to the admission of the patient to hospital. If the children die merely because they are delicate, then there is no special reason why the deaths should be concentrated in the post-admission period. There is no question of the children being acutely ill on admission to hospital. They have been on our waiting-list for up to three years, usually at least one year, and we do not admit acutely ill children—they are referred to a paediatric department.

The problem of post-admission deaths merits further study. It is well known that there is a certain risk in admitting young children to hospital. In this respect mentally defective children seem to react like much younger children. We think that the excess of deaths can be partially explained on the following grounds:

(1) *Infection*.—Very backward children have often been rather isolated prior to admission and have not mixed with other children very much. On entering a large overcrowded ward they are exposed to a very considerable battery of mixed infection, much of which is new to them.

(2) *Status*.—At home most of these children are picked up, nursed, and moved a good deal by their mothers and others.

With the very limited nursing staff available this is not possible in hospital. This is particularly important in cripples. Static pneumonia associated with inefficient cough reflex and repeated inhalation of small quantities of food is the common cause of death.

(3) *Change of routine and fretting*.—Despite their low intelligence, our children have become accustomed at home to a certain diet, method of feeding, maternal attention, and so forth. Hospital admission means a sudden disturbance of this routine, with much reduced attention. Part of the loss of weight and other changes which so often follow admission may be attributable to this. Many of the children are manifestly miserable after admission.

It is not the skilled attention which hastens their death, but rather the shortage of it.—We are etc.,

London, S.W.17.

EVELYN B. LIND.

BRIAN H. KIRMAN.

Vitamin-D-resistant Osteomalacia

SIR,—In our report on "Vitamin-D-resistant Osteomalacia" we remarked upon a too ready acceptance of the theory that the basic causation of this group of disorders was simply a renal tubular defect with excessive phosphate leak (the "phosphate diabetes" of Fanconi). We quoted a paper by Dr. Alan Rose² as an illustration. Dr. Rose has pointed out to us that he did not in his paper actually state that the sole or basic cause of the osteomalacia in his case was a primary phosphate leak, although he emphasized the occurrence of a high renal clearance of phosphate.

In fairness we must agree that we all find a high phosphate clearance in these cases, but whether this is a primary renal tubular defect or whether secondary to some other disturbance (e.g., hyperparathyroidism) is uncertain. The title of Dr. Rose's paper was "Renal Tubular Osteomalacia," which would appear to indicate a basic aetiology, although this is not specifically stated. Certainly we (Jackson and Linder) previously agreed³ that a primary renal tubular defect provided a good explanation of the syndromes of "vitamin-D-resistant rickets and osteomalacia," but we are now less convinced, for reasons discussed in our recent paper.—I am, etc.,

W. P. U. JACKSON.

Treatment of Habitual Abortion

SIR,—Dr. R. V. Sutton's letter (*Journal*, October 4, p. 858) and your annotation on hormone-induced sex changes (*Journal*, July 26, p. 218) suggest there may now be conclusive evidence that progesterone therapy results in the production of some abnormal foetuses, particularly in regard to the genital tract. This is not our experience.

We have recently completed a series of 50 cases using 17- α hydroxy progesterone 17N caproate ("primolut depot"). There were only two abnormalities. One baby had pyloric stenosis, since successfully treated, and the other was an anencephalic foetus stillborn at 29 weeks. We hope shortly to publish our results. Reifstein¹ presented a comparable series to the New York Academy of Sciences on October 8, 1957. He had two abnormalities in 54 cases, neither of which involved the sex organs. Using large doses of this same hormone from the early weeks of pregnancy he had a foetal salvage rate of 69% in habitual abortion. In our own smaller series the salvage rate was just over 80%. We also agree with Reifstein that there does not appear to be any increase in foetal abnormalities in these cases. The average total dose of long-acting progesterone given by us to these patients was 3.375 g., and in seven cases where the therapy commenced within two weeks of the first missed period the total dose approached 5 g. There were no abnormalities in these latter cases.

What are the reasons for embarking on progesterone therapy? We employ this method of treatment when we

reach the conclusion that there is no other explanation for the abortion, threatened or by habit, or where we find an arborization effect in the cervical mucus. What is the type of case? (1) A woman who has had three successive abortions as her first experiences, in the absence of genital tract abnormality, can reasonably be assumed to have a hormone imbalance—that is, progesterone deficiency. Our results support this assumption. (2) The patient who has an abortion in her first pregnancy and threatens in her second frequently has sodium chloride crystals in the cervical mucus. We use this as an indication for progesterone therapy. (3) We also use this latter method of investigation in patients who threaten to abort in their first pregnancy.

We have no experience in the use of vitamin E in habitual abortion, but are confident some of Dr. Sutton's large series of cases must have been deficient in progesterone. Perhaps this vitamin fortifies the corpus luteum, stimulates the luteinizing factor of the pituitary, or in some way accelerates trophoblastic development, thereby facilitating implantation, but, whatever the reason, this large series should be published so that others can study it. We wish to congratulate Dr. Sutton on his results and to prevail on him to give his reasons for this therapy.—We are, etc.,

A.I.D. Investigation Council

SIR,—The Eugenics Society has set up an A.I.D. Investigation Council to consider the present status and future potentialities of A.I.D.—genetic, medical, legal, and social. The Council has in mind the maintenance of a permanent committee which will at all times have a record of all available data on A.I.D. cases done in this country, with all available medical and scientific information relevant thereto. The Council would be grateful to hear from any medical practitioner with a contribution to make towards this investigation.—We are, etc.,

69, Eccleston Square,
London, S.W.1.

PHILIP M. BLOOM,
MARGARET HADLEY JACKSON,
Hon. Secretaries, A.I.D. Investigation Council.

Protein Anabolizers

SIR,—In the interesting and timely annotation on tissue building and protein anabolizers (*Journal*, September 27, p. 785) it is stated that: "This good effect [of testosterone therapy for bone metastases due to breast carcinoma] has been attributed to a consequent change in hormonal environment of the cancer, possibly resulting in some depression of oestrogen action by testosterone. If this is so, no good result would be expected from the use of 19-nortestosterone in this disease." Whether in fact the action of testosterone in breast cancer is due to suppression of oestrogens or not is equivocal, but I would point out that norethandrolone, in addition to its other actions, is an antagonist of oestrone-induced uterine growth in intact immature mice, with seventy times the potency of testosterone propionate. This effect of 17-nortestosterone obviously cannot be due to its androgen activity, as the androgen:anabolic ratio of this steroid is 1:15, as compared to 1:1 for testosterone propionate.² However, so far as I am aware, it is not yet known whether norethandrolone reduces the secretion of, or antagonizes, oestrogens in man, but adrenocortical secretion can be suppressed in man by this new steroid.³—I am, etc.,

Bristol.

Prevention of Lung Cancer

SIR,—I disagree with the suggestion of Mr. Leslie J. Temple (*Journal*, October 4, p. 858) that the coroner should be notified of deaths due to carcinoma of the lung in heavy smokers. He draws a parallel between such deaths and the death of a coal-miner with pneumoconiosis or a mule-spinner with cancer of the scrotum.

The latter are examples of industrial disease and as such are notifiable. There is no significant occupational or industrial link in the case of cancer of the lung, which is basically a natural disease, usually, but not invariably, associated with the habit of smoking over a period of many years. There would therefore seem to be little justification for notifying the death, and, if notified, there is no certainty that the coroner will take further action. If, however, he does hold an inquest, he may put the following questions to the medical witness: Is it possible for a non-smoker to acquire cancer of the lung? Is it possible to smoke 40 cigarettes a day for the whole of one's adult life and escape cancer of the lung? The brief answer to both questions is "Yes," a reply which can only add to the confusion which exists in the minds of the public on this matter.

Certainly our profession should spare no effort to discourage a doubting public from smoking to excess and exposing themselves to the risk of cancer of the lung (and other diseases), but the coroner's court is not, I submit, the proper platform for propaganda directed to this end.—I am, etc.,

Canterbury, Kent.

G. B. FORBES.

SIR,—In the vexed question of the association of lung cancer and smoking, which has evoked much statistical analysis concerning the smoker and the preparations of tobacco smoked, and varying opinions as to their meaning, one wonders whether adequate attention has been paid to methods of igniting the tobacco.

An inveterate pipe-smoker myself, I have for decades refused to use other than a match, as the vapour from a lighter spoils the aroma throughout the entire smoke. Could it not be that pipe-smokers are more free from lung cancer than cigarette-smokers because they seldom inhale the fumes from flint-ignited lighters while those who smoke cigarettes more frequently do so? Lighter fuels consist of petrol and related substances, and, if such could be incriminated, at least a simple and rational link would be provided with the exhaust fumes of internal combustion engines, another frequently cited possible contributory cause.—I am, etc.,

London, W.1.

R. R. WILLCOX.

Informing the Hospital

SIR,—Dr. Norman Gold's letter on the identification of tablets (*Journal*, October 18, p. 978) raises a host of problems. They have naturally engaged the attention of the Joint British National Formulary Committee, to which he refers and of which I am a member, but the following remarks are entirely personal in an attempt to explain some of the points involved.

First of all it must be realized that when B.P. preparations are mentioned in the *Formulary* (or prescribed by the doctor) it is bound rigidly by the provisions of the *British Pharmacopoeia* itself, nor can we get away from this condition by omitting the letters B.P. if we use the same name. And the fact is that the *British Pharmacopoeia* Commission, I think unwisely, has set itself against any distinctive coloration of tablets, specifically stating: "The addition of colouring or flavouring agents, except where permitted in the monographs, is not official." And these permissions are hard to find. They seem to be limited to such things as tabs. mepyramine maleate ("anthisan"), promethazine ("phenegan"), or probantheline ("probanthine") where the substance is only made as a proprietary preparation and where the Commission cannot coerce the maker to its predilection to uncoloured tablets, with all their associated possibilities of confusion. It is true that in a few cases—e.g., tab. butobarbitone—the N.H.S. *Drug Tariff* does say "(may be coloured)," but this is strictly incorrect and, I think, *ultra vires*. In the same way a chemist who

provides pink tablets of stilboestrol, as he usually does, is not dispensing stilboestrol B.P. or B.N.F. and might theoretically be charged with wrongful prescribing, though not likely to incur any penalty. To give "fergon" instead of tab. ferrous gluconate is equally wrong, as fergon is red and the B.P. preparation is white.

The *British Pharmacopoeia* Commission recently replied vigorously to several curiously ill-informed criticisms of the Hinchliffe Committee, but, having participated almost *ad nauseam* in discussions on this question of distinctive coloration of tablets, I do not think that it can escape the conclusion that its present regulations tend to put a premium on doctors prescribing proprietary and avoiding "B.P." as much as possible. I need hardly say that I think this is wrong, and, as the new B.P. chairman was till recently the much-loved chairman of the Joint B.N.F. Committee and has heard all the arguments, we can certainly be sure that the matter will be well considered before the next edition appears.

At the same time there is much to be said for the B.P. It is primarily a book of standards and only secondarily one of preparations. Its aim is to maintain purity, etc., and, although the Commission contains many pharmacologists and practising pharmacists, its bias is more towards maintaining accuracy and stability of products than their sale in shops or use in medicine. This is exacting enough on its own, and it would probably be a mistake to try to saddle it with a lot of manufacturing details as well.

Besides the question of distinctive coloration there are possibilities of circumventing the B.P. regulations by differences in size and shape (though even here the B.P. Appendix XXI C sets strict parameters for its tablets, again excluding proprietaries) or by impressing specific dots, letters, lines, or other markings. Dr. Gold says that his collection contains 49 such specimens, but Bayer's latest handbook gives 33 distinctive marks, while I.C.I., Ciba, and others have long employed similar devices, so I fear his collection is far from complete. It would, I think, be impossible for our hardworking B.N.F. Committee (which for some of us involves about three half-days every month for 9-12 months for each edition) to correlate all these markings and devise new ones for every fresh drug, many of which will never get widely used in this country.

I am sure, however, that this matter is one worthy of serious attention, and that at present it falls between many stools. The B.P. Commission is aloofly concerned; on the B.N.F. we get nearer to the problem if not to the answer; manufacturers and dispensing chemists see their different aspects of it; while hospitals, doctors, and the Government, as the chief consumer, are all involved. One or two conferences of all parties concerned might at least lead to clarification of the main issues, and if they all came with the desire to find a solution and not hold their present ground some progress might be made in alleviating an ever-growing problem.—I am, etc.,

Winsford, Cheshire.

SIR,—The letter from Dr. N. Gold (*Journal*, October 18, p. 978) suggests that there should be a system for identification of drugs. There is an excellent "Tablet and Drug Identification Guide" published by the *Chemist and Druggist* which we find extremely useful in our hospital.—I am, etc.,

JANE M. FULLERTON.

St. Olave's Hospital,
Lower Road, London, S.E.16.

Convulsions and Epilepsy

SIR,—I was most impressed by the clarity and the good sense of the W.H.O. technical report on juvenile epilepsy.¹ It is because of its excellence in all these respects that I feel moved to protest on a matter of nomenclature. There is a trend among the experts in this field to accept all convulsions as synonymous with epilepsy, and in this report "epilepsy refers to all clinical forms of attacks that are investigations to be accompanied by the characteristic electrical activity of the brain recognized as epileptic." This definition may be scientifically accurate, but if every convulsion is going to be labelled as epilepsy it will prove embarrassing to the general practitioner who has an important role to play in the diagnosis and management of this

disorder. To him epilepsy connotes an episodic disease which can in most cases be controlled by anticonvulsants. The epileptic is thus either a person who has repeated fits of one kind or another, or who needs continuous treatment to keep them under control. The occasional fever fit is not considered to be epileptic, although it is appreciated that in a minority of cases such attacks are the beginning of chronic epilepsy.

Our patients accept the dictionary definition of epilepsy as "a nervous disease in which the patient falls to the ground unconscious, with spasms and foaming at the mouth." It is a term that conjures up the worst possible picture in the mind of the distraught mother of a child who has had a convulsion of any kind. Simple arithmetic shows that fever fits and epilepsy are not in fact the same thing. The report suggests that 6% of the population at one time or another have a convulsive episode. The present accepted estimate for chronic epilepsy is 3-4 per 1,000 of the population. This means that only one in every 15-20 people who have an occasional convulsion becomes a chronic epileptic, and of course only a small proportion of these chronic cases (my own figures suggest 12%) deteriorate: the majority, with their fits well controlled, are gainfully employed. My plea, in which I think most general practitioners will support me, is that scientific accuracy should be met by applying the term "convulsive disorders" to all epileptiform attacks and reserving the term epilepsy to describe the chronic case with repeated attacks either occurring or prevented by therapeutic measures. This differentiation will help the family doctor when he has to reassure the parents of a child who throws the occasional fever fit. While I am all in favour of early and full examinations of such cases by experts with all modern equipment, each case must be judged on its merits, and scientific progress must not be made at the expense of increasing parental distress and anxiety.—I am, etc.,

Ibstock, Leicester.

Beds for the Aged

SIR,—Dr. K. M. Tankard can rest assured that the Sunderland Geriatric Unit deals with all the cases he mentioned in his letter to the *Journal* of October 18 (p. 979). He is welcome to visit the department if he would like to see for himself.—I am, etc.,

Sunderland.

E. WOODFORD-WILLIAMS.

Buzzers for Bed-wetters

SIR,—The recent correspondence in the *Journal* has been concentrated on the physical methods of treatment of enuresis. It seems to regard it as due to some physiological dysfunction of the bladder and to ignore the psychogenic factors involved. Enuresis is a source of much unhappiness both to the child and the parents. It is the only symptom which children are ashamed of. The child frequently lacks the support and sympathy which he so desperately needs from his parents, who more often than not administer severe punishment, which nowadays tends to be mental rather than physical. So many parents adopt an attitude of hopelessness accompanied by nagging that the child becomes morose and introverted, and lives his life sodden, sore, odorous, and miserable. The anxiety accentuates the condition. Together with it goes the slacking at school and loss of self-confidence. Some psychogenic factors may complete the vicious circle—a new baby in the family, temporary or permanent loss of a parent, too anxious and worrying parents, illness, and a variety of other causes. Each treatment tried which fails to give permanent results only undermines more the patient's confidence.

The first thing to do, therefore, is to build up the child's confidence in himself and to get the parents to accept the symptom and to understand that their attitude is important. There may be something frightening and worrying the child at home or at school, and the enuresis may be a defensive

mechanism. This has to be discovered and dealt with and the patient's security restored. If the patient can be given confidence that the symptom can be controlled by himself, the anxiety ceases.

Hypnotherapy is by comparison more effective than any other therapeutic method in helping these patients. It makes it possible to deal with the fear, anxiety, and worry and to help them to fight against the habit irrespective of the factors causing it, and to restore their self-confidence. One hears very often from a child after a few sessions of hypnosis, "I don't seem to worry any more; even if I wet my bed I won't worry." By improving the child's confidence in himself one gives him back his self-respect, and one part of the vicious circle is broken. This, coupled with the explanations to the parents, often serves to break the remaining part of the circle. It usually results in a considerable improvement in the child's school progress.

The aim of the buzzer is to establish a conditioned reflex. It acts as soon as the patient passes some urine. It immediately lets the whole household know about it and it makes the unfortunate sufferer still more ashamed and worried. It does not help him to understand and deal with the underlying factors causing his complaint and to break the vicious circle. Dr. Clifford Allen (*Journal*, September 27, p. 799) mentioned in his letter about strong suggestions which he uses when treating enuretics with pituitary snuff. It would be interesting to try some cases giving them similar suggestions but with an inert snuff and see the results.—I am, etc.,

London, S.E.25.

A. FRY.

Coloured Immigrants

SIR,—Racial problems will not be solved by Dr. J. Tudor-Hart's denying (*Journal*, October 18, p. 974) the need for "more research into the results of race-mixing" (*Journal*, October 4, p. 843). Since almost every known species of animal with a wide distribution has differentiated into distinct geographical races, it is hardly surprising that man, who has the widest distribution of them all, should have done the same. A recognition of the differences, physical, mental, and cultural, between the primary races of mankind should go some way towards dispelling the nonsense talked about people simply happening to differ from each other in the colour of their skin and need do nothing to foster any idea of superiority or inferiority. A respect for other peoples' race might be a better basis for mutual co-operation than the rather doubtful compliment of trying to persuade a negro that he is the same as a white man. It has never been suggested in your columns that research should be bedevilled by politics and sentiment as was the case with the German race-scientists and the Russian plant-breeders; provided it is carried out with scientific integrity it can do no more than arrive at the truth.

As to the second problem Dr. Tudor-Hart mentions, it seems fairly obvious that too much money, too little work, no discipline, and less religious training will inevitably breed a generation of cowardly louts.—I am, etc.,

Moreton-in-Marsh, Glos.

E. H. EASON.

Anterior Spinal Artery

SIR,—In their report of a case of anterior spinal artery syndrome Mr. A. Davies, Dr. B. Solomon, and Mr. A. Levene (*Journal*, September 13, p. 654) discuss the anatomy of the arteries of the spinal cord. They state that the anterior spinal artery is virtually an end artery receiving significant collaterals only at the level of T1 and T11. This description is certainly not in agreement with the classic accounts of the circulation of the cord by Adamkiewicz¹ and Kadyj² nor with more recent work.³⁻⁵ The anterior spinal artery presents the appearance of an anastomotic chain made up of ascending and descending rami from a comparatively small number of anterior radicular arteries. In a series of 68 specimens examined by myself these latter vessels were found to range in number from 2 to 12. They were found distributed throughout the length of the

cord, but were most numerous in the cervical and thoracolumbar regions and were usually absent from the mid-thoracic region. The largest anterior radicular artery, the arteria radicularis magna of Adamkiewicz, was found anywhere between T6 and L3.—I am, etc.,

Manchester, 13.

"On Call to a Nation"

SIR,—In this T.V. documentary (see *Journal*, October 25, p. 1053) a G.P. is consulted by a young man suffering from headaches. He hands him a form without further questioning and tells him to go to an optician to get some glasses. He made no attempt to inform the patient that he could have a medical eye examination or one from an optician.

Fortunately many G.P.s realize that a member of their own profession can advise on the medical as well as the optical aspects of the case, and is in the best position to decide whether glasses are likely to relieve symptoms or not. They consider a medical test preferable if the patient has never had glasses before, in children, and of course if any pathological condition is suspected. However, there are quite a number of doctors who deliberately send their cases to opticians, and evidently this T.V. doctor is one of them. I feel that it is a pity that he should have appeared before the public as a champion of the ophthalmic optician in preference to recommending the patient to an ophthalmic medical practitioner. I hope that the T.V. authorities will grant an interview with a member of the N.O.T.B. Association so that the public will be furnished with the true facts.—I am, etc.,

London, W.14.

C. WATNEY ROE.

Premonition of Death

SIR,—The famous Nostradamus, who died on July 2, 1566, knew in the night about his death and at the end of June of the same year wrote with his own hand, "Hic prope mors est." In the evening of July 2 he told his disciple, "you will not see the living at the new dawn."—I am, etc.,

POINTS FROM LETTERS

Back-to-School Syndrome

Dr. J. SAPERIA (London, E.10) writes: Recent entrants to general practice may not be aware of the mothers' "back-to-school syndrome." It arises in those who rush to and from school with their young four times a day. Tiredness and recent loss of weight are the presenting symptoms. A rapid cure results from the organization of a rota, or leaving the child to school dinners.

Obituary

J. A. GUNN, C.B.E., M.D., D.Sc., F.R.C.P.

Professor J. A. Gunn, who died in Oxford on October 20 at the age of 76, was the professor of pharmacology in the University of Oxford from 1917 to 1937, director of the Nuffield Institute for Medical Research from 1935 to 1946, and Nuffield professor of therapeutics from 1937 to 1946.

James Andrew Gunn was born at Kirkwall in Orkney on January 26, 1882, and was educated there until he went to Edinburgh University. There he graduated M.A. in 1901, B.Sc. in 1903, and M.B., Ch.B. in 1905, proceeding M.D.

[Elliott & Fry]

in 1907 (gold medallist) and D.Sc. in 1909. Having distinguished himself greatly in scientific subjects, winning numerous prizes and scholarships at Edinburgh, he began to study pharmacology in the laboratory of Sir Thomas Fraser, and he continued in this field until his retirement. In 1912 Gunn was appointed reader in pharmacology at Oxford, and in the same year he was awarded a Beit research fellowship. After a period of service in the R.A.M.C. in the first world war, he was appointed professor of pharmacology at Oxford in 1917, occupying that chair until 1937, when he became the first Nuffield professor of therapeutics at Oxford. The degree of D.M. was conferred on him in the following year. When he retired in 1946 he was appointed emeritus professor. Besides many contributions to medical and scientific journals, Professor Gunn was the author of *An Introduction to Pharmacology and Therapeutics*, which reached its 9th edition in 1958. He also edited Cushman's textbook on *Pharmacology and Therapeutics* and Whittle's *Pharmacy, Materia Medica, and Therapeutics*.

Professor Gunn was a past-president of the Oxford Medical Society and of the Section of Therapeutics of the Royal Society of Medicine. At Annual Meetings of the B.M.A. Society of Medicine. At Annual Meetings of the B.M.A. he first held office as vice-president of the Section of Physiology and Pharmacology in 1920, and was president of the Section of Pharmacology and Therapeutics in 1927, 1932, and 1936. Elected a member of the first Pharmacopoeia Commission, set up by the General Medical Council in 1928, he later became chairman of the Commission, being appointed C.B.E. for this work in 1947. He also was a member of the B.M.A. subcommittee on the British Pharmacopoeia Commission and of the Committee on the Relation of Alcohol to Road Accidents. At the League of Nations in Geneva he served on the Committee on Narcotics. An honorary member of the Pharmaceutical Society, he was for some years a member of the council of that society. In 1935 he gave the Dohme lecture at Johns Hopkins University and four years later the Oliver-Sharpey lectures at the Royal College of Physicians in London, of which he was elected a Fellow in 1931.

J. H. B. writes: Professor Gunn's chair was very suitably attached to Balliol College, which has always had a strong Scottish connexion, and he was well known and greatly liked throughout the university. Extremely modest, with a cheerful and humorous disposition, he spoke quietly in a slightly husky voice which was full of charm. He had the appropriate degree of professorial absentmindedness,

and perhaps the best-known story of his early days at Balliol is how one evening he had gone by mistake to dine in the hall of St. John's. Balliol has long had a reputation for high thinking but austere living, and Gunn, halfway through his plate of soup, looked up and said, "Surely this cannot be Balliol!"

The grant of money available for running a department of pharmacology was very small in the early years, and for such a situation Gunn was an ideal person. He showed great ingenuity in devising simple experimental methods for which expensive equipment was not required, and built up a series of exercises for a practical class with very little expenditure. When the Sir William Dunn trustees invited the heads of some of the departments to submit proposals for expansion, Gunn's proposal, drawn up with a natural Orcadian sense of economy, was the one which they liked best, and their first intention was to build a school of pharmacology. Sir Walter Fletcher then became very active and persuaded them to build a school of pathology, having first secured Gunn's agreement to take over the existing pathology building for pharmacology.

A great blow which Gunn suffered was his very serious illness about 1925, when he had a streptococcal infection and lost his sight in one eye. At one stage the decision had been taken to remove the eye, but on the morning on which the operation was to be performed his small son, coming in to see him, noticed that his eye was better, and as a result the eye was left in its place. There can be little doubt that this illness compelled him to reduce his scientific activity for some years.

Gunn was a very attractive lecturer, both because of his voice, to which it was a pleasure to listen, and because of his skill in presenting his matter and of the care he took in making it interesting. The same success which he had as a lecturer attended his writings. In this respect his *Introduction to Pharmacology and Therapeutics* was a model, for his style was full of grace. On the title-page appeared a quotation from Oliver Goldsmith: "Were angels to write books, they would never write folios," and this showed how clear a grasp he had of the art of teaching.

The main line of research followed by Gunn was laid down by an interest in adrenaline which he gained as a pupil of Schäfer, who had gone to Edinburgh in 1899. Gunn investigated the action of the amines which formed a series beginning with phenylethylamine and ending with adrenaline. In his Oliver-Sharpey lectures given in 1939 he gave an account of this work, which is of greater interest to-day than it has been in the intervening period. In 1914 Bry had shown that phenylethylamine had a central excitatory action because of its effect on respiratory rate and in causing convulsions. In 1932 Gunn with his colleagues Epstein and Virden observed that this central action was almost abolished when an —OH group was attached to the ring in the *para* position (forming tyramine) and disappeared altogether when a second —OH group was added in the *meta* position (forming dopamine). While the introduction of —OH groups removed the central action, Gunn showed that the introduction of an —OCH₃ group restored it, whether the restoration was in the *para* or *meta* position. He also showed that the central action again disappeared when two —OCH₃ groups were introduced. He concluded that central stimulation was likely to be found when the benzene ring was unsubstituted, when it contained a methoxy group or a methylene dioxy group. The compound which was most active centrally was methylene dioxypheylisopropylamine.

The interest of this work to-day springs from the knowledge that the pathway of the breakdown of adrenaline in the body is through the methylation of the —OH group in the *meta* position in the ring, and that the enzyme which effects this methylation is also present in the brain. Gunn's own interest in his experiments lay in the hope of finding a pressor agent more stable and more prolonged in action than adrenaline or tyramine, but lacking the central action of amphetamine or ephedrine. Starting from phenylethyl-

amine he proposed the introduction of a $-OCH_3$ group in the *meta* position and an $-OH$ group in the *para* position to neutralize the central action. Then he proposed substituting a $-CH_3$ group on the α carbon of the side chain to render the substance immune from attack by amine oxidase. This compound was synthesized by Sir Robert Robinson and did indeed fulfil some of the hopes. Its duration of action was five times as great as that of adrenaline, and its toxicity was only one-sixth that of amphetamine. In later papers he studied the cyclohexylalkylamines, and the effect of introducing unsaturated linkages in the side chain.

Professor Gunn was a wise and learned man, courteous and fair to all who knew him, and a sympathetic examiner of medical students. He was regarded with sincere affection and great respect. In his home life he was blessed in having a devoted wife, who survives him, together with a daughter and two sons. His third son was killed in the fighting in Italy.

D. B. McGRIGOR, O.B.E., M.B., Ch.B., D.M.R.E.

Brigadier D. B. McGrigor, formerly consultant radiologist to the Army, died in Colchester Hospital on October 22, aged 73.

Dalziel Buchanan McGrigor was born on January 20, 1885 at Torry, Aberdeen, the son of James McGrigor, a consulting engineer who practised in Calcutta. Educated at Robert Gordon's College, Aberdeen, he went on to the University of Aberdeen to study medicine, graduating M.B., Ch.B. in 1907. After holding a resident hospital appointment in Perth, he entered the R.A.M.C. in 1907 and, having qualified with distinction as a specialist in electrical services at the Indian X-ray Institute, he served in India from 1909 to 1914. During the early part of the first world war he was on active service in France, with the Indian Expeditionary Force, in charge of No. 1 field x-ray section. Returning to India in 1916, he was appointed D.A.D.M.S. of the 9th Indian Division in 1918. In the following year he was promoted major and appointed O.B.E. From 1919 to 1920 he was D.A.D.M.S. of Northern Command at York. Having taken the D.M.R.E. of Cambridge in 1920 he became specialist in charge of radiology at Queen Alexandra Military Hospital, Millbank, and lecturer to the Royal Army Medical College. Retiring from the R.A.M.C. in 1927, he was appointed adviser and examiner in radiology to the Army Medical Services. In the same year he went on a visit to Army Medical Headquarters in Washington to inspect the radiological services there. Four years later he carried out a similar visit of inspection at Army Medical Headquarters in Paris while attending the Third International Congress of Radiology as a member of the British delegation. In 1939 McGrigor was recalled from the reserve, and as an adviser in radiology to the Army Medical Services he organized the Army School of Radiology. In 1941 he was promoted brigadier, and in the following years undertook tours of inspection in N. Africa, the Middle East, and France. Continuing to serve as consultant radiologist to the Army Brigadier McGrigor finally retired in 1952, when 67 years of age. As a result of his work during the second world war he was awarded the Legion of Merit by the United States Government, the Czechoslovak Military Medal (1st class), and the Polish Silver Star.

Brigadier McGrigor was a member of the executive committee of the British Institute of Radiology for many years, and was president of the Institute from 1939 to 1942. In 1946 he received, jointly with Lieutenant-Colonel Eric Samuel, the Roentgen Award of the Institute. In 1935 he was vice-president of the Section of Radiology and Radiotherapeutics at the Annual Meeting of the B.M.A., held in Melbourne that year. Well known and popular among American radiologists, he was elected an honorary fellow of the American College of Radiology in 1952. He was also an honorary fellow of the Society of Radiographers.

Brigadier McGrigor married Dorothy Macgregor Drysdale in 1912, and she survives him with one daughter and two sons, Dr. A. B. McGrigor, senior registrar in the department of diagnostic radiology at University College Hospital, and Mr. R. B. McGrigor, senior registrar in the department of surgery at St. Bartholomew's Hospital.

We are indebted to Dr. R. BOULTON MYLES for the following appreciation: It was at the Royal Army Medical College at Millbank in 1921 that I first met "Mac." He was then the officer in charge of the x-ray and electro-medical departments of the Queen Alexandra Military Hospital, and lecturer in radiology at the College, so to me, a junior officer on a promotion course, he was a big man. And he remained so, big in knowledge as well as stature, and—how important this—big in heart. The fact that he was a senior officer never obtruded itself, which was one of the reasons why he was such an excellent teacher, as I was to discover later when I was privileged to attend the specialist course under him. Very quick to size up a student's general outlook and possibilities, he seemed to know exactly when to be strict and when to relax, when to be present and when to leave us to work out our problems on our own initiative. Before the end of the course I found that in addition to meeting a first-class teacher I had made a new friendship—one which has now been broken by the only possible means. When he retired from the Army he did not sever his connections with Army radiology, but remained as secretary and mainspring of the Army X-ray Advisory Committee until it was finally disbanded after the war. Meanwhile, though not practising as a radiologist, he was taking a more important place in medical radiology outside the confines of the Services. He was treasurer of the British Institute of Radiology for ten years, and relinquished the office then at his own request because he thought it was time for a younger man to take over. The Institute signified its approval by making him president instead, and keeping him there for three times the normal term of office.

On the outbreak of war in 1939 he was immediately called to the War Office to correlate radiological services in the Army—in other words, to put into practice the fruits of his previous labours on the X-ray Advisory Committee. The Army was indeed fortunate to have at its disposal one whose hobby ever since he left the active list had been the study of medical radiology in its broadest aspects, and undoubtedly with particular reference to the possibility of just such an emergency. His knowledge of the technical problems involved and his close liaison with the designers and manufacturers of the essential apparatus enabled him to take the duties of an onerous post in his stride, so that he appeared always to have time for personal consultation regarding the numerous problems which arose. Since the war his radiological activities had lessened, not through loss of interest, but because, in his own words, "We old men should step aside and let the others carry on." Nevertheless, he remained a staunch supporter of the British Institute of Radiology and attended its meetings with great regularity. Another of his important side-lines was his interest in the R.A.M.C. Officers', Widows', and Orphans' Friendly Society, to which he devoted a great deal of time and thought for many years. Its strong position and smooth running are due in no small measure to his efforts. Mac was, in the best sense of the phrase, a good mixer, and he had friends everywhere. He missed no opportunity of visiting hospitals and x-ray engineering works in Britain and in most parts of the world, and wherever he went he was always asked to return. Only last year he toured Canada and the U.S.A. again at the invitation of the American radiologists, who had a very high opinion of his qualities. In addition to being universally popular outside, Mac was very much a family man, and we who are going to miss our occasional contacts with him realize how much more he will be missed at home. He was a great personality, of a type which we can ill afford to lose.

W. S. FLOWERS, M.B., Ch.B.

Dr. W. S. Flowers, formerly a medical missionary in China, died at Harrogate on September 26. He was 60 years of age.

Wilfred Stephen Flowers was born on May 27, 1898, and studied medicine at Leeds University, where he graduated M.B., Ch.B. in 1925. He had already been trained in missionary work, and after graduation went to China as a medical missionary. He left that country in 1939, after being ill-treated by the Japanese in occupied China, and was medical superintendent of the Wharfedale Hospital, Sheffield, for two years. He then went back to China to take charge of a British Red Cross Hospital on the Burma Road. He also assisted the Chinese Government in its task of medical reconstruction after the defeat of the Japanese in the second world war. In September, 1948, he was among the last to leave Tsinan before that city was captured by the Chinese Communists, and the time of his escape coincided with a breakdown in health, which caused him to give up missionary work abroad. At home he became secretary of the Yorkshire Association for the Care of Cripples, an appointment he held until his death. He leaves a widow and two sons, both of whom are in the medical profession.

R. B. writes: Dr. Wilfred Flowers, "Blossom" to his fellow residents at the General Infirmary at Leeds, had first trained at Rawdon Baptist College in preparation for his work as a medical missionary before proceeding to Leeds University for his medical training. While a student he was a member of the universities debating team which toured South Africa in 1924. After graduation he embarked on his life's work in China. He established and was in charge of the Missionary Hospital at Chowtsun, and had a difficult time when it became Japanese occupied territory. After furlough in England he returned to China in 1942 as leader of a British Red Cross unit. He was the first representative of the Allies to enter the Japanese internment camp at Shanghai with news of deliverance. In 1946 he accompanied Sir Clutha Mackenzie on a tour of China primarily concerned with the "non-sighted." In 1948, when the Communists were coming into power, he was about to board an aeroplane to go and see Mao-Tse Tung about the rehabilitation of missionary hospitals, when he had his first coronary attack. Unable to continue his Yorkshire Association for the over the secretaryship of the Yorkshire Association for the Care of Cripples and established training centres for cripples, first at Harlow Grange and then at St. George's, Harrogate.

WILLIAM DAVIES, M.R.C.S., L.R.C.P.

Dr. William Davies, who was medical superintendent of the Sully Hospital, Glamorgan, from 1935 to 1951, died on September 28 at the age of 73.

William Davies's life was very much a triumph over adversity. Starting to earn his living at a very early age, he found himself forced, at the age of 26, to give up his work or risk the possibility of blindness. Deciding to become a teacher, he went to Carmarthen to prepare himself for his new profession. There a friendly medical practitioner recognized his abilities and persuaded him to switch to medicine. While studying in London he came under the influence of Sir Robert Hutchison, and this period of hero-worship did him much good and was to shape his attitude towards his profession. One could detect the insistence on realism, the tendency to "debunk," and the thoughtful approach to problems. This attitude had been superimposed on a nature that was essentially kindly, a nature marked by a desire to help and with an instinctive knowledge of the psychology of his patients. Shortly after qualifying M.R.C.S., L.R.C.P. in 1918 he went to Brecon, and it was from there that he was induced to join the staff of the newly opened South Wales Sanatorium at Talgarth. The appointment was a temporary one, but he soon found that tuberculosis was to be his life's

work. He never left the service of the King Edward VII Welsh National Memorial Association.

In 1924 he was invited to open the recently adapted Cefn Mably Hospital, near Cardiff. At Talgarth he had helped in the rehabilitation of tuberculous patients, but at Cefn Mably Hospital he had to treat patients in a more active stage of the disease. During the eleven years he spent there he extended his knowledge of his subject by visiting Switzerland to see the treatment of bone tubercle by heliotherapy and then to Paris and Berck-Plage to see the treatment by immobilization in plaster. Before completing his stay in Cefn Mably he was appointed to the Sully Hospital, which was in course of construction. He supervised the construction and equipment of the hospital, and during the year before completion his job was a full-time one. The appointment was a unique one and was fully justified by the saving in mistakes, in time, and in money. He had time to consider the different types of equipment and to make a sound judgment. There was a rare understanding between Davies and his chief, Dr. Dan Powell. Their wish to make the hospital up to date was fulfilled. All this was not accomplished without sacrifice. In addition to his eye trouble he had been plagued by migraine and by sciatica—the latter a reminder of his work in earlier days. His great interest was in radiology, and he specialized in this work. Perhaps the threat to his eyesight made him see in x rays a third eye to help him in his work. It was a source of wonder and amusement to his patients that he recognized them by screening them. At Sully he set the pattern and helped to raise it to the international status it now enjoys. He retired in 1951, but, being much too interested to stop work, he joined the Pneumoconiosis Panel, where his previous knowledge of mining was a great asset. His death is a great loss to those who knew him, and sincere sympathy is extended to his widow and children. His son and daughter have followed his example and are members of the medical profession. It is perhaps fitting that we should remember this well-beloved Welshman by a quotation from the language he loved so much. It is a proverb that sums up his life: A dyf dddwg wybodaeth, a gwybodaeth ddoethineb (Adversity brings knowledge and knowledge wisdom).—H. A. R.

J. A. MORTIMER, M.D., F.R.C.P.Ed.

Dr. J. A. Mortimer, consulting surgeon to the Glasgow Eye Infirmary, died at Law Hospital, Carlisle, on October 10. He was 71 years of age.

John Alexander Mortimer was born on May 16, 1887, the son of an Edinburgh law agent, and was educated at George Watson's College and at Edinburgh University. After an undergraduate career of some distinction, he graduated M.B., Ch.B. in 1909. Two years later he proceeded to the M.D. and was elected a Member of the Royal College of Physicians of Edinburgh, being admitted a Fellow of the College in 1943. After graduation he was an assistant in general practice in Dumfries, before beginning his specialist career at the Bradford Royal Eye and Ear Hospital, where he remained until 1921. During the first world war he served in the R.A.M.C. as an ear, throat, and nose specialist at Étaples. In 1921 he gave up the throat and nose side of his practice to become school oculist to the Lanarkshire education authority, and a year later he was admitted to the staff of the Glasgow Eye Infirmary, where he became a full surgeon in 1935. After his retirement from the hospital in 1947 he carried on his school work in Lanarkshire until shortly before his death. In addition to these appointments, he was a certifying surgeon to the Mission to the Outdoor Blind in Glasgow. He carried on a private practice in Lanarkshire, where his name was well known. Taking a prominent part in the work of the West Church of Hamilton, he was for over 30 years an office-bearer there. He was a very good and enthusiastic golfer. A man of pawky humour, he never lost his east coast accent, nor his command of the Doric. His opinions of all forms of government were

freely expressed in terms which left the politicians—medical or otherwise—in no doubt as to his opinions. In spite of these strongly and vigorously expressed views he was, withal, a kindly man, and his patients and colleagues could see the kindly man under the rough exterior.

W. A. A. FAMUYIWA, M.B., Ch.B.

Dr. W. A. A. Famuyiwa, a young Nigerian who had been in the medical profession only a few months, was killed in a car accident near Berwick-on-Tweed on October 19. He was 35 years of age.

Wilson Adelola Alade Famuyiwa was born on January 18, 1923, and studied medicine at St. Andrews University, where he graduated M.B., Ch.B. last July. At the time of his death he held an appointment at the Bridge of Earn Hospital.

A. P. writes from Dundee: The tragic and untimely death of "Famy" as a result of a car crash came as a great shock to those of us who were privileged to have experienced his friendship. His cheerfulness was infectious—he enjoyed life to the full, and those with whom he was in contact enjoyed it with him. His radiant smile was disarming and a source of delight to his colleagues, nursing staff, and patients. He was always ready to perform acts of kindness and service to his friends; he never bore a grudge, nor had he a harsh word to say to or about anyone. "Famy" was a sincere and good man, and a fine ambassador for Nigeria. His death is a great loss, not only to his friends in Great Britain but also to his own people, among whom he ultimately intended to practise.

H. E. HODGE, M.B., Ch.B.

Dr. H. E. Hodge, better known as Merton Hodge, playwright and actor, died recently at Dunedin, New Zealand, at the age of 54.

Horace Emerton Hodge was born at Gisborne, New Zealand, on March 13, 1904, and was educated at King's College, Otahuhu, at Auckland University College, and at Otago University, graduating M.B., Ch.B. from the University of New Zealand in 1929. After house appointments at the Dunedin, Wellington, and Auckland Hospitals, he came to Britain to take a postgraduate course at Edinburgh, and while there wrote *The Wind and the Rain*, a play which subsequently ran for 1,000 performances in London. On leaving Edinburgh he served in the R.A.M.C. for two years, and this was followed by a further year as an anaesthetist at St. George's Hospital, London. In 1935 he gave up medicine to take his play to New York. For the next four years he concerned himself almost solely with authorship and dramatic work. He anglicized the American play, *Men in White*; he wrote his second play, *Grief Goes Over*, which was presented in London in 1935; and in 1936 he published *The Wind and the Rain* as a novel under the title of *The Island*. Three other plays came from his pen up to 1939, when, on the outbreak of the second world war, he returned to London and to medicine. From 1939 to 1944 he was on the staff of the Camberwell House Hospital for Nervous Diseases. After the war he was in practice in London for a few years, and finally in Dunedin. He was unmarried.

HENRY WALLACE-JONES, M.Sc., M.D., F.R.C.P.

The obituary of Dr. Henry Wallace-Jones was printed in last week's *Journal* (p. 1045).

E. N. C. writes: I had the privilege of working with Henry Wallace-Jones on and off for over 35 years. When he was assistant physician to Professor John Hay I acted as their house-physician and later medical registrar. No one could have been more kind to a young man. He was able in a clear and simple fashion to give excellent clinical instruction to his students and younger staff, and always in a spirit of toleration and understanding of our ignorance.

As time passed and Professor Hay retired, Wallace became head of the heart clinic, which had been founded by his chief, a disciple of Mackenzie: he was therefore in direct succession to the pioneers of British cardiology. At this time I became his assistant physician and was again impressed by his quiet modesty and the sense of happiness which he spread among all of us who had the privilege of working with him. Apart from his outstanding clinical ability, he had an inquiring type of mind, with a great zest for the mastery of the modern instruments of cardiology. If his active life had been prolonged 10 years I am sure he would have been in great sympathy with the modern highly scientific approaches to the problems of heart disease. But in his own day he made the best use of the polygraph, the electrocardiograph, and the radioscope. He did not write extensively, but his publications are such as to have stood the test of time. When he retired from the Royal Infirmary, to which he had loyally given the whole of his professional life, he sought the sunnier climate of South Africa and continued for a little while to practise as a consulting physician. Once a year he came back to England, and only recently we had the pleasure of a short visit by him to the regional cardiac centre. He still had family interests in Liverpool, where one of his sons practises as a radiologist, and I know that much of his retired life was devoted to the furtherance of his children's plans. He was a happy man by disposition, and his devoted and charming wife helped him to spread this happiness to all those who had contact with him. There must be many outside the Royal Infirmary who will mourn his loss but who will be grateful for their pleasant associations with him.

CHARLES M. FRIER, M.B., C.M.

The obituary of Dr. Charles Frier was printed in the *Journal* of October 11 (p. 921).

J. B. A. writes: With the death of Dr. Charles Frier the people of Grantham and its surrounding villages have lost an old and a trusted friend. When he retired three years ago he had been in active practice in Grantham for sixty years. He will be missed by a host of patients who had also become his friends, and though his manner at times was abrupt they knew they could trust him. He was typical of the best of the general practitioners of his generation, being efficient in all branches of medicine and surgery, including gynaecology and ear, nose, and throat work. He had his own x-ray apparatus, which he managed himself. He also did refractions. In fact, he was both "Jack" and "Master" of all trades. On coming to Grantham he purchased a small declining practice, and when he retired he was the senior partner in a large firm of six principals. One of his lifelong interests was the welfare of children, and for years he was the secretary of the local branch of the National Society for the Prevention of Cruelty to Children. He was the treasurer and founder of a local fund, known as Dr. Frier's Crippled Children's Holiday Fund, whereby about thirty children—not now, I am glad to say, all cripples—are sent to the sea each year for a fortnight. This year was the first year he was unable to be there in person to see them off. For many years he was an active member of the local bench and chairman of the juvenile court, where his wisdom and understanding were of great value. He was a most generous person, and his name figured prominently in all charitable appeals. I was told a story the other day by an old district nurse, which is typical of "The Old Man." One day, years ago, she saw his bicycle outside a cottage in a village five miles away at about 8 a.m. She went in and found Dr. Frier on his knees setting and lighting the fire. The patient upstairs was about to have a baby, and there was no hot water and no help. He was, of course, looked up to by all the profession in Kesteven. Anyone in trouble or difficulty always turned to him for advice and help, which was unfailingly given.

F. J. J. writes: Dr. Charles Frier was regarded for many years as the doyen of the medical profession of the Kesteven

area of Lincolnshire. He came to Grantham some sixty years ago, and when he retired a few years ago the partnership had risen to one of six doctors. He represented the old school, and his Gladstonian manner of dress lent dignity to his appearance at the meetings of the Representative Body, at which he was a well-known figure. His rugged personality deceived a little, but hid a kindly character. Always ready to help, his charitable acts were known to only a few. Apart from his vast medical knowledge he possessed considerable surgical skill in his younger days and undertook operative procedures under conditions that would test the courage of a modern surgeon. He had untiring energy, and up to the age of 70 would work until the early hours of the morning. He retired from practice only a few years ago, though he continued to visit a few favourite patients. He was one of the early members of the Kesteven Division, and was its representative in the Representative Body, alternately with the Holland Division, before the two Divisions were granted separate representation. He continued to serve in this capacity for nearly forty years, until, in different health made it difficult for him to attend. A former president of the Lincolnshire Branch and chairman of the Kesteven Division, his knowledge of B.M.A. affairs and medical politics was phenomenal. He acted as secretary of the panel committee from its inception and of its successor, the local medical committee, for some years, and he was treasurer of the latter until his death. During the second world war he was for a time chairman of the local medical war committee. He served on the staff of the Grantham Hospital for twenty-five years until 1948, and held the appointments of public vaccinator and Poor Law medical officer. He instituted a local charity for providing seaside holidays for sick children. As a token of esteem the Lincolnshire Branch of the B.M.A. presented him with a pair of antique candlesticks some ten years ago, and his election as a Fellow of the Association this year gave him considerable pleasure. He became a widower fifteen years ago, and the loss of an only son under tragic circumstances while at school left a permanent scar, although assuaged by the loyal and devoted care and companionship of his only daughter. Dr. Frier will be long remembered in his locality as an outstanding figure reminiscent of the Victorian era, a wise counsellor, a friend to everyone, and a practitioner who embodied all that is noble and fine in the medical profession.

Medico-Legal

CERTIFICATION WITHOUT SEEING PATIENT

[FROM OUR LEGAL CORRESPONDENT]

While her husband was a prisoner in Barlinnie Prison Mrs. George Black, of 11, Black Street, Glasgow, got his doctor to certify without seeing him that he was unfit on the usual National Health Service Act form stating: "I certify that I have examined you . . ." Mrs. Black told the doctor, who knew that Black's foot was in plaster and had hospital reports on his condition, that as her husband's foot was swelling he was staying at home. She did not reveal the fact that he was in prison. The doctor was prosecuted for granting medical certificates falsely stating that he had examined his patient. He was found not guilty in the Sheriff Court at Glasgow on July 14, but the Crown appealed. In the Scottish Justiciary Appeal Court the Solicitor-General said that if the Crown succeeded no further proceedings would be taken against the doctor, but the aim was to get the Court's ruling on whether the Sheriff-Substitute had been entitled to acquit him.

In his judgment (*Glasgow Herald*, October 10) Lord Clyde said that to certify that a patient had been examined when he had not was a contravention of the National Health Service (Scotland) Act. In the issue of a certificate authorizing the expenditure of public money laxity was to be

deplored. No doubt partly with this in view the statutory form demanded not only a diagnosis but a statement that there had been an examination of the patient. The Sheriff-Substitute had not been entitled to find the doctor not guilty.

CRIMINAL ABORTION AND MANSLAUGHTER SENTENCE REDUCED ON APPEAL

[FROM OUR LEGAL CORRESPONDENT]

On October 15 the appeal of Louis Aimee Newton against his sentence of three years' imprisonment for manslaughter and two years for unlawfully using an instrument to procure a miscarriage was heard by the Court of Criminal Appeal (*The Times*, October 15). Mr. Justice Ashworth at the trial had ordered the two sentences to run consecutively (*Journal*, May 24, p. 1242).

The Lord Chief Justice said that the consecutive sentences had been given for what was really the same offence, since it was the use of the instrument, and not any criminal negligence apart from that, which had caused the death. It was wrong in principle to give consecutive sentences for what was in effect one offence. Moreover, the judge in sentencing Newton had made it clear that he had it in his mind that Newton was a professional abortionist. There was no evidence whatever of that, and he ought to have been dealt with on the basis that it was an isolated case, although it was a serious offence. Accordingly the Court substituted sentences of 3 years' and 2 years' imprisonment concurrent for the consecutive sentences.

Newton's counsel told the Court that the proposed appeal against conviction had been abandoned on advice that the summing up at the trial could not properly be criticized.

BROADMOOR PATIENT TREATED AS SANE

[FROM OUR LEGAL CORRESPONDENT]

Frank Samuel Mitchell, aged 24, escaped from Broadmoor on July 8 (see *Journal*, July 19, p. 174) and robbed Mr. and Mrs. Peggs, of Wokingham, of clothes and a car and some money in furtherance of his escape, using violence towards them. After being at large for two days he was arrested in a Bournemouth-to-London motor coach at Hartley Witney. He was charged on October 2 at Reading Assizes with robbery with violence and pleaded guilty, asking through his counsel to be treated as a sane man (*The Times*, October 3).

Dr. Francis Brisby, the medical officer of Brixton Prison, said in evidence that although Mitchell was an aggressive psychopath he was not in his opinion certifiably insane. Mitchell at the age of 5 had been found to be of subnormal intellect, and was placed in the care of the L.C.C. He had greatly improved as a result of his treatment in Broadmoor, where he was sent in April, 1957, and was now in the process of maturing slowly, as could be seen from his progress educationally, emotionally, and in the ability to control his impulses. He had worked very hard to overcome the stigma of intellectual subnormality.

In sentencing Mitchell to life imprisonment Mr. Justice Byrne said that the medical evidence had satisfied him that Mitchell was sane and had been sane when he had committed these offences. The sentence of life imprisonment enabled the Secretary of State to review matters periodically and did not necessarily mean Mitchell would be in prison for the rest of his life.

Another Broadmoor patient, Clive Pickering, after being found unfit last June at York Assizes to plead to a murder charge, is now to stand his trial (*Daily Telegraph*, October 21). He is charged with the murder of John Frederick Boucher, aged 45, who died in the River Hull in May. After medical evidence at the Assizes, Pickering, aged 27, was ordered to be detained at Broadmoor. In a statement on October 20, Pickering's solicitor said: "We received two letters from Pickering. In view of the contents of the letters we made representations to the Secretary of State, and as a result Pickering will stand his trial."

Vital Statistics

England and Wales in Third Quarter

Live births numbered 180,167, giving a rate of 15.8 per thousand population, as compared with 15.9 in 1957 and 15.5 in 1956. Deaths numbered 105,547, giving a rate of 9.3 per thousand population. The rates in the September quarters of 1957 and 1956 were 9.7 and 9.3 respectively. The infant mortality rate, 19.8 per thousand live births, was again a record low figure for the quarter. The previous lowest for this quarter was 20.1, recorded in 1956. In 1938 the corresponding rate was 42.5. The stillbirth rate was 21.4 per thousand live and stillbirths; in the corresponding quarter of 1957 it was 22.4.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the years 1949-57 are shown thus - - - - -, the figures for 1958 thus ———. Except for the curves showing notifications in 1958, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Week Ending October 18

The increases in notifications of infectious diseases in England and Wales during the week ending October 18 included 961 for measles, from 2,778 to 3,739, 147 for scarlet fever, from 648 to 795, 146 for dysentery, from 512 to 658, 35 for acute pneumonia, from 216 to 251, and 30 for food-poisoning, from 229 to 259; the largest decreases were 43 for acute poliomyelitis, from 113 to 70, 24 for whooping-cough, from 500 to 476, and 15 for diphtheria, from 25 to 10.

10 cases of diphtheria were notified, 15 fewer than in the preceding week; 6 of these cases were notified in London (Finsbury 4, Islington 1, St. Pancras 1) and 2 in Barking M.B.

The largest rises in the incidence of measles were 114 for Yorkshire West Riding, from 306 to 420 (Halifax C.B. 104, Keighley M.B. 68); 109 in Yorkshire East Riding, from 110 to 219 (Kingston-upon-Hull C.B. 190), 94 in Middlesex, from 102 to 196 (Harrow M.B. 60), 83 in Kent, from 25 to 108 (Dover M.B. 68), 73 in Buckinghamshire, from 15 to 88 (Bletchley U.D. 87), 73 in Cheshire, from 176 to 249, 68 in Wiltshire, from 90 to 158 (Swindon M.B. 85). The largest increases in the notifications of scarlet fever were 31 in Lancashire, from 105 to 136, 29 in Yorkshire West Riding, from 77 to 106, 23 in London, from 47 to 70. The only large fluctuation in the returns of whooping-cough was a rise of 24 in Lancashire, from 47 to 71.

The notifications of acute poliomyelitis numbered 70, and these were 36 fewer for paralytic and 7 fewer for non-paralytic cases than in the preceding week. The largest returns were Lancashire 15 (Manchester C.B. 5, Liverpool C.B. 3), Yorkshire West Riding 9 (Huddersfield C.B. 3), London 7 (Shoreditch 2), Sussex 5 (Portslade-by-Sea U.D. 2, Shoreham-by-Sea U.D. 2).

The chief centres of dysentery were Yorkshire West Riding 123 (Leeds C.B. 32, Dearne U.D. 28, Ripon and Patley Bridge U.D. 21), London 73 (Islington 23), Hampshire 49 (Southampton C.B. 46), Lancashire 45 (Liverpool C.B. 21), Staffordshire 43 (Kidsgrove U.D. 41), Glamorgan-shire 34 (Rhondda M.B. 24), Northumberland 28 (Newbiggin-by-the-Sea U.D. 19), Warwickshire 28 (Coventry C.B. 18), Gloucestershire 27 (Bath C.B. 26), Nottinghamshire 26, Middlesex 25, Monmouthshire 23 (Newport C.B. 23).

Medical News

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending October 11 (No. 41) and corresponding week 1957.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the whole of England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES	1958					1957

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenza pneumonia.
‡ Includes puerperal pyrexia.

Nuffield Orthopaedic Centre.—At Oxford on October 27 QUEEN ELIZABETH THE QUEEN MOTHER opened a new building for teaching and research at the Nuffield Orthopaedic Centre. Professor J. TRUETA, its director, described the Centre in an article in the *Journal* in 1951 (April 28, p. 940). Two years ago Lord NUFFIELD added a further £200,000 to the £50,000 he had already given "to create in perpetuity an orthopaedic teaching centre under the guidance of the Nuffield professor of orthopaedic surgery in the University of Oxford," its main purpose being to offer facilities for training and research to young orthopaedic specialists, mostly from the Dominions, Colonies, and abroad. The new building substantially increases the Centre's facilities by providing a new and larger records office, clinical examination rooms, a department of radiology, and offices for the clinical consultants. But the most important addition is the new university department of orthopaedic surgery. Besides offices for the teaching staff and scholars, the department has laboratories for histology, pathology, electron-microscopy, and x-ray diffraction, together with a museum and an enlarged library. There are also residential quarters for some of the scholars in the grounds. A lecture hall for 140, a dining-room, and a common-room for the medical staff and scholars are among the features of this notable new example of Lord Nuffield's munificence. They combine to give the Centre more the aspect of a college.

Society of Medical Officers of Health.—The president of the Society, Dr. J. A. STIRLING, M.O.H. for Chesterfield, was in the chair at the annual dinner, held last week at the Royal College of Surgeons, Lincoln's Inn Fields. Proposing the health of the Society, Mr. DEREK WALKER-SMITH, the Minister of Health, spoke of two great contemporary social problems, old age and mental health. As to the latter, he said that the Government intended at an early date to introduce legislation to implement some of the recommendations of the Royal Commission on Mental Illness and Mental Deficiency, which would mean some further expansion of the health services of local authorities. The shift of emphasis to community care would result in more active prevention of illness, and in this the medical officer of health could play an important and distinguished part. Thanking medical officers of health for their splendid efforts in connexion with poliomyelitis immunization, the Minister said that by far the greatest share in those arrangements had fallen on the M.O.H., and very rapid progress had been made. Out of the total of 5½m. people who had had two injections, 4m. had had their inoculations this year. The Ministry could really claim that its campaign had succeeded, but a still greater response from parents was needed. Nearly half the parents in this country had not seen fit to register their children for immunization, and there was a good deal more to do if all were to be vaccinated who should be. Dr. STIRLING, in his reply, looked back over the 40 years he had been in the public health service. Giving a word of warning about diphtheria, he said that they must still persevere with the mothers of to-day and see that the children got immunized. The three great public health problems were now atmospheric pollution, care of the aged, and mental health. Dr. G. H. GIBSON, toasting the guests, had hoped a recent annotation in the *Journal* (October 11, p. 904) would help him in his task, but, although he said this hope was not fulfilled, he appeared to have taken its grim warning very well to heart. Sir KENNETH COWAN, replying, struck an optimistic note and sent his hearers away confident that work of importance lay before the M.O.H.

Royal College of Surgeons of Edinburgh.—After the annual meeting of the College on October 15 it was announced that the following would hold office for the ensuing year: *President*, Professor JOHN BRUCE; *vice-presidents*, Professor NORMAN M. DOTT and Mr. WALTER W.

GALBRAITH; secretary, Mr. CHARLES W. A. FALCONER; treasurer, Mr. J. J. MASON BROWN; president's council, Mr. D. Band, Mr. R. S. Barclay, Mr. J. R. Cameron, Mr. I. L. Dick, Professor D. M. Douglas, Mr. E. L. Farquharson, Mr. A. J. C. Hamilton, Mr. J. N. J. Hartley, Professor R. J. Kellar, Mr. J. A. Ross, Professor G. I. Scott, Mr. J. A. Shepherd, and Mr. R. Leslie Stewart; conservator of museum, Professor D. E. C. Mekie; and honorary librarian, Dr. D. Guthrie.

F.R.C.S.Ed.—At a meeting of the Royal College of Surgeons of Edinburgh on October 15 the honorary fellowship was conferred upon Professor CHARLES B. HUGGINS, professor of surgery at Chicago University. At the same meeting the following candidates who passed the requisite examinations were admitted fellows:

J. Abrahamson, W. R. Allan, L. W. Baker, D. B. Berryman, K. S. Bhargava, N. Bhattacharyya, R. Cowley, S. J. Crews, P. J. E. Cruse, B. K. Datta, B. Dawka, N. C. Desai, H. Dovey, G. H. Dunstone, H. M. El-Sayed, K. D. Glass, G. D. Goel, A. J. Grant, P. Gupta, M. Habibulla, P. Harnarayan, F. W. Harrison, E. T. Heath, A. W. B. Heywood, H. K. Ismail, N. D. Jeyasekharan, M. J. Killingback, H. M. Learoyd, J. E. Lorang, M. H. Luntz, M. J. Lyons, M. M. A. Mahran, F. P. S. Marriott, P. R. Mehta, D. N. Menzies, R. E. Mickel, D. M. Millar, M. C. Misra, S. R. Mitra, B. C. Mukerjee, V. G. Muzumdar, D. W. Pfanner, R. Pringle, D. C. Provan, P. A. Rachow, J. A. Ryan, M. Sabetian, C. D. Sagar, K. M. Shah, R. P. Singh, J. G. Smith, J. H. Tait, C. F. Tham, T. T. Thomas, M. Vasudevan, N. H. Welsh, and T. Wilson.

Christmas Cards.—Unicef is once again launching its annual campaign to raise funds for its world-wide activities in the field of child welfare. The funds necessary for the organization's objectives are supplemented by the sale of its Christmas cards. A leaflet illustrating the cards is obtainable from Unicef Greeting Card Fund (Dept. C), 14-15, Stratford Place, London, W.1. These very decorative cards illustrate such themes as "Children Bearing Gifts," "A Time of Joy," and "Festive Times." Their cost is 7s. 6d. for ten cards. The subject of the Deaf Children's Society's Christmas card is "A Gay Winter Scene," designed by a deaf boy aged 11. Packets of six of these cards, with six Christmas seals, may be obtained for 3s. 6d. per packet from 1, Macklin Street, Drury Lane, London, W.C.2. The Muscular Dystrophy Group also offers Christmas cards for sale. They may be obtained in packets of six (from 2s. to 3s. a packet) from 34, Eccleston Square, London, S.W.1.

B.M.A. Clinical Meeting.—Details of the Sunday outings at the B.M.A. Annual Clinical Meeting next month at Southampton are given at p. 189 of the *Supplement*. This is to assist those registering for the meeting in choosing which outing they would like to attend.

R.S.M. Library.—The Royal Society of Medicine has been offered a grant of £24,000 by the Rockefeller Foundation for the general support of its library over the next five years. The Rockefeller Trustees make it clear that the grant is to help provide an adequate budget for the library while endowment for its continued maintenance is sought.

Leeds University.—Dr. D. B. BRADSHAW, lecturer in the department, has been appointed to the chair of public health. Dr. Bradshaw, who graduated in medicine from Dublin in 1932, is also deputy M.O.H. of Leeds. Among other appointments at Leeds are Dr. M. W. ATKINSON as tutor in psychiatry, Mr. R. G. BURWELL as lecturer in anatomy, Dr. A. J. KENNY as lecturer in biochemistry, Dr. N. R. ROWELL as tutor in dermatology, and Mr. F. G. SMIDY as lecturer in surgery.

Professor W. A. Bain has resigned the chair of pharmacology at Leeds University on his appointment as director of the Smith Kline and French Research Institute. The institute, which is expected to be completed next summer, is at Welwyn Garden City.

Professor Ian Aird has been elected an honorary fellow of the Swedish Surgical Society, and has been awarded the society's Olof Af Acrel medal.

Chair of Social Medicine, Otago.—Dr. C. W. DIXON, reader in epidemiology in the department of preventive medicine and public health at Leeds, has been appointed to the chair of social and preventive medicine at Otago University. Dr. Dixon qualified from King's College Hospital in 1935, later proceeding M.D. London. Previously he was an M.O.H. in the New Zealand Government Service and a W.H.O. medical consultant on smallpox.

COMING EVENTS

Institute of Dermatology.—Semi-permanent exhibition, November 5 to 26, on "The Skin and Friction."

Robert Jones Lecture.—Mr. NORMAN CAPENER will lecture on "Spondylolisthesis: Spinal Strain" on November 13 at 5 p.m. at the Royal College of Surgeons, Lincoln's Inn Fields.

Institute of Laryngology.—Annual address will be given by Mr. T. G. WILSON on "The Modern Treatment of Deafness in Historical Perspective" on November 14 at 4.30 p.m. The institute will be "At Home" to medical visitors from 2 p.m. The joint annual dinner of the institute and the associated Royal National Throat, Nose, and Ear Hospital will be held the same evening at University College, Gower Street, London, W.C.1.

Institute of Diseases of the Chest.—Panel discussion for general practitioners on "Virus Infections of the Respiratory Tract," December 2, at 2.30 p.m. at the Brompton Hospital, London, S.W.3. Practitioners wishing to attend should notify the dean.

British Institute of Radiology.—Annual congress and exhibition, December 4 and 5. Details from the general secretary of the Institute, 32, Welbeck Street, London, W.1.

NEW ISSUES

SPECIALIST JOURNALS AND ABSTRACTS

The journals listed below are obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

British Heart Journal.—Issued quarterly (£3 annually). The new issue, Vol. 20, No. 4, includes:

THE ORIENTATION OF THE HEART AND THE APPEARANCE OF ITS CHAMBERS IN THE ADULT CADAVER. Robert Walmsley.
SELECTIVE CINÉ-ANGIOCARDIOGRAPHY WITH IMAGE INTENSIFICATION. Hamish Watson, C. Pickard, K. G. Lowe, and Ian Hill.
THE CORRELATION BETWEEN VARIOUS ASSESSMENTS OF PULMONARY ARTERIAL PRESSURE IN MITRAL STENOSIS. J. F. Boyd, S. D. Scott Park, and George Smith.
THE FUNCTIONAL AND CLINICAL ANATOMY OF THE MITRAL VALVE. J. C. Van Der Spuy.
RESIDUAL LUNG VOLUME IN MITRAL DISEASE. R. Garbagni, P. F. Angelino, A. Brunca, and E. Minetto.
THE ELECTROCARDIOGRAM IN SYPHILITIC HEART DISEASE. Geoffrey Storey.
THE ELECTROCARDIOGRAM IN PECTUS EXCAVATUM. Jorge Martins de Oliveira, Mohinder P. Samghil, and Henry Zimmerman.
MODIFICATION OF VENTRICULAR GALLOP RHYTHM INDUCED BY POOLING OF BLOOD IN THE EXTREMITIES. James J. Leonard, Arnold M. Weissler, and James V. Warren.
THE AORTIC LESION OF ANKYLOSING SPONDYLITIS. B. M. Ansell, E. G. L. Bywaters, and I. Doniach.
THE CEREBRAL BLOOD FLOW IN MITRAL STENOSIS AND ITS RESPONSE TO CARBON DIOXIDE. H. A. Dewar and L. A. G. Davidson.
THE EFFECT OF VALVOTOMY ON THE MURMURS OF PULMONARY AND AORTIC STENOSIS. Bertrand G. Wells.
PULMONARY HYPERTENSION IN CONGENITAL HEART DISEASE. William Evans and D. S. Short.
FOETAL PAROXYSMAL AURICULAR TACHYCARDIA. C. W. Kesson.
THE VASOCONSTRICTIVE FACTOR IN PULMONARY HYPERTENSION. Paul Wood.

British Journal of Venereal Diseases.—Issued four times a year (£3 annually). The new issue (Vol. 34, No. 3) includes:

FIGURES AND FANCIES. S. M. Laird.
GUMMATOUS OSTEITIS OF THE SKULL. W. V. Macfarlane and Ian Rennie.
THROMBOSIS OF THE POSTERIOR INFERIOR CEREBELLAR ARTERY OF LUETIC AETIOLOGY. R. V. Rajam, N. Vasudeva Rao, and P. N. Rangiah.
LYMPHOANGIOMA VENOSUM. A REVIEW OF 61 CASES. David Erskine.
CANDIDA ALBICANS URETHRITIS. REPORT OF A CASE. W. Fowler.
STUDIES ON THE EFFECT OF VARIATION OF CONCENTRATION AND ORIGIN OF LECTHIN (NATURAL AND SYNTHETIC) IN CARDIOLIPIN COMPLEMENT-FIXATION ANTIGEN. Alice Reyn and Michael Weis Benzon.
SACRO-ILIITIS IN REITER'S DISEASE. J. K. Oates.
STUDIES IN PROSTATITIS. Edward Garlman.
DIAGNOSIS OF TRICHOMONAS VAGINALIS URETHRITIS IN THE MALE AS A ROUTINE CLINIC PROCEDURE. C. S. Nicol.
PENICILLIN TREATMENT FAILURES IN MALE GONORRHOEA. Neil L. Dallas.
REITER'S PROTEIN COMPLEMENT-FIXATION TEST. REPORT OF A TRIAL IN 1,000 UNSELECTED CASES. W. D. Foster, C. S. Nicol, and A. H. Stone.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, November 3

DENTAL AND MEDICAL SOCIETY FOR THE STUDY OF HYPNOSIS.—At Trocadero Restaurant, 7.15 p.m., annual dinner, Dr. D. Keir Fisher: Anaesthesia—the Anaesthetist—and You.
GUY'S HOSPITAL.—At Anatomy Lecture Theatre, 5.15 p.m., lecture-demonstration in endocrinology by Dr. P. M. F. Bishop: Hypothyroidism.
LONDON UNIVERSITY.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Heath Clark Lecture by Dr. Karl Evans (Norway): Health Service, Society and Medicine: Present-day Health Services in their Relation to Medical Science and Social Structure—Introduction—Main Types of Existing Health Services.
MARLBOROUGH DAY HOSPITAL.—8.15 p.m. Dr. Louis Minski: Psychosomatic Problems.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Dr. B. Ackner: Psychogenic Pain.
UNIVERSITY COLLEGE LONDON: DEPARTMENT OF BIOCHEMISTRY.—At Physiology Theatre, Gower Street, W.C.1, 5 p.m., Dr. J. R. Postgate: Sulphur Bacteria—Oxidative Stages of the Bacterial Sulphur Cycle.

Tuesday, November 4

FOUNTAIN HOSPITAL.—5.30 p.m., Dr. J. Tizard: Impressions of Work in Mental Deficiency in the U.S.S.R.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. P. F. Borrie: Cutaneous Vascular System.
●INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—At Hammersmith Hospital, 3 p.m., Guest lecture by Dr. J. Goodwin: Heart Disease and Pregnancy.
LONDON UNIVERSITY.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Heath Clark Lecture by Dr. Karl Evans (Norway): Health Service, Society and Medicine: Present-day Health Services in their Relation to Medical Science and Social Structure—Role of the Hospital.
MANCHESTER UNIVERSITY: DEPARTMENT OF OCCUPATIONAL HEALTH AND NORTH-WEST ENGLAND FACULTY, COLLEGE OF GENERAL PRACTITIONERS.—At Theatre 1, Clinical Sciences Building, York Place, 8.30 p.m., Radiation Hazards in Modern Industry.
ST. ANDREWS UNIVERSITY.—At Physiology Lecture Theatre, 6 p.m., Dr. G. L. Jackson (U.S.A.): Biologically Based Dentistry.
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Institute Theatre, 5 p.m., Mr. Roger de Vere: Fibrinoids and Allied Tumours.
UNIVERSITY COLLEGE LONDON: DEPARTMENT OF PHARMACOLOGY.—At Physiology Theatre, Gower Street, W.C.1, 5.30 p.m., Professor J. F. Danielli, F.R.S.: Generalized Cell Theory and its Relevance to Certain Problems of Drug Action.
WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Dr. Colin Edwards: neurological demonstration.

Wednesday, November 5

ASSURANCE MEDICAL SOCIETY.—At Medical Society of London, 5 p.m., Dr. J. Maurice Campbell: Life Assurance for those Applicants with Heart Disease.
COLLEGE OF GENERAL PRACTITIONERS: NORTHERN HOME COUNTIES FACULTY.—At the George Hotel, Enfield, 8.30 p.m., symposium: Research in General Practice.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. W. Riddell: Subcutaneous Infections due to Fungi.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. Paul Wood: Bedside Techniques in Cardiology.
INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—5.30 p.m., Dr. I. Friedmann, Dr. D. A. Osborn, and Dr. A. Jeanes: clinical pathological conference.
INSTITUTE OF UROLOGY.—At Royal College of Surgeons of England, 5 p.m., Clifford Morson Lecture by Professor C. Dent: Metabolic Causes of Renal Stone Formation.
LONDON UNIVERSITY.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Heath Clark Lecture by Dr. Karl Evans (Norway): Health Service, Society and Medicine: Present-day Health Services in their Relation to Medical Science and Social Structure—Role of the General Practitioner.
MANCHESTER MEDICAL SOCIETY: SECTION OF MEDICINE.—At Large Anatomy Theatre, Medical School, Manchester University, 5 p.m., Dr. P. J. D. Snow: The Carcinoid Syndrome. Dr. D. Longson: Adrenal Hyperfunction.
MIDLAND MEDICAL SOCIETY.—At Birmingham Medical Institute, 8.15 p.m., Dr. P. H. Davison: Management of Chronic Cardiac Failure.
●NATIONAL COLLEGE OF RUBBER TECHNOLOGY, Northern Polytechnic, Holloway Road, N.—6.30 p.m., Dr. J. T. Scales: Synthetic Materials in Orthopaedics.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Guest lecture by Dr. G. M. McGowan: Potassium Metabolism.
ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—3.30 p.m., Dr. A. B. Stewart: London County Council Health Services.
ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE: EDINBURGH BRANCH.—At West Medical Theatre, Edinburgh Royal Infirmary, 5 p.m., Professor G. W. A. Dick: Tropical Viruses.

Thursday, November 6

FACULTY OF HOMOEOPATHY.—At Royal London Homoeopathic Hospital, 5 p.m., Richard Hughes Memorial Lecture by Dr. D. M. Gibson: Aetiological Aspects of Homoeopathic Materia Medica.
LIVERPOOL UNIVERSITY: FACULTY OF MEDICINE AND LIVERPOOL MEDICAL INSTITUTION.—Surgery Theatre, Old Medical School, 5.15 p.m., Joint History of Medicine Lecture by Dr. W. Brockbank: The Ancient Art of Enema Administration.
LONDON UNIVERSITY.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Heath Clark Lecture by Dr. Karl Evans (Norway): Health Service, Society and Medicine: Present-day Health Services in their Relation to Medical Science and Social Structure—Role of Drugs. At Royal Society of Medicine, 5 p.m., Semon Lecture by Professor L. Rüedi (Zurich): Some Observations on the Histology and Functions of the Larynx.
ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH.—5 p.m., John Matheson Shaw Lecture by Dr. W. M. Arnott: Climate of Medical Education.
ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., Bradshaw Lecture by Dr. K. W. Donald: Heart Disease and Exercise.
ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Dr. Desmond Curran: Postgraduate demonstration in psychiatry.
UNIVERSITY COLLEGE LONDON.—At Anatomy Theatre, Gower Street, W.C.1, 1.15 p.m., Dr. D. Wilkie, Ph.D.: Aims of Sexual Reproduction.

Friday, November 7

●INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. T. Brain: clinical demonstration.
INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. J. N. Pattinson: clinical demonstration.
INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—3.30 p.m., clinical discussion for general practitioners by Mr. G. H. Howells: Sinusitis.
LIVERPOOL UNIVERSITY: FACULTY OF MEDICINE.—At Large Lecture Theatre, New Medical School, Ashton Street, 5.15 p.m., McMurray Lecture in Orthopaedic Surgery by Professor W. P. Blount (Wisconsin): Fractures in Children.
LONDON UNIVERSITY.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Heath Clark Lecture by Dr. Karl Evans (Norway): Health Service, Society and Medicine: Present-day Health Services in their Relation to Medical Science and Social Structure—Public Health Service.
MANCHESTER MEDICAL SOCIETY.—At Clinical Sciences Building, York Place, 4.30 p.m., Sir Roy Cameron, F.R.S.: The Principle of Reversibility in Liver Pathology.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—10 a.m., Guest lecture by Mr. A. S. Kerr: Relief of Pain.
●ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS.—4 p.m., William Blair-Bell Memorial Lecture for 1958 by Dr. J. M. Crawford: Study of Placental Growth in Normal Pregnancy and in Erythroblastosis Fetalis.
ROYAL MEDICO-CHIRURGICAL SOCIETY OF GLASGOW.—At Royal Faculty of Physicians and Surgeons of Glasgow, 8.30 p.m., (1) Mr. T. Gibson: Domestic Burns—Their Prevention and Treatment. (2) Mr. I. MacGregor: Changing Pattern of Treatment in Hand Infections.
ROYAL SOCIETY OF HEALTH.—At New Lecture Theatre, Newcastle upon Tyne, 10.30 a.m., Symposium on Atmospheric Pollution. Professor G. R. Clemo, F.R.S.: Chemistry of Cigarette Smoking and its Possible Implications. Dr. A. G. Ogilvie: Chronic Bronchitis in Newcastle upon Tyne; Mr. L. Mair: Second Appointed Day on Tyneside.

Saturday, November 8

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—11.30 a.m., Guest lecture by Professor L. Rüedi (Zurich): New Developments in the Surgery of Otolosclerotic Diseases.

APPOINTMENTS

EAST ANGLIAN REGIONAL HOSPITAL BOARD.—B. H. Hand, M.S., F.R.C.S., Consultant Surgeon, Ipswich and East Suffolk Hospital; M. D. Mehta, M.B., B.S., F.F.A.R.C.S., Consultant Anaesthetist, King's Lynn Area; Margaret M. Downes, M.B., Ch.B., M.R.C.O.G., Part-time Consultant Obstetrician and Gynaecologist, Lowestoft and Great Yarmouth Hospitals; M. F. T. Yealland, M.B., B.Chir., M.R.C.P., Consultant Neurologist, United Cambridgeshire Hospitals and Regional Board Hospitals; J. P. Hughes, M.B., B.S., M.R.C.P., Senior Medical Registrar, Ipswich and East Suffolk Hospital; A. R. Walker, M.B., B.S., Registrar in Psychiatry, St. Andrew's Hospital; M. K. Basu Mallick, M.B., B.S., D.Obst.R.C.O.G., Registrar in Obstetrics and Gynaecology, Peterborough Group of Hospitals; Sheila M. Griffiths, M.B., B.S., Registrar in Geriatrics, Ipswich and East Suffolk Hospital Group; M. A. Jafri, M.B., B.S., D.T.M.&H., Medical Registrar, Peterborough Hospital Group; P. R. H. Slade, Ch.M., F.R.C.S., Senior Registrar in Thoracic Surgery, Papworth Hospital; I. B. Munro, M.B., Ch.B., F.R.F.P.S., M.R.C.P., M.R.C.P.Ed., Senior Medical Registrar, United Norfolk Hospitals; J. Ludbrook, M.B., Ch.B., F.R.C.S., Surgical Registrar, Norfolk and Norwich Hospital; S. P. Kumar, M.B., B.S., D.O.M.S., D.O., Ophthalmic Registrar, Norfolk and Norwich Hospital; Miss F. Husain, M.B., B.S., and W. S. Sykes, B.M., B.Ch., Anaesthetic Registrars, Ipswich and East Suffolk Hospital; Hazel M. Wilson, M.R.C.S., L.R.C.P., Registrar in Mental Deficiency and Child Psychiatry, Little Plumstead Mental Deficiency Group of Hospitals, and Child Psychiatry Service.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Bexon.—On October 10, 1958, at Dryburn Hospital, Durham, to Muriel, wife of Dr. Wallace H. Bexon, of Grange Farm Cottage, Durham, a sister for Fiona—Alison.
Gordon.—On October 17, 1958, at Sale, Victoria, Australia, to Drs. Nesta and William F. Gordon, a son.
Lovel.—On September 29, 1958, to Joan (formerly D'Arcy), M.D., D.C.H., and Lester Lovel, of 46, The Ridge Way, Sanderstead, Surrey, a son—Paul D'Arcy.
Palfrey.—On October 22, 1958, at University College Hospital, London, W.C., to Ann and John Palfrey, of University College, Ibadan, Nigeria, a brother for Michael and Susan—Christopher Mark.
Perry.—On October 19, 1958, at the County Hospital, Haverfordwest, to Dr. Elizabeth Perry (formerly Thomas), wife of Dr. Lynn Perry, a daughter, sister for William and David.

DEATHS

Chubb.—On September 28, 1958, at Kenilworth, Cape Town, South Africa, Elsie Mary Chubb, M.D., D.P.H.
Clark.—On October 6, 1958, at 6, Henderland Road, Edinburgh, Katherine Jane Stark Clark, M.D., D.P.H., aged 92.
Eaton.—On October 8, 1958, Douglas Arthur Tighe Eaton, L.R.C.P.(S.I.) & L.M., of Whole Farm Cottage, Stone-in-Oxney, Tenterden, Kent, late of South Benfleet, Essex.
Homan.—On September 27, 1958, William Travers Homan, L.M.S., L.M., of Donegan, Portland Road, Greystones, Eire, late of Dover, Kent.
Hughes.—On September 20, 1958, David Morgan Hughes, F.R.C.S., of 24, West End Avenue, Pinner, Middx., aged 82.
Muirson.—On September 28, 1958, at Trotton Old Rectory, Rogate, Sussex, Taylor David Muirson, L.R.C.P.&S.Ed., L.R.F.P.S., Lieutenant-Colonel, I.M.S., retired.
Prager.—On September 29, 1958, Gertrude Anna Prager, M.D., of Manchester, aged 47.
Seingry.—On September 26, 1958, at Llandough Hospital, Heinrich Egon Seingry, M.B., B.Ch., of 4, Danycoed Road, Cardiff, aged 48.
Wanhill.—On September 29, 1958, at Broadstone, Dorset, Charles Frederick Wanhill, M.R.C.S., L.R.C.P., D.P.H., Lieutenant-Colonel, R.A.M.C., retired, aged 86.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

Abortion and Bicornuate Uterus

Q.—Is hormonal treatment indicated during pregnancy in a woman who has a bicornuate uterus and a history of repeated miscarriages?

A.—The incidence of abortion, and of premature labour, is raised when the uterus is malformed, probably either because the abnormal organ cannot grow and stretch normally, or because of inadequate placentation (especially if sited on the spur or septum between the horns), or both. Theoretically hormone therapy with oestrogen and progesterone might counter these factors to some degree, for the prognosis for a viable baby seems to improve with successive pregnancies, but in practice such therapy has not yet been shown to be effective. In general the prognosis is better the greater the degree of imperfect fusion (e.g., better in uterus didelphys than bicornis). Nevertheless, gross degrees of bicornuity are sometimes corrected between pregnancies by the reconstructive operation of uteruloplasty, but in minor degrees the operation is difficult and of doubtful value.

Risk of Meningocele

Q.—What are the risks of malformation in further children of a young couple who have already had two children born with a meningocele?

A.—The risks for a further child after a mother has had two children with meningocele are not yet accurately known. The risk after one such child is of the order of 1 in 25,¹ and the risk is probably further increased when two such children have been born. A small personal series indicates a risk of about 1 in 10. The risk is probably somewhat modified by the part of the country in which the parents live, and by the parents' social class.

Oral Contraceptives

Q.—What is the latest information about oral contraceptives?

A.—Data of a kind which can be appraised critically are available on two oral contraceptive agents. In a trial in Puerto Rico, directed by Dr. Gregory Pincus, and referred to in an annotation in the *Journal*,¹ the steroid known as "enavid" administered in a dose of 10 mg. daily for 20 days, beginning on the 5th day of each menstrual cycle, proved 100% effective in preventing conception in those volunteers who omitted no tablets while under treatment. The mechanism involved is inhibition of ovulation, which some might regard as potentially dangerous if long continued, and particularly if children were desired at a later date. Further drawbacks to this method are its costliness, the need for regular daily treatment in 20-day courses, and the intolerance to the drug which a proportion of women show. None of the patients in the trial had any untoward effects from the treatment.

The second agent is *m*-xylohydroquinone, which Sanyal²⁻⁴ considers to be the antifertility factor of pea oil, acting by virtue of its anti-progesterone and anti-vitamin E effects. This has been tested fairly extensively in India, the patients taking a capsule of 300-350 mg. on the 16th and 21st days of the cycle—that is, twice a month only. A significant reduction in fertility rates has been observed—but to the extent only of reducing them by about half, so that this agent would appear to be far less effective than enavid.

It is encouraging that a good deal of high-quality research into the problem of devising the ideal contraceptive is now being undertaken by first-class investigators, and, though "the pill," in its ideal form, is probably still a long way off, optimism would appear to be not unwarranted.

High-fat Reducing Diet

Q.—In view of recent work showing the efficacy of high-fat reducing diet, what percentage of fat, carbohydrate, and protein should the average reducing diet contain?

A.—Some of the recent work in relation to high-fat reducing diets has related only to diets suitable for experimental purposes.¹⁻³ Others, notably Pennington,^{4,5} have used similar diets to reduce obese patients, apparently with success. There is at the moment no fixed agreement as to the relevant portions of fat, carbohydrate, and protein, but the usual practice in reducing diets is to diminish the carbohydrate intake and thus to increase the relative proportions of fat and protein. These latter can be increased if the resulting diet is unsatisfactory.

NOTES AND COMMENTS

Intestinal Hurry.—Dr. IAN STEWART (Keighley) writes: In the advice on intestinal hurry ("Any Questions?" October 4, p. 868) there is the sentence: "In severe dysentery morphine by injection may greatly help the patient, but it can only be used once or twice." In infections with Shiga's bacillus and the presence of a powerful exotoxin, I would have thought that morphine by injection was extremely dangerous. During the 12 years I was working with this group of diseases no form of opium was used until the diagnosis was established.

OUR EXPERT replies: Opium has been used for over 200 years with benefit in the treatment of dysentery. Manson-Bahr¹ says nothing against its use, and morphine is strongly recommended by Strong.² In extensive experience with cases of dysentery I have used morphine as described in patients whose diarrhoea and pain were severe. No ill effects occurred and the patients were always greatly relieved.

Correction.—In the article on "Sedatives and Tranquillizers" by W. Sargent (*Journal*, October 25, p. 1031) the dose of bromide in the paragraph headed "Bromides" should have been 20-30 gr., not 20-30 mg.

MEDICINE'S CHALLENGE TO THE EDUCATOR*

BY

Sir GEORGE PICKERING, M.D., F.R.C.P.

Regius Professor of Medicine, University of Oxford

An invitation to speak on the problems of medical education in Britain that would be of interest in the United States is one that offers much freedom of choice. Some would choose to display how most of our doctors, particularly the more energetic and talented, are being submerged by uncontrolled growth of committees; and they would discuss how this strange phenomenon has come about, and perhaps how it could be controlled. Others would take the registrar problem, with its temporary interruption in the flow of men through the training posts. Related to this would be the disparity between numbers of permanent posts in the National Health Service and of those being trained to fill them, and the effect of the monopoly created by the National Health Service on recruitment to medicine. Or he might wish to show how the universities can best utilize their new-found freedom to provide a better curriculum, thanks to the new wisdom of the General Medical Council. All these subjects require more study than I have been able to give, and to do justice to each would require a separate essay. Besides, some of these problems, though not the first and the last, are largely administrative, and therefore of restricted interest to our colleagues abroad.

I propose, therefore, to interpret the invitation liberally and to take three issues that affect our attitude to medicine and the teaching of medicine. These three are, firstly, the issue of instruction versus education; secondly, the importance of the proper use of words; and, lastly, the growing importance of population studies in clinical research. I have to confess that these are three old hobby-horses of mine. But I always find the ride exhilarating, and can only hope you may do so too.

Instruction versus Education

My own introduction to the conflict between education and instruction took place during my undergraduate days at Cambridge. One of my friends, who was a teacher of English, pointed out to me that medical students were not being educated; they were being instructed. He explained that education was a training of the mind; that in education a student is set to work in his own time; and the chief function of his teacher is to appraise his efforts, to cure him of bad mental habits, and to encourage him in good ones. He explained to me that this was what was done in the arts faculties of our ancient universities, where a man attended lectures for not more than two hours a day and spent the rest of his time preparing work for his tutor to criticize. The process of instruction, on the other hand,

was a process of forced feeding, in which nothing was required of the student except to memorize and to reproduce what he remembered. In such a process the student was required to know the conclusions but not necessarily the evidence on which these were based.

It was clear to me that he was right, and this became even clearer to me in the clinical years, when many teachers did not themselves know what the evidence was or where it could be found. We students were receiving not education but instruction. We went to so many lectures and classes and had so many textbooks to read that we learned things by sheer memory. And we learned the conclusions, not how these had been arrived at. The contrast was all the more striking because between the preclinical and clinical parts of the medical course proper it had been my privilege to take Part II of the Natural Sciences Tripos in Physiology. That was true education under a brilliant collection of teachers—Langley, Barcroft, Adrian, W. B. Hardy, Hopkins, Roughton, Hartridge, Marshall, and others. We had very few lectures, all very much to the point and highly critical, and we were expected to read the more important original papers. I personally owe most to Joseph Barcroft, who not only inspired us in his lectures and practical classes but who also made us write essays for him once a week. There were but four of us. It is not difficult to imagine what a contrast there was between this thrilling intellectual exercise and the dreary grind of instruction of the medical course proper.

My first point is therefore this, that in any branch of university education, including medical education, we should aim at using the methods of education rather than instruction. We must teach the student how to collect the facts, to verify them, to assign a value to them, and how to draw conclusions from them and test those conclusions; in short, how to form a judgment. As Karl Pearson said, "the true aim of the teacher should be to impart an appreciation of method rather than a knowledge of facts," for method is remembered when facts have been forgotten, and method can be used in a new situation where there are no, or too few, facts. The student learns how to learn and can go on acquiring knowledge for the rest of his life.

To obtain some insight into the effect of instruction as opposed to education on a sensitive mind, may I quote Charles Darwin's experiences as a medical student in Edinburgh University in 1825: "The instruction at Edinburgh was altogether by Lectures, and these were intolerably dull, with the exception of those on chemistry by Hope; but to my mind there are no advantages and many disadvantages in lectures compared with reading. Dr. Duncan's lectures on Materia

*Adapted from an address given to the Cardiovascular Program Directors of the United States Public Health Service, Williamsburg, Virginia, on June 7, 1958.

Medica at 8 o'clock on a winter's morning are something fearful to remember. Dr. Munro made his lectures on human anatomy as dull, as he was himself, and the subject disgusted me. It has proved one of the greatest evils in my life that I was not urged to practise dissection, for I should soon have got over my disgust; and the practice would have been invaluable for all my future work." In medicine the great difficulty in using the educational approach used to be the small number of teachers and the wide range of subject-matter to be covered. Logistics determined the didactic approach by lectures and large practical classes. This still holds in countries like India, Germany, and elsewhere.

Two Difficulties

In the United States and in Britain two developments have made the educational approach possible—namely, a great increase in staffing of medical schools, and a great development of postgraduate education. The obstacles in our way are now different. They are two. In the first place, knowledge is growing apace. And since man is only one of a very large number of living creatures having many features in common, and since it is believed that ultimately physico-chemical behaviour will be shown to be at the root of all biological behaviour, there is almost no piece of natural knowledge that may not be turned to account in medicine. Our first difficulty is then what limits to set to the fields of knowledge in which to practise the educational method. Our second difficulty is how to teach, whether by lectures, seminars, ward clinics, out-patient clinics, discussion groups, or their variants. My own view is that the ground covered and the precise method used are of less importance than the attitude of mind of the teacher himself.

A true educator must have certain innate characters. He must be intelligent and thoughtful; he must be interested in the material he is using for teaching, and in the minds of those taught. He is more likely to have the right attitude if he has come into close contact himself with a great teacher. Finally, he must be able to detach himself from the ever-increasing pressure of modern life, which tends to crush all individuality from him. Let me quote Fridtjof Nansen, who began life as a zoologist, spent three years of his life drifting across the North Polar ice, one of it with a single companion, and who ended his life as the greatest humanitarian of this century: "The first great thing is to find yourself, and for that you need solitude and contemplation, at least sometimes. I tell you deliverance will not come from the rushing noisy centres of civilization. It will come from the lonely places."

Proper Use of Words

I now come to my second topic, the need for the correct use of language. Of the various points I have to try to make to you I would myself regard this as the most important because the most neglected. The function of language is the transfer of information not only from the mind of one individual to that of another but also, what is often overlooked, to transfer information from one part to another of a single individual's mind. It would seem self-evident that the information that is transferred must be accurate if the action taken is to be closely related to the information received. Electronics, servo-mechanisms, cybernetics, and their amazing products, the automatic machines of great power, versatility, and accuracy; guided missiles; and the like have made us familiar with the importance of transmitting accurate information in order to obtain precise and predictable performance. It is a continuing

source of wonder to me that we doctors are so little concerned with the accurate transmission of information within our own minds, and between other minds and ours.

The chief source of inaccuracy in the transfer of information is, I think, the use of technical jargon. On another occasion, in your country, I devoted a little time to the way in which scientists nowadays fence off their subject with technical terms, so that those who have not first learned the language of the specialty cannot understand what the author is trying to say. Those of us who teach and work in the field of cardiovascular diseases are not entirely blameless in this matter. This is, if you like, a manifestation of the growth of nationalism in science, just as the move to teach in Erse, in Welsh, in Afrikaans, and other tongues is one example of the growth of nationalism within the general cultural life of the British Commonwealth. This is important. Nevertheless, I will say no more of it. I want to deal rather with two other aspects—namely, the transfer of information from the mind of the patient to that of the doctor, and from one part of the doctor's mind to another.

In taking a history of the patient's illness I teach my students that they are eliciting an account of the patient's experience. They must use the patient's own words, provided always that both the patient and the doctor are sure that the information conveyed in these words is so far as possible accurate and unequivocal. They must never use terms, like "chesty," which means nothing at all. Nor must they use technical terms, such as anginal pain, or asthma, bronchitis, haemoptysis, or haematemesis, because these are not terms descriptive of experience but are terms that attempt to interpret that experience. Used by the patient, they are often used wrongly, as also indeed they are sometimes by the doctor, who, in using them, prematurely comes to a conclusion. To my mind a good history is one that is expressed entirely in words that are as simple and well known to us as the words used to describe events in the old and new testaments of the Bible. And I suspect we would all agree that a good history is perhaps the most important part of the evidence that takes us to an understanding of our patient's disability.

I always feel I have great difficulty in persuading my colleagues of the importance of what I have just related, but I have even greater difficulty with the next—namely, the errors that we make our own minds commit by the use of technical terms. To illustrate my point I would ask you to consider four examples from cardiovascular and related pathology—namely, shock, arteriosclerosis, bronchospasm, and hypertension.

"Shock"

Shock was a name that came to be used to describe a failure of the circulation, quite distinct from failure of the heart. It became a problem of first importance in the first world war because so many wounded soldiers died presenting this clinical picture. Many distinguished scientists devoted themselves to it, notably Cannon from your side and Bayliss from ours. And the conclusion that emerged from that war was that shock was a traumatic toxæmia produced by the effects of vaso-active substances like histamine released from the injured muscles. It needed the genius of your Dr. Alfred Blalock and the experience of the second world war to show that this was not so, and was shown that, arising from war wounds, the clinical condition was usually due to loss of blood but could also be due to infection, loss of plasma (as in burns), loss of other body fluids, or due to the vasovagal or fainting attack.

Now, why Cannon, Bayliss, and other distinguished physiologists went wrong was because they were not clinicians familiar with the variety of circumstances in which this clinical picture called shock could arise. They assumed that because the same word was used, therefore the circumstances leading to the final picture were the same; and because in some cases they could exclude the

obvious cause, loss of blood, they assumed that there must be another and more important cause that must operate in all cases. The history of our understanding of traumatic shock is to my mind a most illuminating one. Cannon and Bayliss were most distinguished scientists with a deep insight into the phenomena with which they were dealing. There were few subjects they touched that they did not illuminate. The error came because information was not fully or accurately transmitted in their minds, but was transmitted in the form of a technical term. It is the kind of error that is easily committed where the mind tries to grapple with a problem with which it is not fully and deeply familiar. And too often and to too many of us understanding is limited by the concept consciously or unconsciously conjured up by the technical term to express it.

"Arteriosclerosis"

My second example is arteriosclerosis. As a student this term confused me utterly, and the confusion was worse confounded by its being sometimes used as almost synonymous with hypertension. Cowdrey's book on arteriosclerosis first showed me the light. It became apparent to me that the distinguished authors were equally confused and were talking about different things. In fact, it became apparent that a large number of conditions affecting different coats and different sizes of vessels were there considered, and indeed E. T. Bell said so.

Nowadays our own specialty runs hotfoot to find the reason why increasing numbers of males in the richer countries die young because their coronary arteries become occluded. This is generally described as the problem of atherosclerosis. Now, this term was introduced by Marchand, in a paper given in 1904 to the German Medical Congress, to include both the fatty proliferative nodular change in the intima characteristic of atheroma and the other degenerative, cellular, and calcific changes of intima and media included in the term arteriosclerosis. His paper was indeed entitled "Über Arteriosclerose." He proposed the term not as an alternative to atheroma, but as an alternative to arteriosclerosis, including lesions of both intima and media, but emphasizing the importance of the intimal fatty change. Atherosclerosis is currently used by most to signify atheroma, which is purely an intimal lesion and is the proper term to describe the coronary lesion that produces ischaemia. Others, however, used it, as it should be used, in Marchand's sense. In fact, I have seen a leading pathologist in this field show a group such as this how atherosclerosis might produce a coronary artery that was wider than normal or one that was narrower. To my rather sceptical eye it seemed that in the first the chief change was in the media, in the second in the intima.

A great deal of wealth and a great deal of man-hours of work are now being invested in this arresting problem. I am tempted to wonder whether the greatest hindrance to our understanding of myocardial infarction lies in the term atherosclerosis. And I wonder if a careful and critical review of the types of arterial change that occur in disease, and their bearing on coronary occlusion, is not the first step that will have to be taken before we reach our goal. As I tried to illustrate by the history of shock, the kind of misconception that technical jargon conjures up is one of the most potent causes, and certainly the most insidious cause, of erroneous conclusion. Many of the distinguished scientists now invading this field of arterial diseases, and particularly ischaemic heart disease, are unfortunately not themselves deeply conversant with the clinical and pathological facts. I often wonder if they really understand what they are seeking to explain, and whether they know how much and how little the term atherosclerosis really means. Or are they being misled as Cannon and Bayliss were by a technical term?

"Bronchospasm"

My third example is bronchospasm. This clearly implies to my mind, and I think to most, that contraction of their

muscular walls has greatly narrowed the bronchi. For some years it has been a common practice, even among skilled chest physicians in my country, to describe the association of difficult breathing with rales and rhonchi as bronchospasm. A few years ago I was concerned in a therapeutic trial on the effects of a certain drug on status asthmaticus. As the results came to be set out several of the distinguished doctors wished to refer to the bronchial obstruction that characterizes this state as bronchospasm. This seemed to me to be an intellectual lapse that is characteristic of the age. As every experienced pathologist knows, the characteristic feature of the post-mortem appearances of the lungs in status asthmaticus is the swelling of the bronchial mucosa, and the blocking of the lumen by mucus and other material. To describe this by a term signifying smooth-muscle contraction is surely to reveal a mind that has lost all pretence of being an instrument of precision.

"Hypertension"

My fourth example is hypertension. I will just say this, that the introduction of this technical term, its evolution into the concept of essential hypertension as a disease entity, and the necessity of defining normal blood pressure and hypertension, represent a sequence of events that the readers of Wilfred Trotter's (1941) essays on "The place of general ideas in medicine" and "Has the intellect a function?" will recognize as inevitable. But, as I mentioned earlier, they have made it very difficult for the average doctor to understand the nature of so-called essential hypertension.

Importance of Population Studies in Clinical Research

I would like to leave this rather damaging assessment of a common behaviour of the mind of many who actually lead in medicine to-day and proceed to consider the new importance being given, particularly in Britain, to the study of selected populations with the object of identifying the factors concerned in producing disease and the effects of treatment.

In recent years clinical science has been dominated by what the late Sir James Spence described as phenomenology; that is to say, the application of the methods of physiology and biochemistry to the search for causal sequences in the individual patient. This method has been quite invaluable in showing how the various organs work in disease and what happens when they fail. It has also been invaluable in demonstrating the precise action of drugs which act quickly. Nevertheless, there is no doubt that a great deal of unnecessary effort is put into this form of investigation. I remember the editor of a well-known journal telling me that he had had 53 papers submitted to him in one year on the effects of exercise on the cardiac output in mitral stenosis. Moreover, invaluable as this method is in its proper sphere, it can tell us next to nothing about the genetic and environmental factors producing disease nor how to prevent it or control it. Thus the physiological approach has enabled us to understand the symptoms and signs and electrocardiographic changes in coronary heart disease and assess the effects of vaso-active drugs on exercise tolerance. But it is virtually useless in identifying or measuring the effects of genetic and environmental factors in producing myocardial infarction, or the effects of treatment in preventing recurrence or prolonging life. In other words, the physiological approach is of little value in the prevention or control of disease.

The study of populations to assess the influence of genetic and environmental factors began with Francis Galton, the cousin of Charles Darwin, in his studies in inheritance in man. Galton (1889) found that there were two kinds of inheritance, that of alternative characters such as blue or brown eyes, and that of blended or graded characters such as height. The former type of inheritance was later explained by Mendel's work as representing the effects of single genes, distributed in allelomorph pairs and behaving as dominants or recessives. The latter type of inheritance is believed to be polygenic—that is, to repre-

sent the sum of many genes, each of which probably behaves in Mendelian fashion. Hamilton, Roberts, Sowry, and I (1954), and Miall and Oldham (1955, 1957) have shown, using extensions of Galton's method, that blood pressure is also inherited as a graded character over the whole range. In the field of cardiovascular disease this method has thus shown that the distinction between so-called normal blood pressure and essential hypertension is nothing else but an artifact and that in the production of levels of blood pressure ordinarily termed essential hypertension genetic factors are important but not exclusive; environmental factors as yet unidentified are probably also concerned.

The aim of this method is to study populations that are alike in every respect except for the variable studied. Because of the complexity of factors concerned and the impossibility of assessing and controlling them all, this means the study of large numbers, with the expectation that the influence of these uncontrolled factors will be the same in the two populations, the differences thus representing the influence of the variable factor. This was achieved by us by measuring blood pressure under the same circumstances in three populations—a sample of the general population, the first-degree relatives of subjects with normal blood pressure, and the first-degree relatives of subjects with so-called essential hypertension. The second essential is to be able to measure a character or to assess the presence or absence of a peculiarity with some precision in the population studied. Finally, there is the mathematical analysis which may need to employ devices for allowing for sex, as Galton had to in his study of height, and allowing for sex and age, as we did in blood pressure. May I just mention an aside here, and say that the most important point is the careful planning of the experiment and collection of data. There is a tendency now to under-emphasize the reliability of the data and their suitability for mathematical treatment. As L. J. Henderson once said of a distinguished colleague, "his mathematical ingenuity is such that he can provide a formula for any set of data, however erroneous."

Much use is being made of the epidemiological method to try to identify the genetic and environmental factors concerned in producing coronary heart disease. There are two major difficulties—namely, the identification of coronary disease with precision in the kind of population samples that need to be compared, and the difficulty of obtaining two populations alike in all respects but one. Thus the higher-income groups in Western countries in which ischaemic heart disease is more prevalent usually differ from the lower-income groups in which the disease is less prevalent in at least four factors: the composition of their diet, their consumption of tobacco, their mental life, and the exercise taken. Nevertheless, I cannot help thinking that a correct choice of groups and a more precise index of prevalence, morbidity, and mortality will ultimately lead to the truth.

Assessing the Effects of Therapy

The other great function of the scientific study of populations is to assess the effects of therapy. The method known in Britain as the controlled therapeutic trial, and developed particularly by Bradford Hill (1951), had its roots in biological assay on the one hand and the testing of chemical manures on the other. Curiously enough, the dominant parent of the controlled clinical trial is the method perfected by R. A. Fisher and his colleagues for the testing of chemical manures, and developed theoretically in Fisher's (1951) "Design of Experiments," for the two methods are used to assess differences in behaviour over weeks, months, and years. Thus development of these two techniques showed how it was possible to measure reasonably accurately the effects produced by altering a single environmental factor, or even two or more environmental factors, despite the variability common to all biological systems.

The principles for such a trial are relatively simple. In the first place, the group of patients for study must be

defined as exactly as possible, the reasons for selecting some patients and rejecting others. Secondly, a method must be adopted for allocating about equal numbers of patients at random to the two treatment groups to be compared. Note that allocation of alternate patients to the two groups and allocation by day of admission to hospital are not acceptable, since both give the doctor an opportunity of influencing selection and therefore introducing bias. The two groups selected are then each treated according to the therapies to be compared, by the same doctors in the same institutions, both doctors and patients being, if possible, ignorant of the precise therapy used. The results are finally compared, using objective criteria and eliminating observer error wherever practicable.

I might illustrate the usefulness of the controlled therapeutic trial by contrasting our knowledge of the effects of sympathectomy on the course of hypertensive disease, and the knowledge gained by trial of the anti-tuberculosis drugs. Now, it is an unfortunate fact that, despite the many thousands of patients subjected to sympathectomy by most skilful surgeons, it is still unknown whether this operation affected the prognosis in hypertension, if so how much, and in what groups of patients. Many series of patients were followed and the results analysed and published. But to the best of my knowledge there was not a single series with adequate controls selected at the same time and with the same criteria as the operated group and followed by the same doctors. The control groups were either series such as the well-known one of Keith, Wagener, and Barker at the Mayo Clinic, or patients seen at the same hospital as those selected for surgery but rejected for, or refusing, operation. It is thus quite impossible to judge whether observed differences in mortality were due to treatment or due to initial differences between the groups.

M.R.C. Trial of Anti-tuberculosis Drugs

We may contrast this with the Medical Research Council's therapeutic trial of anti-tuberculosis drugs. The story begins in 1946, when the M.R.C. obtained a small amount of streptomycin to assess its usefulness. Quickly a committee was assembled and a trial arranged (M.R.C., 1948). Six hospitals participated. Patients with acute progressive bilateral tuberculosis of presumably recent origin bacteriologically proved, unsuitable for collapse therapy, aged 15 to 30 years, were selected for study. About one-half (52) were allocated bed rest only, the other half (55) were allocated bed rest and streptomycin. The allocation was made strictly at random. After six months' and one year's treatment the results were compared objectively. At six months in the streptomycin-treated group 69% had improved and 7% were dead, as compared with 33% improved and 27% dead in the control group. At one year the streptomycin-treated group showed improvement in 56% and death in 22%, as compared with improvement in 31% and death in 46% of the controls. By the time this trial had been completed a new anti-tuberculosis drug was available—namely, para-aminosalicylic acid (P.A.S.). The Medical Research Council (1950) therefore decided that this should be tried in the same way as streptomycin. The results with P.A.S. seemed less good than with streptomycin, but much the best results were used with the two drugs in combination.

By the time the trial with P.A.S. was completed another anti-tuberculosis remedy had appeared and had passed with great distinction all the preliminary tests. It was isonicotinic acid hydrazide, hereafter referred to as isoniazid. A new trial was therefore planned by the same Medical Research Council Committee, using very much the same methods but with these differences: (1) The scope of the trial was greatly enlarged; no fewer than 39 hospitals collaborated; (2) the variety of cases included was increased. Thus the following criteria were adopted. The sputum must be positive, and the bacilli must not be streptomycin- or P.A.S.-resistant at the beginning of treatment. The patient should not have had more than 15 g. of streptomycin nor 300 g. of P.A.S. during the previous three months. The patient must not be

undergoing collapse therapy. The records from the proposed patients were examined centrally and the cases classified into three main groups and seven subgroups and allocated at random to the two methods of treatment to be compared. (3) Reports of progress were received at one month, two months, three months, and six months from the beginning of the trial.

The speed with which this trial achieved its objective is one of its most impressive features. In February, 1952, preliminary announcements were made in the American press indicating the effects of isoniazid on clinical tuberculosis. The Medical Research Council trial was initiated the same month and treatment begun on March 29, 1952. The preliminary report of the trial was published the same year (M.R.C., 1952), and it established that isoniazid alone was not superior to a combination of streptomycin and P.A.S. During this time 173 patients had been treated with 200 mg. of isoniazid daily, and 158 with 1 g. of streptomycin plus 20 g. of P.A.S. daily. Improvement in general condition was rather better on isoniazid alone, but radiological changes did better on the combination. Acquisition of bacterial resistance to isoniazid was a severe problem, and occurred in 11% of cases at the end of the first month, 52% at the end of the second month, and no less than 71% at the end of the third month. The trial was therefore modified to compare the results of 1 g. of streptomycin daily plus 200 mg. of isoniazid daily with those of streptomycin and P.A.S. It was concluded that the degree of radiographic improvement was essentially the same on streptomycin and isoniazid as on streptomycin and P.A.S., and better in either than on isoniazid alone. Improvement in general condition and conversion of positive to negative culture were more frequent with streptomycin and isoniazid than with streptomycin and P.A.S. Thus it seemed that a combination of streptomycin and isoniazid was in general the most effective treatment known for pulmonary tuberculosis.

In this account I have omitted many details of method and of the knowledge achieved, and I would refer those interested to the article by the late Dr. Marc Daniels (1951). To whose personal qualities so much of this success was due. But I do want to say that I cannot conceive how so much and so exact a knowledge of the relative efficacies of these drugs could have been got so quickly and with so little expenditure of human life and suffering in any other way. Imagine the fate of the tuberculous patients if these drugs had been prescribed without plan or purpose and their assessment left to "clinical judgment." When I reflect on this I am amazed, stupefied, and I confess rather horrified that some of my colleagues, of unquestioned integrity and of no mean intelligence, adopt the attitude they do to controlled therapeutic trials.

I would also like to add that the controlled clinical trial is to my mind the most important new method introduced into clinical science in recent years. It should not only tell us what drugs can do, but if only the practical details can be overcome it could tell us, for example, whether or not an indulgence in fat, or in a particular kind of fat, is a contributing factor in the pathogenesis of ischaemic heart disease. Patients must be treated, and it would seem only sensible that treatment should be designed so that the results shall add to knowledge and help us in the prevention and control of disease, so long as the trial is not against the best interests of the patients.

SERUM GLUTAMIC OXALACETIC TRANSAMINASE IN ACUTE MYOCARDIAL INFARCTION

BY

H. A. DEWAR, M.D., F.R.C.P.

Assistant Physician, Royal Victoria Infirmary,
Newcastle upon Tyne

N. R. ROWELL, M.B., M.R.C.P., D.C.H.

AND

A. J. SMITH, M.D.

Lecturer in Chemical Pathology, University of Durham,
and Royal Victoria Infirmary, Newcastle upon Tyne

The estimation of glutamic oxalacetic transaminase in serum (S.G.O.T.) as an aid in the diagnosis of acute myocardial infarction was first introduced into clinical practice by LaDue, Wróblewski, and Karmen in 1954. Since then a fairly extensive literature, most of it American, has developed. Particularly comprehensive papers are those of Chinsky *et al.* (1956), Ostrow *et al.* (1956), Kattus *et al.* (1957), and Ratner and Sacks (1957).

The enzyme is widely distributed in the tissues, and high concentrations are present in cardiac and skeletal muscle and in brain, liver, and kidney. It is liberated into the blood on the death of cells of these organs. It is also present in erythrocytes, so that when samples of blood are collected for its estimation, haemolysis must be avoided and the serum or plasma separated as soon as possible. The enzyme will retain its activity for two weeks if the serum is stored at 0–5° C. (LaDue and Wróblewski, 1955). Its concentration can be estimated by the spectrophotometric method of Karmen *et al.* (1955) or by the colorimetric method of Reitman and Frankel (1957).

The level of S.G.O.T. activity in normal controls varies from 5 to 40 units per ml. of serum, with a mean of approximately 21 units (Wróblewski and LaDue, 1955; Kattus *et al.*, 1956). In a normal person the level does not vary by more than 10 units from day to day and is independent of time of day, meals, or previous exercise (Chinsky *et al.*, 1956).

Agress *et al.* (1955) showed that graded experimental infarction in dogs was associated in all cases with increase in S.G.O.T. Infarction of as little as 10%, and possibly less, of the total myocardium produced a significant rise in S.G.O.T. and there was a linear correlation between the peak S.G.O.T. level and the amount of infarction at necropsy. Nydick *et al.* (1957) found that there was no rise in S.G.O.T. in experimental myocardial ischaemia in dogs unless myocardial necrosis had occurred. The rise in S.G.O.T. begins within three hours after infarction, attains a peak in 9 to 23 hours, and returns to normal in three to six days. Agress *et al.* (1956), in other experiments, made the useful observation that if pericarditis was produced by sand, talc, or bacterial infections the S.G.O.T. would rise only if the underlying heart muscle was involved in the injury.

Since the enzyme is widely distributed in the body it was realized early that elevation of S.G.O.T. would occur after necrosis of tissues other than heart muscle. In man a rise in S.G.O.T. has been found after necrotic

lesions of the liver (Wróblewski and LaDue, 1955, 1956; Madsen *et al.*, 1958); of brain (Lieberman *et al.*, 1957), where the peak concentration is attained rather later than in cases of myocardial damage; of skeletal muscle (Merrill *et al.*, 1956); and of the pancreas (Chinsky *et al.*, 1956; Shabetai *et al.*, 1957). A small rise in S.G.O.T. may occasionally occur after pulmonary embolism (Goldstein *et al.*, 1956; Nydick *et al.*, 1957). S.G.O.T. also rises in haemolytic crises (Ostrow *et al.*, 1956) and sometimes with salicylate therapy, but only if the dosage is heavy and prolonged (Manso *et al.*, 1956).

This paper is an account of the part that estimations of S.G.O.T. have to play in the diagnosis and management of acute myocardial infarction.

Material and Method

Observations were made upon 34 episodes of acute myocardial infarction occurring in 28 patients admitted to the Royal Victoria Infirmary, Newcastle upon Tyne. Of these, 18 gave a preceding history of angina of effort. Four patients died, and necropsies were obtained in three. In addition, three patients with status anginosus or acute coronary insufficiency were studied, as well as a few cases of acute cardiac failure with, or without, severe arrhythmias. The cases of myocardial infarction and acute coronary insufficiency were treated with anticoagulants (heparin and phenindione).

Specimens of blood were collected daily for 10 to 14 days, and in some instances for much longer, and examined by one of us (A. J. S.) for the level of S.G.O.T. by the colorimetric method of Reitman and Frankel (1957), using the standardized reagents produced by the Sigma Chemical Company. Estimations were also made of other enzymes, of which an account will be given separately. The erythrocyte sedimentation rate (E.S.R.) was estimated daily by the Westergren method. Twelve-lead electrocardiograms were taken on the day of admission and not less than twice weekly thereafter. In seven cases the electrocardiogram was taken daily.

Estimation of the level of S.G.O.T. in 25 healthy adults gave a range of 10 to 34 units with a mean of 19.0 units (standard deviation ± 6.0 units).

Time of Onset, Height, and Duration of Rise

In many instances the patient was not admitted to hospital early enough for the time of onset of the rise in S.G.O.T. to be gauged, but from observations from those who were, and those who had further infarction in hospital, the average time of appearance of an abnormal figure was one and a half days, and the average duration of the abnormal elevation was three and a half days from the onset of pain, with a range of one to six days. These figures agree well with those of other authors—for example, LaDue *et al.* (1954), Denney *et al.* (1956), Chinsky *et al.* (1956), and Ostrow *et al.* (1956), who found that the rise may begin as early as three hours after the onset and that the enzyme returns to normal in one to eight days, most often by the end of the third day.

The peak concentration reached in the uncomplicated cases in the present series varied from 24 to 620 units, with a mean of 194 units—that is, nine times the normal level. Two cases of myocardial infarction with congestive heart failure and centrilobular necrosis of the liver at necropsy had peak levels of 950 and 8,400 units.

Relationship to Body Temperature and E.S.R.

Compared with the fever and the rise in E.S.R., which so commonly follow myocardial infarction, the rise in serum transaminase appeared a full 24 hours sooner. It fell to normal again two days before the temperature and at least a week sooner than the E.S.R. Fig. 1 shows curves from a typical case.

It proved also a more dependable index of infarction, since in only three cases where the blood samples were taken early enough was the S.G.O.T. negative (8.8%). In one-third of the infarcts no rise in temperature took place at all, and even the E.S.R. remained normal in one-fifth. Presumably a larger infarct is needed to raise the E.S.R. than the S.G.O.T. and a still larger one to induce fever.

FIG. 1.—Curve showing the relationship between S.G.O.T., temperature, and E.S.R. in a typical case of acute myocardial infarction.

There were in the series several cases where coincidental infections, such as pneumonia, were also responsible for a raised body temperature and E.S.R. as well as a few where the latter was depressed by congestive heart failure. Serum transaminase is unaffected by infections (Ostrow *et al.*, 1956), and, as shown below, rises only in a minority of cases of congestive heart failure. To sum up, the rise in S.G.O.T. is more prompt, more striking, more brief, more sensitive, and more specific than either the body temperature or the E.S.R.

Relationship to the Severity of the Infarct

The size of the infarct has been graded according to the number of leads in which Q wave and T wave changes were detected in the electrocardiogram. In Fig. 2 these have been plotted against the peak levels of S.G.O.T. in the blood of those patients in whom the form of the curve has demonstrated that the peak level had not been missed. It will be seen that there is a linear relationship, although this is a very rough one, not only because the electrocardiographic method of assessing the size of infarct is crude but also because when the S.G.O.T. curves are examined, and are related to the clinical history, a significant number of patients sustain their infarcts in stages over a period of several days. In them, a time-concentration curve would doubtless constitute a much better guide to severity than the single-peak reading, as has already been stressed by Kattus

et al. (1957). Fig. 3 is taken from a good example of such gradual infarction.

Since it has been shown experimentally that an infarct of less than 10% may not produce an elevation of serum transaminase (Agress *et al.*, 1955), it seems likely that in human subjects, too, infarcts may be so small that they do not produce an elevation. This is borne out by experience in the present series, where, on three occasions, pain and electrocardiographic changes in the course of a patient's treatment in hospital suggested that there had been an extension of infarction but no rise of transaminase took place. There was one further and more clear-cut case where the electrocardiogram showed clearly a fresh infarct but the serum transaminase was not elevated. There was also one patient in whom the clinical features were extremely suggestive of fresh myocardial infarction but both electrocardiogram and transaminase remained normal.

one further and more clear-cut case where the electrocardiogram showed clearly a fresh infarct but the serum transaminase was not elevated. There was also one patient in whom the clinical features were extremely suggestive of fresh myocardial infarction but both electrocardiogram and transaminase remained normal.

FIG. 2.—Relation of peak S.G.O.T. level and E.C.G. grade of infarct in 20 patients with acute myocardial infarction.

FIG. 3.—Curve of S.G.O.T. showing myocardial infarction occurring in stages over several days.

In some instances, however, the probability is that the elevation of the transaminase above the normal does not attain the arbitrary 40 units which has been set as the upper limit of the normal range. Fig. 4 shows an example where the clinical features and the electrocardiogram strongly suggested a fresh infarct, and the acute rise in serum transaminase is in accord with this even though the maximal elevation is below 40 units.

Cases with Previous Infarction

In nine cases there was a history of previous myocardial infarction, and in five of these, as well as in two others—

that is to say, in 21% of the episodes of definite fresh myocardial infarction—the electrocardiogram was so distorted by the previous infarct that on the single initial tracing alone it was impossible to deduce with certainty that fresh infarction had occurred. In these patients the serum transaminase was abnormally high within 48 hours and proved most helpful. Subsequent electrocardiograms confirmed the diagnosis. There is no doubt that in cases of suspected acute myocardial infarction where there is either a history or electrocardiographic evidence of previous infarction the estimation of serum transaminase has its greatest value in establishing that there has been a fresh lesion. Such cases constitute about a quarter of the fresh infarcts seen.

The serum transaminase is also helpful when patients are already under treatment for an acute myocardial infarct and the occurrence of pain, collapse, or other signs suggests that there has been fresh extension of infarction. In such cases the electrocardiogram is often so distorted by the recent necrosis, and perhaps by pericarditis occurring with it, that it is most difficult and often impossible to decide whether

FIG. 4.—Curve of S.G.O.T. and E.S.R. in a patient with acute myocardial infarction, with the peak S.G.O.T. level below 40 units.

FIG. 5.—Curve of S.G.O.T. in a patient with further myocardial infarction during the course of treatment.

there has been fresh necrosis. It is in these cases that serial estimations of serum transaminase are most likely to be helpful, since they will show the baseline level to which that individual's transaminase falls, and any striking elevation above this closely following upon an attack of pain can be taken as evidence of new damage. Fig. 5 shows such a case.

Other Obscuring Factors in the Electrocardiogram

The diagnosis of myocardial infarction by electrocardiography is less often obscured by arrhythmias, such as the tachycardias and bundle-branch block, by digitalis effects, and by previous left ventricular strain than it is by previous infarction. In the present series there were only two cases in which such factors created serious difficulties compared with five in which previous infarction operated similarly. Nevertheless, the serum transaminase is helpful in this minority, for in both these cases it was normal and the conclusion reached was that there had been no infarction.

Acute Coronary Insufficiency

Other authors (Rudolph *et al.*, 1955; Nydick *et al.*, 1957) have found in experimental narrowing of coronary arteries in animals that unless necrosis is produced in the myocardium a rise of serum transaminase will not be observed, and it has been found in human beings, too, that if the clinical and electrocardiographic picture is solely one of ischaemia without necrosis then the transaminase remains unaltered (Kattus *et al.*, 1956). In the present series there were three such cases of acute coronary insufficiency or status anginosus, all treated with anticoagulants. The usual difficulty in such cases is to distinguish on the electrocardiogram between such ischaemia and limited infarction, often subendocardial. Repetition of the tracings, trying the effects of nitroglycerin upon them, and observing the E.S.R. and body temperature may all help, but sometimes the difficulty remains unresolved. One would expect the serum transaminase to assist in a similarly circumscribed way, for if necrosis is small enough and gradual enough in onset, it would seem likely that no diagnostic curve or level might be observed. Experience of the three cases in this series has borne this out, and has suggested that the enzyme estimation is complementary to, but not necessarily more reliable than, the electrocardiogram in showing whether or not necrosis has taken place.

False Negatives

The S.G.O.T. was elevated in all except three of the cases of definite infarction here described where the blood samples had been taken early enough—that is, false negatives were 8.8%. Denney *et al.* (1956) found false negatives

Fig. 6.—Curve showing transient elevation of S.G.O.T. in acute myocardial infarction.

in only 4.75% of definite infarcts, while Kattus *et al.* (1957) had none amongst 111 patients with proved myocardial infarcts, probably because of the frequency with which they took blood samples for analysis. In a review of 264 patients, Ratner and Sacks (1957) had 8% false negatives among 64 patients with definite myocardial infarction, and this will probably prove to be a representative figure in clinical practice, for the S.G.O.T. rise may be very transient, as is shown in Fig. 6, and very frequent sampling is hardly practicable as a routine.

False Positives

Since the enzyme is so widely distributed it is obvious that significant rises in the blood level may be produced by a variety of mechanisms. If care is taken to separate the

serum or plasma of the blood sample from the red cells then false elevation due to liberation of the enzyme from haemolysed erythrocytes should not occur. Its liberation into the blood stream from other tissues is a much more important cause of false-positive results. Destruction of red cells in the tissues is one important cause, and particularly so where there has been some tissue destruction as well as haemorrhage; haemorrhagic pancreatitis is a conspicuous example of this. Where the enzyme content of the tissue is low, as in the brain and in the lung, infarction brings only slight rises. When it is high, as in the liver, the elevation consequent upon tissue damage may be enormous. This does not often cause trouble in diagnosis, although one patient, not included in this series, was admitted under the care of one of us (H. A. D.) with the diagnosis of suspected myocardial infarction, and investigation showed that the rise in his transaminase (109 units) was due to subacute alcoholic hepatitis, his heart being clinically and electrocardiographically normal.

It is apparent that serum transaminase is helpful in the differential diagnosis of myocardial infarction only if one is fully aware of the capacity of other tissues to liberate it. Much more important in cardiology is the possibility of the enzyme being liberated in substantial amounts from a liver congested and necrotic from heart failure. The literature about this is scanty. Conrad (1957) mentions DuToit's (1956) report of an elevation in S.G.O.T. in 16 out of 23 patients in uncomplicated cardiac failure. When it does occur the blood level attained may be very high, as in one case in the present series where a young woman of 29 years with acute cor pulmonale due to emphysema and pulmonary infection was found to have a transaminase level of 710 units; nothing in the history or the electrocardiogram suggested that there had been myocardial infarction. Two of DuToit's cases had S.G.O.T. levels of more than 2,000 units, and one of these had advanced central necrosis of the liver at necropsy. It has been said that in cases of liver disease the serum glutamic pyruvic transaminase (S.G.P.T.) is elevated to a greater extent than the S.G.O.T., in contrast to the findings in myocardial necrosis. In the present series this was occasionally true, but exceptions were too numerous for the double estimation to be worth while as a routine test.

Prognosis

It has been said (Chinsky *et al.*, 1956) that a peak level of S.G.O.T. greater than 200 units carries a poor prognosis. However, the peak level may not be observed, either because the patient dies before the maximum is reached or because the patient is admitted on the downstroke of the transaminase curve. In this series two patients died with S.G.O.T. levels of 57 and 70 units, and in both of these the peak was probably missed. There were eight patients with a peak S.G.O.T. level above 200 units and only two died. Both of these, with S.G.O.T. levels of 950 and 8,400 units, had only moderate-sized recent infarcts at necropsy, but there was marked centrilobular necrosis of the liver.

Many factors are involved in the prognosis of acute myocardial infarction, of which the size of the infarct, reflected in the peak level of S.G.O.T., is only one, and this peak level may in any case be further raised if there is acute heart failure with hepatic centrilobular necrosis, and perhaps also if there is acute haemorrhagic pericarditis complicating the picture.

S.G.O.T. in other Cardiac Conditions

Also of interest in cardiology are the affections of the heart other than acute myocardial infarction in which a raised S.G.O.T. may be found. The role of pericarditis has already been mentioned. The arrhythmias *per se* do not raise the enzyme level, but may do so in occasional instances, including one case of the present series and one case out of 14 in the series of Chinsky *et al.* (1956), where the extremely rapid heart rate precipitated acute heart failure with presumed centrilobular necrosis of the liver. The same is true of acute pulmonary oedema (Chinsky *et al.*, 1956).

Ostrow *et al.* (1956) quote one case of Fiedler's myocarditis in which the S.G.O.T. was elevated as one would expect, and Chesler (1958) reports elevated levels in diphtheritic myocarditis. Nydick *et al.* (1955a, 1955b) give an interesting account of its elevation in acute rheumatic carditis. The latter at any rate cannot often be confused with myocardial infarction, and no such difficulty arose in the present series.

Summary

Serial daily estimations of serum glutamic oxalacetic transaminase (S.G.O.T.) for at least 10 days have been made in 34 acute episodes of myocardial infarction occurring in 28 patients. The results have been compared with changes in erythrocyte sedimentation rate (E.S.R.), temperature, and electrocardiogram.

Estimations of S.G.O.T. are most useful (a) when the electrocardiogram is obscured by previous myocardial infarction, arrhythmias, bundle-branch block, left ventricular strain, and digitalis; (b) when extension of myocardial infarction is suspected; and (c) to distinguish between acute coronary insufficiency and myocardial infarction.

There was no rise in S.G.O.T. in 8.8% of the cases of fresh myocardial infarction.

The maximum elevation of S.G.O.T. roughly corresponds with the electrocardiographic estimation of the size of the infarct only if other causes of a raised transaminase can be excluded. The most important of these in myocardial infarction is centrilobular necrosis of the liver secondary to cardiac failure.

In small infarctions serial estimations of S.G.O.T. may show a characteristic curve even though the peak does not exceed 40 units.

We thank the following house-physicians, Drs. W. S. B. Cherry, R. Hart, J. M. Kendall, and J. King, for their practical help in this investigation. We are also grateful to Mr. D. P. Hammersley for help with the diagrams, and to Dr. A. Latner for facilities in the department of pathology.

SERUM TRANSAMINASE: ITS CLINICAL USE IN DIAGNOSIS AND PROGNOSIS

BY

R. BRUCE, M.B., B.S.
Medical Registrar

J. K. TODD, M.B., B.S.
House-Physician

AND

L. LeDUNE, M.B., B.S.
Senior House Officer

The General Hospital, Chester-le-Street

Human serum contains several enzymes concerned with the reaction of transamination. The one most commonly determined is serum glutamic oxalacetic transaminase (SGO-T), which catalyses the reversible reaction:

Similarly serum glutamic pyruvic transaminase (SGP-T) catalyses the reaction:

Cohen and Hekhuis (1941) showed that transaminase was in highest concentration in cardiac and skeletal muscle. LaDue *et al.* (1954) also found it to be present in the brain, liver, and kidney in lower concentrations.

The serum transaminase level (SGO-T) has been found to be elevated following myocardial damage, hepato-cellular necrosis, pancreatitis, trauma to skeletal muscle, myositis (including dermatomyositis), active rheumatic carditis, and any process associated with active damage to skeletal or cardiac muscle (LaDue and Wróblewski, 1955; Wróblewski and LaDue, 1956; Ratner and Sacks, 1957).

The curve of serial serum transaminase estimations would appear to be characteristic in cases of myocardial infarction, and it has been suggested that a characteristic curve occurring within the normal range of values may be found in some cases of angina (Chinsky *et al.*, 1956) or associated with a very small infarct (Ratner and Sacks, 1957). These authors also found that the serum transaminase level remains normal in patients with cerebrovascular damage, acute or chronic infections, acute phlebitis, uraemia, neoplastic, allergic, or metabolic diseases, unless associated with damage to skeletal or heart muscle. Further, there appears to be no apparent correlation with age, sex, colour, weight, leucocyte count, blood sedimentation rate, the presence or absence of fever, heart failure or shock, or the use of anticoagulant drugs or cortisone.

The above evidence suggests that serial transaminase readings are a possible aid to diagnosis in cases of doubtful myocardial infarction and might prove to be related to the actual size of infarct and, because of this, a possible guide to prognosis. We felt, therefore, that a small series of cases investigating these points was justified.

Technique Employed.—The technique we used was that devised by Frankel and Reitman (1957). In this method the amount of keto-acid formed in one hour is determined colorimetrically by the formation of

a highly coloured "hydrazone," using a spectrophotometer or photoelectric absorptiometer in the range 500 to 520 m μ .

Results

Serum transaminase levels were estimated in 31 cases of myocardial infarction and the typical findings in several cases are described below.

(47) *Case 1.*—Woman, aged 69. Angina three weeks; eight hours' central chest pain. Serum transaminase: 24 SGO-T units 8 hours after onset, 156 units at 32 hours, 27 units at 4 days, 18 units at 8 days. E.C.G.: (a) posterior infarct eight hours after onset; (b) much improved six weeks later.

(21) *Case 2.*—Man, aged 59. Angina two years; eight hours' central chest pain. Serum transaminase: 216 SGO-T units 56 hours after onset, 64 units at 4 days, 54 units at 6 days, 32 units at 7 days. E.C.G.: antero-lateral infarct 80 hours after onset.

(3) *Case 3.*—Man, aged 63. Hypertension; angina one week; four hours' central chest pain. Serum transaminase: 184 SGO-T units 12 hours after onset, 103 units at 36 hours, 49 units at 60 hours. E.C.G.: (a) postero-lateral infarct 24 hours after onset; (b) unchanged seven days later.

FIG. 1.—Case 4. Serum transaminase readings.

These cases show the typical transiently raised transaminase values in myocardial infarction, the diagnosis in each case being confirmed clinically and on electrocardiography.

(8) *Case 4.*—Man, aged 49. Angina one year; five hours' central chest pain. Serum transaminase: 23 SGO-T units 6 hours after onset, 160 units at 24 hours, 102 units at 54 hours, 30 units at 6 days (Fig. 1). E.C.G.: normal bar Q wave V₁₋₇ 48 hours after onset; antero-septal infarct 10 days after onset (Figs. 2 and 3).

FIG. 2.—Case 4. E.C.G. 48 hours after onset.

FIG. 3.—Case 4. E.C.G. 10 days after onset.

(44) *Case 5.*—Man, aged 62. Chronic bronchitis; cor pulmonale; jaundice (painless). ? Cardiac cirrhosis. Serum transaminase: 460 SGO-T units day after admission. E.C.G.: left bundle-branch block day of admission. Serum bilirubin, 11.3 mg./100 ml. (total). Necropsy: Enlarged heart; right ventricular hypertrophy; extensive recent septal infarct involving anterior wall of both ventricles; liver showed cardiac cirrhosis.

(17) *Case 6.*—Man, aged 77. Prostatic carcinoma with metastases. Atrial fibrillation. Serum transaminase: 40 SGO-T units 3 days after admission, 30 units at 5 days, 86 units at 6 days, 77 units at 7 days. E.C.G.: auricular fibrillation and right bundle-branch block three days after admission (Fig. 4). Necropsy: Terminal bronchopneumonia; carcinoma of prostate with metastases; recent occlusion of circumflex coronary artery.

FIG. 4.—Case 6. E.C.G. 3 days after admission.

Case 4 appears to demonstrate transaminase levels confirmatory of recent infarction before fully diagnostic electrocardiographic changes had occurred. In Case 5 the transaminase level again agreed with the proved diagnosis in the absence of confirmatory E.C.G. changes. The raised serum bilirubin level might be expected to cause a rise in transaminase values due to the high transaminase content of bile. However, the results in this case were consistent with the proved diagnosis at necropsy.

Case 6 was also proved at necropsy despite non-confirmatory electrocardiography and in the presence of carcinomatosis.

Case 7 reveals apparently diagnostically raised transaminase values, whereas the electrocardiographic changes are merely suggestive. Although permission for necropsy was not obtained there is felt to be no doubt on purely clinical grounds about the diagnosis.

Cases 4 to 7, therefore, are instances in which transaminase levels proved of greater diagnostic aid than initial electrocardiography.

(15) *Case 8.*—Man aged 76. Diabetic; sudden collapse and death in two hours; no prior history of cardiac pain. Serum transaminase: 36 SGO-T units at onset of collapse. E.C.G.: postero-lateral infarct three days before collapse. Necropsy: fibrotic myocardium; 2-cm. thrombus in right coronary artery proximal part several (? 10) days old, distal part quite fresh.

(28) *Case 9.*—Woman, aged 76. Hypertensive "collapse" 10 days previously. Serum transaminase: 20 SGO-T units 10 days after collapse. E.C.G.: antero-lateral infarct six days after collapse; much improved 13 days after collapse. Recovered.

Cases 8 and 9 illustrate the need for transaminase levels to be estimated at the appropriate times after infarction if they are to prove of help in assessment. Thus in Case 8 the estimation was too soon after the terminal infarction to reveal any change, and in Case 9 the time interval of 10 days after infarction is too long. The optimum times after infarction appear to be from 24 hours to five days.

(7) *Case 10.*—Woman, aged 55. Depressive; hypertension; five hours' epigastric pain. Serum transaminase: 83 SGO-T units 48 hours after onset, 47 units at 3 days, 16 units at 4 days. E.C.G.s taken 48 hours and 10 days after onset are shown in Figs. 5 and 6.

FIG. 5.—Case 10. E.C.G. 2 days after onset.

Of the 31 cases of myocardial infarction, 23 occurred clinically within seven days prior to serum transaminase estimation being obtained. Of the 23 patients with acute infarctions, 16 recovered and 7 died (see Table). The 16 recoveries reveal an average peak transaminase value of 111 SGO-T units. The deaths reveal an equivalent average figure of 576 SGO-T units. These figures are not altogether accurate, as in a few of the recovered cases the transaminase levels

FIG. 6.—Case 10. E.C.G. 10 days after onset.

Results in 23 Cases with Acute Infarctions

Case No.	Observed Serum Transaminase Peak Values	Outcome	Necropsy
2	216 units 56 hours after onset	Recovered	
3	184 " 12 " admission	"	
4	160 " 24 " onset	"	
5	460 " 1 day after admission	Died	Extensive infarct of both ventricles
6	86 " 6 days " "	"	Recent circumflex artery occlusion
7	550 " 5 days after onset	"	No necropsy
8	36 " at the time of infarct	"	Old and recent infarcts
10	83 " 48 hours after onset	Recovered	
12	200 " 36 " "	"	
13	61 " 78 " "	"	
14	120 " 12 " "	"	
15	73 " 5 days after admission	"	
16	43 " 24 hours after onset	"	
17	129 " 12 " "	"	
18	41 " 7 days " "	"	
19	95 " 3 " "	"	
20	900 " 3 " "	Died	No necropsy
21	156 " 32 hours " "	Recovered	
22	24 " 4 days " "	"	
23	280 " 48 hours " "	Died	Extensive infarct
24	114 " 33 " "	Recovered	
25	75 " 48 " "	"	
26	1,720 " 48 " admission	Died	No necropsy

obtained were not necessarily the highest that actually occurred. Similarly in the fatal group, one case reveals a low value as it was too soon after infarction to expect a rise, and one patient with infarction died from bronchopneumonia and carcinomatosis rather than the infarct, and consequently the low value obtained agrees with the necropsy findings of a small infarct.

These points would possibly cause a higher average figure in the recoveries, but also would increase the figure in fatal cases, and it is felt, therefore, that the difference is probably significant.

The average time of peak transaminase level relative to the time of infarction was estimated from cases where serial transaminase levels were known. Where the time of infarction was in doubt it has been accepted as from the moment of admission. The average figure so obtained was 62 hours after infarction in the 18 suitable cases.

Serum transaminase estimations were carried out both during and for several days after attacks of angina in appropriate cases. On each occasion the transaminase value was found to be within the normal range. On several occasions, in two cases of old myocardial infarction with recurrent attacks of angina, we found transaminase value of help in distinguishing prolonged anginal pain from that due to further myocardial infarction, the transaminase values correlating well with subsequent electrocardiography and clinical progress.

In this series the overall average age of the patients with myocardial infarction was 60 years. The average age of the males was 58 years, and of the females 67.

Discussion

It is appreciated that the majority of cases of myocardial infarction can be diagnosed on clinical grounds, but a group remains in which the diagnosis is initially in doubt.

This small series of cases confirms reports in America and this country that recent myocardial infarction can be detected in some cases by a typical rise and fall in serum transaminase values before diagnostic electrocardiographic changes have occurred. The correlation of degree of rise in serum transaminase level with size of infarct and immediate outcome suggests that transaminase values of over 250 units are of serious portent and such cases are unlikely to recover.

The importance of time of transaminase estimation after infarction was well shown in several cases. It is suggested that transaminase values should be estimated at 24-hourly intervals from the time of infarction for at least four and preferably seven days, or until the peak value is passed, if full information is to be obtained from the results.

In differential diagnosis, too, the transaminase levels may be of help. On several occasions we found it useful in assessing whether severe cardiac pain was due to prolonged angina pectoris or actual infarction, the transaminase results correlating in each case correctly with electrocardiographic findings and subsequent clinical progress.

No diagnostic rise in transaminase levels was detected in two cases of pulmonary infarction, two cases of gall-bladder dysfunction, two cerebral catastrophes, and six cases of pneumonia.

It is of interest that one case of active rheumatic pericarditis (not included in this series) revealed a transiently raised serum transaminase level. This suggests concurrent myocardial damage of a temporary nature, and it will be of interest in the future to ascertain whether serum transaminase levels will help in assessing activity in cases of rheumatic carditis where this is in doubt.

In carrying out these estimations of serum transaminase levels the method of Frankel and Reitman (1957) was found to have several inherent disadvantages regarding cost and technique. These seem to be overcome in the method described by King (1958), and the simpler technique and its cheapness should place it well within the scope of all routine laboratories.

Summary

Serum transaminase estimations in a small number of cases of myocardial infarction are related to clinical, electrocardiographic, and necropsy findings. The test's possible value and advantages in early differential diagnosis and prognosis are discussed.

This series reveals close correlation between peak transaminase levels, size of infarct, and immediate outcome.

Evidence is presented which shows that cases in which transaminase values rise above 250 SGO-T units do not usually recover.

We thank Dr. R. Mowbray and Dr. T. A. Grimson for permission to publish this report and for their interest and encouragement, Dr. J. Ennis for his help in assessing the pathological findings, and Miss Haigh for her unstinted secretarial help.

Rank Precision Industries (B.A.F.) Ltd. has issued a leaflet describing the films and filmstrips on hospital and medical training in the G.B. Film Library. The leaflet lists 44 films and 33 filmstrips which are available from the library. It gives brief details of their length, number of reels or frames, hire rates, and purchase prices. Handbooks containing essential information for the guidance of teachers or film users are supplied with the films and filmstrips. Films are available for either outright purchase or hire; viewing copies will be supplied free of charge on application. Filmstrips are for outright purchase only, but may be previewed under a 14-days "sale or return" approval scheme. Further details from the G.B. Film Library, Aintree Road, Perivale, Greenford, Middlesex.

SCURVY FOLLOWING BILATERAL ADRENALECTOMY

REPORT OF TWO CASES

BY

DIGBY CHAMBERLAIN, Ch.M., F.R.C.S.

Professor of Clinical Surgery, University of Leeds

AND

N. V. ADDISON, F.R.C.S.

Senior Surgical Registrar, the General Infirmary at Leeds

During the convalescent period of two patients who had undergone bilateral adrenalectomy and oophorectomy for advanced breast cancer it was noticed that they developed petechial skin haemorrhages on the arms and legs. One of these patients also complained of bleeding gums. A diagnosis of scurvy was made and the vitamin-C saturation test was carried out. In the first patient only 21 mg. of the vitamin appeared in the urine, following an intravenous injection of 1,000 mg. of ascorbic acid, and in the second case only 31 mg. was excreted. The average amount of ascorbic acid excreted during this test in a normal healthy individual varies between 300 and 500 mg.

These findings stimulated us to investigate two other patients in the ward who had recently had their adrenals and ovaries removed, and in both cases the test showed a vitamin-C deficiency. Further patients were investigated and of nine who were subjected to the test similar deficiencies were found in seven. The remaining two patients had been operated upon several months previously; both had progressed well, had good appetites, and had increased in weight, and in them the values were 370 and 570 mg. respectively. The average amount of vitamin C excreted in the seven patients (average age 53 years) in whom the figure was low was 85 mg.

A control series of tests was carried out on nine patients who had recently undergone operations such as radical mastectomy, cholecystectomy, appendicectomy, and colectomy. The average amount of vitamin C excreted by them was 300 mg., their average age being 49 years. None of these patients had been given vitamin C therapeutically.

Although there is some doubt about the reliability of the vitamin-C saturation test, these figures seemed significant and led us to believe that patients who had both adrenals and ovaries removed might be deficient in vitamin C, especially in the early post-operative period.

We record the two case histories of scurvy following bilateral adrenalectomy and oophorectomy, and discuss the possible cause of this, together with the relationship of vitamin C to the adrenal glands.

Case 1

A housewife aged 37 was admitted to hospital on June 17, 1958. Nine months earlier she had noticed a swelling in the left breast which had ulcerated through the skin. She complained of loss of energy, tiredness, and poor appetite. On examination she had a foul-smelling, fungating cancer of the left breast, with an infected carcinomatous ulcer in the left axilla. She was pale and listless, with oedema of the legs and sacrum. A blood count showed a haemoglobin level of 22%, and 16,600 white blood cells, of which 95%

were polymorphonuclears. X-ray examination of the chest revealed secondary carcinomatous deposits in the mediastinum and ribs.

Following a blood transfusion a right adrenalectomy and bilateral oophorectomy was carried out on June 19. The left adrenal gland was removed two weeks later. Her general condition improved after the second operation, but some days later she developed a temperature, and pus from an infected haematoma began to discharge from the wound in the right loin. Culture of the pus from the breast and

FIG. 1.—Case 1. Petechial haemorrhages of scurvy on the hands following bilateral adrenalectomy.

the loin showed a heavy growth of *Staphylococcus aureus*, sensitive to chlortetracycline and erythromycin.

On the eleventh post-operative day she developed purpuric spots on the hands (Fig. 1), arms, and abdomen, together with sore bleeding gums. At this time she was taking a normal well-balanced diet. A blood count showed a haemoglobin level of 72%, white cells 18,600 with 95% polymorphs, platelets 210,000, and a bleeding-time of 6½ minutes. A diagnosis of scurvy was made, and the vitamin C saturation test revealed a marked vitamin-C deficiency, there being only 21 mg. of ascorbic acid excreted in the urine.

She was given 300 mg. of ascorbic acid daily by mouth, and the rash eventually disappeared. Following a course of deep x-ray therapy to the ulcerating breast, which had become a little smaller and cleaner, she was sent home on August 8.

Case 2

A housewife aged 62 was admitted to hospital on June 28, 1958, having had a radical mastectomy in January, 1957, for an anaplastic round-celled carcinoma of the left breast. She had developed secondary carcinomatous deposits in the skin

FIG. 2.—Case 2. Subcutaneous haemorrhages of scurvy on the thigh following bilateral adrenalectomy.

of the right chest wall, and an x-ray examination showed lung deposits and a pleural effusion. Her haemoglobin level on admission was 82%.

On June 30 a left adrenalectomy and bilateral oophorectomy was carried out. The liver was found to contain extensive deposits of secondary growth. The adrenal gland was infiltrated with carcinoma, and this was confirmed on histological examination. Ten days later a right adrenalectomy was performed, but a week later her right loin wound became infected following the discharge of a haematoma. She also developed multiple bedsores, which became infected. At this stage she was being given a high-protein diet, but was reluctant to eat.

Culture of the pus in the wound revealed a growth of *Staph. aureus*, which was insensitive to all antibiotics except novobiocin, which was given in doses of 250 mg. six-hourly for five days.

On the tenth post-operative day she developed purpuric spots and haemorrhages on the hands, arms, and legs (Fig. 2). The gums appeared normal, but she was edentulous. A blood count showed a haemoglobin level of 71%, white cells 13,300 with 94% polymorphs, platelets 47,000, and a bleeding-time of 3½ minutes. A vitamin-C saturation test was carried out and 31 mg. of ascorbic acid was excreted.

She was given 300 mg. of vitamin C daily and the purpuric spots diminished in number, but did not disappear as in Case 1. Although her wounds became cleaner and began to heal, her general condition deteriorated and she died on August 1.

Discussion

It is possible for most vitamins, an exception being vitamin C, to be synthesized in the body, and we depend entirely on extraneous sources for our essential requirements of it. It can be stored to a limited extent in the body, and this is said to occur mainly in the adrenal cortex, pituitary body, corpus luteum, and lens. Investigations have shown that the guinea-pig behaves in a similar way to man and cannot synthesize the vitamin, whereas the rat, dog, and mouse are able to do so. The site of this synthesis is not known, but it may be in the adrenals, as Dumm and Ralli (1949) observed that the ascorbic acid excretion by rats after bilateral adrenalectomy fell to low values. On the other hand, the synthesis is not entirely dependent on the adrenals, as adrenalectomized dogs and rats can be maintained on a vitamin-C-free diet.

A great deal of experimental work has been carried out to determine the relationship between ascorbic acid and the adrenal cortical hormones. In animals, following stress or the administration of corticotropic hormones, the increased secretion of adrenocortical hormones is associated with a rapid decrease in the amount of ascorbic acid and cholesterol in the adrenal gland. There appears to be considerable doubt about the relation of vitamin C to the synthesis of the adrenocortical steroids. In persons dying after continuous stress the enlarged adrenals were found to contain about 50% less than the normal amount of ascorbic acid and cholesterol (Uotila and Pekkarinen, 1951).

That ascorbic acid is not essential for the actual synthesis of the hormones is seen in scorbutic animals, when cortical hormones are elaborated in the absence of the vitamin. On the other hand, when the adrenals are removed from guinea-pigs, and vitamin C is withheld, the animals die rapidly (Clayton and Prunty, 1953). In classical cases of scurvy in man, the typical findings of eosinopenia and increased 17-ketosteroid excretion are noted after corticotrophin therapy and are not changed after vitamin C administration. After saturation with vitamin C there is a marked increase in urinary ascorbic acid following treatment with corticotrophin.

The effect of corticoid release on ascorbic acid excretion in man is described by Stefanini and Rosenthal (1950) and by Holley and McLester (1951). In each case two male patients with rheumatoid arthritis were treated with cortico-

trophin for periods of six months. In all four patients symptoms of scurvy developed which responded to vitamin C. Holley and McLester have suggested that ascorbic acid plays the part of a reducing mechanism in the production of the steroid hormones. In order to conserve the ascorbic acid content of the adrenal cortex, the body is apparently able to deplete other structures. Corticotrophin therapy reduces the stores of ascorbic acid in the adrenal cortex, and prolonged administration produces a deficiency and symptoms of scurvy.

Kayahan (1952) states that following the taking of large doses of vitamin C by mouth in man, there is an increased corticoid but decreased 17-ketosteroid excretion in the urine, indicating a direct action on the adrenal cortex.

Finally it has been shown that ascorbic acid is used up more rapidly when infection is present.

Summary and Conclusion

The adrenal cortex is the main storage depot of vitamin C in man.

The release of cortical hormones is associated with an increased excretion of ascorbic acid and a reduction of the ascorbic acid content in the gland itself.

Large oral doses of vitamin C appear to increase corticoid but decrease 17-ketosteroid excretion in the urine, indicating a direct action on the adrenal cortex.

It is open to discussion whether or not vitamin C is concerned with the actual synthesis of the adrenocortical steroids, but it is suggested that the power of the adrenal cortex to secrete the hormones is dependent on the presence of ascorbic acid.

In the cases of scurvy described here it is significant that infection was present in each case, and also in another patient with a low ascorbic acid excretion. Infection was not recorded in any other case which had undergone bilateral adrenalectomy. The presence of infection is believed to cause vitamin C to be utilized more rapidly, and thus deplete the limited reserves. We believe that patients who have their adrenal glands and ovaries removed tend to have a lowered reserve of the vitamin immediately after the operation. This belief is based on the finding of a low vitamin excretion in seven patients following adrenalectomy and oophorectomy, and comparing these values with a group of patients who were recovering from other types of operation.

We suggest that these cases should receive an adequate intake of ascorbic acid if they are not to develop deficiency symptoms.

The National Council of the National Deaf Children's Society held its first meeting on October 18. The constituent societies are the former Deaf Children's Society, which has amended its constitution to become a national organization, and the following affiliated regional associations: the Herefordshire and Worcestershire Association for Parents of the Deaf; the East of Scotland, the Hertfordshire, the Oxford and Districts Regions; the N.-E. and N.-W. Deaf Children's Associations; and the South Wales Parents' Association for Deaf Children. The Society's address is: 1, Macklin Street, Drury Lane, London, W.C.2.

SURGERY OF ATRIAL SEPTAL DEFECTS

BY

E. F. CHIN, F.R.C.S.

AND

D. N. ROSS, F.R.C.S.

Thoracic Unit, Southampton Chest Hospital

The shunting of significant amounts of blood from the left to the right atrium through a septal defect should in most cases be corrected surgically. Whether this is performed by the closed method, as devised by Gross *et al.*, or by suture under the direct vision with hypothermia, as first practised by Lewis *et al.* (1955), will depend upon the practice of the individual clinic. In this unit open heart surgery is the method of choice, combined with hypothermia.

Surgical Anatomy

This has been dealt with in many communications (Rokitansky, 1875; Hudson, 1955; Lewis *et al.*, 1955; Ross, 1956; Bedford *et al.*, 1957).

Three main types of defect may be found, and any of these may be associated with anomalous pulmonary venous drainage: (1) The high defect, or sinus venosus type, is always associated with some anomaly of pulmonary venous drainage. There is no postero-superior margin, and the upper portion lies within the mouth of the superior vena cava (Fig. 1). (2) The fossa ovalis or ostium secundum defect. These are well-defined anteriorly, and there are a number of variations as seen in Fig. 2, A, B, and C. (3) The ostium primum defects. The anterior margin of the defect in these cases is formed by the ventricular septum. These ostium primum defects are associated with other anomalies, particularly a cleft mitral valve, producing mitral regurgitation, but the tricuspid valve and the upper portion of the ventricular septum may be deficient (Fig. 3).

Clinical Findings and Catheter Studies

Excellent clinical descriptions of the conditions are available (Kjellberg *et al.*, 1955; Wood, 1956; Bedford *et al.*, 1957; and many others). In the uncomplicated cases with a low pulmonary vascular resistance the findings are those that would be expected when many litres of blood escape from the left to the right atrium and pass through the right heart and pulmonary bed. The right ventricle is overactive and the increased blood flow gives rise to a pulmonary systolic murmur audible along the left sternal edge. There may be a thrill associated with the murmur. Characteristically, the second sound is widely split and fixed. In most cases a tricuspid diastolic flow murmur is audible on inspiration. This, like the pulmonary systolic murmur, is due to the torrent of blood flowing through the right heart. The radiograph shows the characteristic findings of an enlarged right atrium and pulmonary artery with varying degrees of pulmonary plethora and in association with a small aorta. In the secundum type the electrocardiogram shows right ventricular hypertrophy and a partial right bundle-branch block type of pattern.

All cases have been subjected to cardiac catheterization with the object of confirming the clinical diagnosis and of determining the pulmonary resistance and the magnitude of the shunt. This has sometimes been useful in determining whether anomalous pulmonary venous drainage is present. A gradient across the pulmonary valve does not necessarily mean that there is associated pulmonary valve stenosis, because a significant gradient can be produced by a large flow across a normal valve. In one case there was a considerable gradient across the valve, the right ventricle pres-

sure being 60/0 and the pulmonary artery pressure 18/6. After closure of the defect the thrill in the pulmonary artery disappeared and the right ventricular pressure dropped to 28/4 with a pulmonary artery pressure of 20/10.

Indications for Surgery

The volume of the shunt has been the indication for surgery, not the presence or absence of symptoms in the patient. Ideally, the shunt should be arrested before the right heart has developed permanent secondary organic changes.

The closure of a proved atrial septal defect can now be regarded in the same light as a persistent ductus; that is, to prevent the ill effects of the shunt on the heart and pulmonary bed. It is quite wrong to wait for the development of symptoms.

In the pre-operative assessment, the presence and volume of the shunt and the level of the pulmonary vascular resistance are all taken into consideration. Shunts of 2:1 or more are considered suitable for surgery, while a raised pulmonary vascular resistance (particularly with a small shunt) makes surgical closure hazardous. The late development of cyanosis as a result of reversal of the shunt is an absolute contra-indication to surgery.

The electrocardiogram must show right ventricular hypertrophy and right axis deviation. Right axis deviation is of some importance, since a tendency to a left axis deviation may suggest an ostium primum defect. In the two ostium primum defects we have encountered, left axis deviation has been present and we do not now operate in such cases.

Cases in failure and those in the older age group should not be excluded provided that the pulmonary vascular resistance is not raised and the agreed indications are present, but a higher operative risk may have to be accepted. On the other hand, this must be set against the unfavourable natural history of the disease. The average age at death in three published series is as follows: Roesler (1934), 36 years; Welch and Kinney (1940), 33 years; and Burrett and White (1945), 39 years.

FIG. 1.—Sinus venosus, or high defect. These cases are associated with one or more anomalous veins draining into the dilated superior vena cava.

FIG. 2.—A, Typical fossa ovalis or ostium secundum defect. There is a well-defined anterior margin. B, Lacwork type of ostium secundum defect due to incomplete remnants of the septum primum. C, Large ostium secundum defect. Note how the inferior margin is overlapped by the eustachian valve. There are two apparently anomalous pulmonary veins visible.

Clinical Analysis

This surgical series consists of 49 cases—46 secundum defects, 2 primum defects, and 1 sinus venosus defect. The Table shows the age distribution in relation to symptoms. It will be seen that 18 cases in this series had symptoms.

Age Distribution

Age:	0-5	6-10	11-15	16-20	21-30	31-40	41-50	51-60
No. Symptoms	1	2	8	4	5	0	8	1
Symptoms	0	1	3	1	4	0	8	1

The sex distribution consists of 12 males and 37 females. The majority of those with symptoms complained of dyspnoea on moderate exertion accompanied by palpitations. Recurrent chest infection was present in four and two had suffered haemoptysis. Frank cardiac failure had been present in five and their ages were 30, 47, 48, 49, and 56. The patient over 56 had been virtually incapacitated for 18 years. This group survived surgery and has done well, except for the patient of 56, who succumbed during surgery. This was due to a heavily calcified pericardium around the inferior vena cava, which made the dissection of this vessel hazardous. After release of the clamp across the inferior vena cava it was found that the calcium had produced disruption of the vessel wall, with uncontrollable haemorrhage. The patients with symptoms were, in the main, over the age of 20, but those with recurrent chest infection were in the younger age group and had been investigated elsewhere for bronchiectasis. There was one further case in failure; this was in a child with an ostium primum defect.

It has been stated that there is retardation of growth in these cases; certainly in our series there were several patients who were quite definitely undersized.

Anaesthesia is to be fully described elsewhere by Dr. E. S. Machell.

Surgical Technique

This type of surgery must be carried out by a team fully trained in this work, and the operating team must be thoroughly integrated with the anaesthetic and nursing teams. All the steps in the

FIG. 3.—An ostium primum defect. It is well defined posteriorly, but the anterior margin is formed by the ventricular septum. The mitral valve is deeply cleft.

Britain or abroad, and it is difficult to escape the belief that the different picture is consequent upon their way of life, as they are never housed. Most of the cases of tuberculosis in sheep are due to the avian type (Griffith, 1925; Creech, 1940). While it is impossible to trace the source of infection, it seems logical to conclude that wild birds, which are frequently infected with avian tubercle bacilli, are responsible for avian tuberculosis in sheep.

The rarity of the disease in sheep is confirmed by the statistics of the Bureau of Animal Industry in the United States. Out of 17 million animals slaughtered, only two were condemned because of tuberculosis. Information concerning tuberculosis in goats is very scanty, and with one or two exceptions tubercle bacilli obtained from tuberculous goats have been of the bovine type. Experimentally, goats and sheep can be readily infected with bovine tubercle bacilli. In naturally occurring tuberculosis in sheep and goats lesions were observed in the liver, lung, spleen, and lymph nodes, and on the pleura and peritoneum.

Tuberculosis in Pigs

The incidence of tuberculosis in pigs is an indicator of the amount of tuberculosis in cattle, people, and poultry in a given community, because pigs are susceptible to human, bovine, and avian types of tubercle bacilli.

Tuberculosis of pigs due to the human type of infection is rather rare. Information concerning percentage of human types varies: Gerbert (1939), in his studies on typing tubercle bacilli isolated from 50 tuberculous pigs, demonstrated 33 cases caused by the bovine type, 5 by the avian type, 3 by the human type, and 9 by mixed infection of avian and bovine types.

When infection of pigs by the human type of tubercle bacilli is known the fact should be of interest to those concerned with the public health. If the dissemination of human tubercle bacilli is occurring in a community in sufficient numbers to produce tuberculous lesions in pigs, it is reasonable to believe that the source of such pathogens is a potential danger to human beings.

Natural infection of pigs with human tubercle bacilli, which often occurs in pigs kept on the farm attached to sanatoria, seldom results in more than localized tuberculous adenitis.

The bovine type of the tubercle bacillus is capable of producing in pigs more severe and more widely disseminated tuberculosis than either of the other two types of the organism. Early spread via the blood is an outstanding feature, with the result that miliary lesions are common in the lungs, liver, spleen, and kidneys, with involvement of the bones and joints. While the incidence of the bovine type of infection in pigs has steadily declined as tuberculosis is being eliminated from cattle, the incidence of the avian type is still high. Pigs may be infected either from tuberculous poultry or from wild birds. Tuberculosis in pigs caused by the avian type is predominantly a localized disease of the lymph nodes of the alimentary tract. However, the disease may become widely distributed, with involvement of the liver, spleen, lungs, and kidneys.

Hermansson (1939) demonstrated that water in which a meat inspector and workers dealing with tuberculous pigs had washed their hands produced tuberculosis in guinea-pigs in 11 samples out of 16; similar results were obtained with towels. These experiments clearly show that working with meat and organs of tuberculous animals entails a considerable risk both for those engaged in the slaughtering and for those examining the meat, and may explain the frequency of skin tuberculosis in meat inspectors and butchers. Tubercle bacilli are also often spread to clean carcasses by using the same knife as for examining slaughtered animals.

Tuberculosis in Horses

Almost all cases of tuberculosis in the horse are due to the bovine type, and about half of the strains are of reduced

virulence. A few cases of tuberculosis due to the avian type are on record, and one case due to the human type has been described by Griffith (1928a). No accurate figures concerning the incidence of tuberculosis in horses in this country are available. This is mainly due to the fact that horses slaughtered in this country because of old age, general disability, or illness are not examined by the veterinary surgeon or even by the sanitary inspector. Nieberle (1931) stated that in German knackeries between 1904 and 1924 0.14% of the horses were tuberculous. Magnusson (1944) reported that, in Sweden, out of 461,436 slaughtered horses in the years between 1921 and 1942, 433 were tuberculous. Statistics of the incidence of tuberculosis in horses in various countries of Europe show that the disease has been very rare in these animals. The disease is often insidious in its onset and protracted in its course, and may be clinically inapparent for a long time.

The chronicity of equine tuberculosis, the proliferative nature of the lesions with the formation of large tumour-like masses, the non-caseating character, and the difficulty of recovering acid-fast organisms are the main characteristics of tuberculosis in a horse. Equine tuberculosis has something in common with Boeck's sarcoid or sarcoidosis, and may even support the view that Boeck's sarcoid and all related lesions are a form of non-caseating proliferative tuberculosis. It is interesting that the tuberculin test in this highly resistant animal is less reliable than in the case of many cattle or pigs. The organs mostly affected include lungs, liver, spleen, and nasal mucosa. Many other organs have been reported from time to time as being affected in individual cases.

Tuberculosis in the Dog

Tuberculosis in the dog is relatively rare. The available figures are highly selective and mainly based on necropsy material. The incidence of tuberculosis in dogs in Great Britain varies between 4 and 6% (Lovell and White, 1941; Jennings, 1949). The disease is most common between 1 and 5 years of age and relatively rare in old dogs. The animal is equally susceptible to human and bovine strains of tubercle bacilli, but it is much more resistant than man or cattle. From the fact that after the experimental intravenous inoculation of moderate doses (0.001 mg. per lb. (0.0022 mg. per kg.) of body weight) lungs will show lesions while other organs often remain uninvolved, it is evident that the lung in the dog, as in most other animals, offers a good soil for the development of tuberculosis. According to most workers the human type occurs in nearly 70%, and bovine in 30% of cases. It is generally agreed that the dog often acquires tuberculosis from a tuberculous person in the household or in restaurants, hotels, workshops, etc. The organs most often affected are lungs 72%, liver 67%, pleura 49%, kidneys 48%, and peritoneum 32% (Hjärre, 1939). Serous membranes in general appear to be more often involved in the dog than in the cat or any other animal.

Many workers found that in the dog the tuberculin test, whether intradermal or subcutaneous, is of little value in the diagnosis of tuberculosis because the animal develops only a low and irregular degree of allergy.

Tuberculosis in the Cat

Cats have a strong resistance to infection with tubercle bacilli of human and avian type, but are susceptible to the bovine type. Although there are a few records of the human type isolated from cats, it is not possible to say whether mistakes were made during typing. Griffith (1926) considers that cats are sensitive only to the bovine type.

Cobbett (1926) and Kuwabara (1938) found cats resistant to the human type of tubercle bacillus. These workers' results were confirmed by me. I was able to infect a cat with a dose of 0.001 mg. of the bovine type, but failed to infect cats with a dose of 10 mg. of the human type. The incidence of tuberculosis in cats varies between 3.6 and 13%. As in the dog, most of the figures are highly selective and mainly based on necropsy material.

Available evidence indicates that in most instances the infection in cats has its portal of entry by way of the digestive tract. Milk containing bovine tubercle bacilli and consumed by cats is the obvious source of most infections in these animals.

Tuberculin reaction in the form of thermoreaction appears to be more reliable than intradermal reaction.

Tuberculosis in Birds

With the exception of pets such as the parrot and the canary, in which the human tubercle bacillus is sometimes encountered, tuberculosis in birds is caused by the avian type of *Myco. tuberculosis*. Practically all species of domesticated birds and wild birds are susceptible to the avian tubercle bacillus. Tuberculous lesions occur most often in the liver, spleen, intestinal wall, and bone marrow. Other organs, including the central nervous system, may also be affected.

Human beings have a high resistance to the organism of avian tuberculosis, and therefore every alleged case of avian tuberculous infection in man must be established by convincing evidence. Even though true avian tubercle bacilli are obtained from materials of human origin, one should be cautious in assuming that the organism was actually responsible for the morbid progress in which it occurred.

Captive Wild Animals

Griffith (1928b) points out that tuberculosis in warm-blooded animals living in the wild state is unknown, but, on the other hand, it is common in animals kept in zoological gardens and menageries. It is an interesting finding of Griffith (1928b) and Lovell (1930) that the proportion of attenuated strains of tubercle bacilli isolated from these animals is much higher than from human or bovine cases.

The Public Health Aspect

The numerous publications presenting evidence incriminating the bacilli of bovine tuberculosis as a cause of tuberculous infections of human beings need no comment. Pasteurization of the public milk supply is now almost universal, except for some rural populations. It is interesting to know that 72 out of 570 milk samples examined biologically by the Veterinary Investigation Centre, Cambridge, during 1957, contained tubercle bacilli. This need cause no surprise, as Cambridgeshire, the Isle of Ely, and neighbouring counties have a very small percentage of attested cattle. In spite of the great advances in control of tuberculosis in cattle, there will be a constant potential hazard so long as only a few infected animals exist.

The gains made in controlling bovine tuberculosis can be maintained only by recognition of the fact that constant vigilance is necessary. It must be realized that not only a tuberculous animal but also a tuberculous person infected with the bovine type may transmit the infection. There are many records of persons who infected herds of cattle. Magnusson (1941) reported an instance where in a herd of 74 cows that had been free from tuberculosis for seven years 49 reactors suddenly appeared. Infection was traced to a woman milker who had assisted on the farm for a few weeks and was later discovered to be suffering from open pulmonary tuberculosis of the bovine type.

The part played by ruminants other than cattle and horses in spreading infection is less certain, since it is not known how far they are potential sources of danger to man. In all probability the horse, sheep, and goat can be disregarded on account of the relatively slight incidence of the disease.

Dogs and cats, however, which are in such intimate contact with man, may be responsible for the dissemination of infection. The public health aspect of tuberculosis in dogs and cats must receive much closer consideration. We may anticipate that with the progress in eradicating tuberculosis in cattle the disease should automatically become extinct in

cats; but in the dog, on the other hand, the reduction of bovine infection will not influence the incidence of tuberculosis to the same extent. The predominant danger for the dog is the human being with an active pulmonary focus from which tubercle bacilli are disseminated in the sputum. For this reason it is important that, so far as is possible, the type of the bacillus responsible for canine cases should be typed.

Stableforth (1929) reported that in four out of six canine cases of tuberculosis there was a history of human infection. Herlitz (1939), carrying out an investigation on transmission of tuberculosis from dogs and cats to human beings, observed that only 13 out of 65 families who had owned tuberculous dogs were affected with tuberculosis. Evidence that infection had passed from animal to man was adjudged as probable in two cases only. Similar investigations were carried out by Hawthorne *et al.* (1957) in Glasgow. They examined not only animals living with tuberculous patients but also human beings living among tuberculous animals. They found nine significant cases of tuberculosis in 14 families living in contact with tuberculous dogs. The dogs and cats owned by 37 patients with active tuberculosis were examined for the isolation of *Myco. tuberculosis*. It was recovered from the alimentary tracts of two dogs and two cats.

In addition to these two large-scale investigations there are several small ones of sporadic cases of transmission of the disease from dogs or cats to man. Urwitz (1949) described five cases of tuberculosis in human beings all infected by one dog; De Kock and Le Roux (1956) recorded one case of tuberculosis contracted from a dog. Lewis-Jonsson (1946) described tuberculosis in a 3-year-old boy who was bitten on the forearm by a tuberculous cat. The wound started to heal, but after 23 days sores developed at one site of the bite. Further examination of the child revealed miliary tuberculosis in the lungs, and he died three and a half months after receiving the bite. These observations seem to indicate that tuberculosis in household animals must be regarded as a possible source of danger, and much more energy should be displayed in attempting to eliminate these cases and drawing attention to the risk of the dissemination of infection by dogs and cats. Unfortunately, at present very little can be done in preventing the spread of tuberculosis from the small animals to man. The following example illustrates the difficulty.

A cat was brought to the veterinary hospital for examination. On examination it showed the clinical picture of tuberculosis, confirmed by a strong positive tuberculin reaction. The owner of the cat was a mother of two children aged 2 and 6, and she was warned about the danger of having the animal in the house. She refused to allow the cat to be destroyed, and it was therefore handed back to her. This situation often occurs, particularly when the animal is a special pet of the family, and legally nothing can be done.

At present the control and prevention of animal diseases, so far as it affects the animal population, is vested in the Ministry of Agriculture and is under the direction of Government veterinary officers. But all questions referring to animal diseases in relation to human health are dealt with by the Ministry of Health in England and Wales and by the Department of Health for Scotland through local authorities. Neither of these health departments employs a veterinarian as an adviser on veterinary matters affecting public health in Great Britain, as is done in many countries on the Continent and in the United States. More and more stress is being placed on animal production; consequently as the density of the animal population increases the incidence of diseases transmissible from animals to man increases also. Therefore the medical and veterinary professions should work hand in hand.

However, let us hope and believe that tuberculosis in animals and man in this country will be reduced to a disease of minor importance, or perhaps to a disease of the past, such as pleuropneumonia in cattle and plague in man.

Perhaps I may fairly sum up by pointing to improvement of living conditions of man and animals as the most

CLINICAL COMPARISON OF METHY- PRYLONE AND QUINALBARBITONE AS HYPNOTICS

SEQUENTIAL ANALYSIS USED

BY

THOMAS J. THOMSON, M.B., F.R.F.P.S., M.R.C.P.

From the Materia Medica Department, Glasgow University,
and the Medical Wards, Stobhill General Hospital, Glasgow

Methypylone ("noludar"; 2,4-dioxo-3,3-diethyl-5-methyl-piperidine) is a non-barbiturate hypnotic. Stewart (1956) reported that in a dose of 200 mg. it had a hypnotic effect comparable to 100 mg. of either amylobarbitone sodium or butobarbitone. Lasagna (1956) found that 250 mg. of methypylone produced results "essentially indistinguishable" from those of 100 mg. of pentobarbitone or 100 mg. of quinalbarbitone.

The purpose of the present investigation was to compare the hypnotic effects of methypylone and standard doses of quinalbarbitone; ascorbic acid was used as a control.

Method

The patients were in general medical wards and presented a wide variety of diagnoses; there were 92 men and 36 women, and their ages ranged from 24 to 74 years. Only those who required hypnotic drugs were included in the trials. All other sedatives were withdrawn during the period of observation. The plan was similar in each of the four clinical trials. The two drugs to be compared were dispensed as white powders of similar bulk, labelled A or B, their content being unknown to patient, nurse, or clinician.

The Table lists the contents of the powders used in the four trials. If powder A was given on the first night, powder B was ordered on the second, and vice versa. To

Content of Powders A and B in the Trials

Trial No.	A	B
1	200 mg. ascorbic acid	200 mg. methypylone
2	400 " " methypylone	400 " " ascorbic acid
3	400 " " "	200 " " quinalbarbitone + 200 mg. ascorbic acid
4	400 " " "	100 mg. quinalbarbitone + 300 mg. ascorbic acid

avoid bias, the order of giving powder A or B on the first of the two test nights was decided by random selection; after mixing 20 labels marked A and 20 of B, the order in which they were then drawn from a box was listed, and this determined the order of administration. When it was found during a trial that more than 40 patients were required to complete the study (51 in trial 1 and 67 in trial 3), a further list of 40 was compiled by the same method of random selection. The appropriate powder was given with a small draught of water at 10 p.m. Each patient was informed that he was receiving "a sleeping powder"; he was not told that a comparative study was in progress. The nurse was asked to observe the patient during the night and record her opinion of the soundness of sleep in the following terms: "good," "intermediate," or "poor." In the morning after the second hypnotic I asked each patient, "On which of the two nights did you have the better sleep?" Care was taken to use the same form of words, with the deliberate intention of eliciting a comparison.

The results were examined statistically by the method of sequential analysis as described by Bross (1952), and the original paper should be consulted for a detailed explanation of the statistical significance of this sequential plan. The outstanding feature of this method is that observations are charted as soon as they become available. Looking at

Fig. 1 as an example, only a stated preference between A and B is plotted as X; if a patient states that there is "no difference" between the treatments, no entry is made on the chart. If the patient states a preference for A, a mark X is placed in the square to the right of the last entry on the chart; if the preference is for B, the mark is placed in the square above the last entry. When the path of these symbols travels "north" and emerges from the boxed area, "B treatment" is superior; if beyond the "eastern" barrier, "A treatment" is superior. If the data as plotted fall into the zone between the two boxed areas, this denotes "no important difference between treatments." The clinical trial—to compare A and B—ends when the X path crosses any boundary of the boxed areas.

Results

The results are shown in Figs. 1-4, which should be read in conjunction with the Table. The first trial demonstrated no important difference between 200 mg. of methypylone

FIG. 1.—Sequential plan in trial 1, showing no important difference between the "treatments."

FIG. 2.—Trial 2, in which "A treatment" was superior to "B treatment."

FIG. 3.—Trial 3, showing 200 mg. of quinalbarbitone to be superior to 400 mg. of methypylone.

FIG. 4.—Trial 4, in which there was no important difference between 100 mg. of quinalbarbitone and 400 mg. of methypylone.

and 200 mg. of ascorbic acid as hypnotics. To reach this conclusion 51 patients were studied, of whom 24 stated there was "no difference" between the drugs. The second trial (Fig. 2) showed that 400 mg. of methypylone was superior as a hypnotic to 400 mg. of ascorbic acid. This superior study required only 12 patients, as 8 stated a preference for powder A, and 4 "no difference" results were obtained. Trials 3 and 4 were planned to allow a comparison to be made of the hypnotic effect of 400 mg. of methypylone with the hypnotic effect of quinalbarbitone in the commonly prescribed doses of 100 or 200 mg. The results (Fig. 3) indicated that 200 mg. of quinalbarbitone was superior to 400 mg. of methypylone; the "eastern" boundary was crossed after 37 preferences and there were 30 "no difference" results. When the hypnotic effect of 400 mg. of methypylone was compared with that of 100 mg. of quinalbarbitone, no important difference was found; this trial required 40 patients, 16 of whom found "no difference" between the drugs.

Discussion

There are many factors which can be considered while comparing the therapeutic value of two hypnotic drugs. The present trials have not sought to define the time of onset of hypnotic action, or its duration, the presence of disturbing dreams, or toxic effects. In this study, only the patient's judgment of the quality of sleep after different hypnotics has been used. It is interesting to note, however, that the data obtained during these clinical trials also permit of some comment on the degree of correlation existing between a clinician's assessment and that of the nurse. When the preferences for the sequential analysis were based on the nurses' considered opinions, the paths travelled in the same directions as in Figs. 1-4, but more slowly. The latter was due to the greater number of "no difference" results offered by the nurses.

Summary

The hypnotic effect of methypylone (noludar) has been compared with the hypnotic effect of quinalbarbitone, using the double-blind technique. Powders of ascorbic acid were used as a control. The results were assessed by sequential analysis.

No important difference could be detected between the apparent hypnotic action of 200 mg. of methypylone and the control powder. When the hypnotic effects of 400 mg. of methypylone and 100 mg. of quinalbarbitone were compared no important difference was discovered.

RATIONALE OF ANTIHISTAMINIC THERAPY IN THERMAL INJURY AN EXPERIMENTAL EVALUATION IN THE GUINEA-PIG

BY

D. L. WILHELM, M.D., Ph.D.

AND

BRENDA MASON, B.Sc.

Lister Institute of Preventive Medicine, London

Clinical trials with antihistamines in the early treatment of burns suggest that these drugs, applied locally or given orally, are useful in combating pain, blistering, oedema, and infection, and consequently in accelerating healing (see correspondence in the *British Medical Journal*, cited by Sevtitt, Bull, Cruickshank, Jackson, and Lowbury, 1952). This clinical finding is consistent with Lewis's (1927) observation that the triple response elicited by pricking histamine into human skin is also induced by thermal injury, and with the fact that histamine is readily released *in vitro* by heat from the skin of various species of animal (Rosenthal and Minard, 1939). However, in human volunteers given an oral antihistamine immediately after experimental burns were made, Sevtitt *et al.* (1952) could not confirm the clinical findings; and the increased vascular permeability induced by high-temperature burns in rabbits (Weeks and Gunnar, 1949) and by thermal injury in anaesthetized guinea-pigs (Sevtitt, 1949) is not antagonized by high doses of antihistamines. Evidence of this kind from the rabbit and guinea-pig must be given

considerable weight because in each animal histamine has the same high order of permeability-increasing potency as it has in man (Miles and Wilhelm, 1958a).

In re-examining the possible role of histamine in thermal injury, we investigated the response in guinea-pig skin to a minimal injury that consistently induced a substantial increase of vascular permeability. A minimal injury avoids two factors that possibly complicated the interpretation of the work of Weeks and Gunnar (1949) and of Seivitt (1949): firstly, the pharmacological picture is less likely to be complicated by non-specific breakdown products that almost certainly appear after high-temperature injury; and, secondly, since the stimulus is not painful, it permits the investigation to be made in unanaesthetized animals, thus avoiding the depression which anaesthesia induces in the permeability response of the peripheral vessels (Miles and Miles, 1952).

After establishing the maximal tolerable stimulus first on ourselves and then on guinea-pigs, thermal injury was induced by applying a copper disk, 9 mm. in diameter, maintained at a temperature of 54° C. by flowing water at a constant temperature, to the depilated skin of the back of the trunk of guinea-pigs for periods up to 30 seconds. This degree of heat stimulus is so mild that it can be applied to completely unrestrained animals without their moving away from the disk. The animals, 650–750 g., were previously given intravenous pontamine blue, 50 mg./kg. Such animals are referred to as "blued." Increased vascular permeability at the heated sites, indicated by the local exudation of the blue dye, was graded $\pm$, $+$, $++$, $+++$, up to $++++$; $\pm$ represents the faintest trace, and $++++$ an intense dark blue.

We found at heated skin sites two distinct permeability responses: an immediate response, best elicited by five seconds' heating, which appears in less than one minute, and is almost certainly mediated by liberated histamine; and a delayed response, which appears one hour after 20 seconds' heating and which is apparently not induced by histamine, or in any way dependent on the magnitude of the immediate response to liberated histamine which precedes it.

The Immediate Response

Skin sites heated at 54° C. for five seconds become erythematous in 30–40 seconds, and blue after a further 5–10 seconds; the blueing is maximal ($++$ to $+++$) in five minutes (Fig. 1). Tested by the technique of Miles and Wilhelm (1952), the permeability of the blood vessels in the heated skin returns to its normal low level in 10 minutes (Fig. 2, A). The heated skin neither blisters nor becomes necrotic.

This immediate response is highly susceptible to anti-histamines previously injected locally into the skin or given intravenously. In our hands the preferred antihistamine in guinea-pigs (Mason and Wilhelm, to be published) is triprolidine ("actidil," see Green, 1953). The prior intracutaneous injection of 2 μ g. of triprolidine base in 0.1 ml. of saline into the test site consistently decreases responses of $++$ to $++++$ to less than $\pm$, and even 0.02 μ g. has a substantial effect (Fig. 1). However, the application immediately after heating of lint squares soaked in a 1% solution of triprolidine does not affect the response. Thermal lesions were also compared in the same animal before and after the intravenous injection of triprolidine. Intravenous triprolidine antagonized the immediate response even more effectively than intracutaneous; doses of 100 μ g./kg. decreased responses of $++$ to $+++$ to less than $\pm$, and of as little as 10 μ g./kg. to $\pm$ (Fig. 1).

In unblued guinea-pigs, slight oedema of the heated skin corresponded in onset and development with local blueing in blued animals, and had the same susceptibility as local blueing to intravenous triprolidine. Erythema, however, was not affected by triprolidine.

Eight other antihistamines, in intravenous doses of 1 mg./kg., each substantially antagonized the immediate response in blued animals; but in doses of 0.1 mg./kg. they decreased the response in the following descending order of potency: triprolidine, mepyramine, chlorpheniramine, triphenylamine, promethazine, diphenhydramine, chlorcyclizine, thenalidine, and antazoline, the last two having only a slight effect. These drugs are effective in practically the same order as inhibitors of the permeability increase induced by intracutaneous histamine and by the histamine-liberator 48/80.

FIG. 1.—Maturation of the immediate permeability effect in the blued guinea-pig during the 30 minutes following a mild heat stimulus to the skin (A); and the influence of prior treatment with the antihistamine triprolidine, 0.02 μ g. (B) and 2 μ g. (C) intracutaneously, and 10 μ g./kg. (D) and 100 μ g./kg. (E) intravenously.

FIG. 2.—The diphasic nature of the permeability effect of a moderate heat stimulus in the skin of the guinea-pig.

The high susceptibility of the immediate response to small doses of antihistamines suggests that only small amounts of histamine are liberated. This is supported by the low histamine content that we found in intercellular perfusates (Miles and Wilhelm, 1958b) from skin strips, 10 by 30 mm., which had been heated *in vivo* (0.015–0.03 μ g. of histamine per heated strip, compared with <0.007 μ g. per control strip). Furthermore, when finely chopped and washed skin from normal animals was heated in Locke's solution at 54° C. for five seconds to five minutes, the Locke's solution contained only 1–5% of the histamine liberated by heating at 95–100° C. for five minutes (cf. Rosenthal, Samet, Winzler, and Shkolnik, 1957). Skin, in pieces 5 by 5 mm., heated at 98° C. for five minutes yielded only 20% of its

histamine (cf. Rosenthal *et al.*, 1957). All the liberatable histamine was, in fact, released at this temperature, because when this heated skin was finely chopped the remaining 80% readily leached into the suspending fluid.

The Delayed Response

Sevitt (1958) records that, in anaesthetized guinea-pigs, heating at 60° C. for 10 seconds induces substantial local oedema maximal eight hours after injury. We induced a similar delayed response in our unanaesthetized animals by heating for 20 seconds at 54° C. The immediate response was now minimal, being represented by only a thin ring of blueing not more than 1 mm. wide at the periphery of the heated site; and, like that to 54° C. for five seconds, it was abolished by prior antihistamine treatment. However, after a half to one hour, additional blueing appeared within the peripheral ring of colour, and the entire lesion became evenly blued ($++$ to $+++$) during the next two to three hours. This delayed response is illustrated by the experiment recorded in Fig. 2, B, in which intravenous dye was given to animals bearing lesions from one minute to 30 hours old.

In anaesthetized animals, heating at 58° C. for 10–20 seconds hastened the development of the delayed response; but, even so, central blueing did not appear until the lesions were 5–10 minutes old, and took 60–90 minutes to mature.

We were unable to identify the permeability factor mediating the delayed response. Intravenous triprolidine, 0.1–1 mg./kg., given before or during the development of the lesions, did not affect the response; and inhibitors of the globulin permeability factor in guinea-pig serum and the tissue fluid of the skin (Miles and Wilhelm, 1955, 1958b; Wilhelm, Miles, and Mackay, 1955) were also ineffective.

The serum-globulin permeability factor in the guinea-pig, as well as in other species, including man (Mill, Elder, Miles, and Wilhelm, 1958), is a protease that is highly susceptible to soya bean trypsin inhibitor (S.B.T.I.) and to the esterase inhibitor di-isopropyl fluorophosphonate to the esterase inhibitor di-isopropyl fluorophosphonate (D.F.P.; see Becker, 1958; Miles and Wilhelm, 1958a). Injected locally into the skin, both before and during the development of the delayed response, relatively large doses of S.B.T.I. and of D.F.P. each failed to affect the response. Intravenous S.B.T.I. also was ineffective; and, contrary to Spector and Willoughby's (1958) finding in the rat, intraperitoneal D.F.P. in our guinea-pigs induced only a non-specific depression of the vascular responsiveness. The immediate response was also insensitive to local S.B.T.I. and D.F.P.

Summary and Conclusions

Mild heat treatment of the skin of the guinea-pig is followed by an immediate and short-lived increase in vascular permeability, which is mediated by histamine. With moderate heat treatment the immediate response is followed by a delayed and more prolonged response, which, so far as our evidence goes, is mediated neither by histamine nor by other recognized endogenous permeability factors.

If it is justifiable to generalize from the guinea-pig to man, then we expect a substantial liberation of effective histamine only in the very mild burn with no ostensible damage to or rupture of the skin; and little or none in moderate or severe burns, owing to changes in the tissues that either inhibit histamine liberation, restrain the movement of liberated histamine to susceptible blood vessels, or otherwise alter the capacity of the vessels to manifest a permeability effect.

Since the histamine effect lasts only 10 minutes, in any efficient treatment of mild burns by an antihistamine, the drug would have to be applied within a few minutes, either locally in a form capable of rapid pene-

tration of unbroken skin or intravenously. Moreover, since the intensity of the delayed vascular response we observed was not diminished when the early histamine effect was neutralized, the antihistamine would do nothing to inhibit these delayed effects, even supposing the burn were severe enough to induce them.

It is possible, however, that histamine liberated and held in the tissue of more severe burns might later be released to the detriment of surrounding tissues and consequently that prophylactic antihistamine might diminish later deleterious responses to the injury. An *in vivo* experimental proof of such an action in severe burns was beyond the scope of this investigation.

As regards the delayed permeability response, the time relation of which is similar to that induced in the guinea-pig by bacterial infection (Burke and Miles, 1958) and certain bacterial toxins (Elder and Miles, 1957), we have as yet no evidence of the nature of the mediating factor and can offer no rationale for its treatment.

We are indebted to Allen and Hanburys Ltd., London; Ciba Laboratories, Horsham; May and Baker Ltd., Dagenham; Parke, Davis and Co. Ltd., London; Sandoz Products Ltd., London; and the Wellcome Research Laboratories, Beckenham, for supplies of antihistamines; and to the Nuffield Trust for financial help in the prosecution of this work.

Minds Matter: A New Approach to Mental Health is the title of a 62-page booklet published by the Conservative Political Centre on behalf of the "Bow Group." The author, Miss BERYL COOPER, is a 30-year-old Birmingham graduate who is stated to have worked for seven years in the Hospital Service, three of them "as hospital secretary at a teaching hospital in London." After an introductory chapter on the extent of the present problem, Miss Cooper discusses in turn past and present legislation on the care of the mentally ill, the Royal Commission's report, local responsibilities and voluntary sources of help, costs and staffing, the administrative structure, and community services. She ends with a "four-point plan for mental health": (1) Certification to be abolished, with admission to mental hospitals to be voluntary whenever possible and with a procedure as simple as with general hospitals. (2) Most patients to be treated at home so that they do not become cut off from the community. (3) Hostels for milder cases and the old, training-schools for the younger, and more "day" and "night" hospitals to be built. (4) 138 new committees to take over hospital administration now shared between 14 regional boards and 400 management committees, and be financed by five-yearly direct Government grants.

HYPOTHERMIC MYXOEDEMA COMA
THREE CASE REPORTS

BY

DONALD W. MACDONALD, M.B., Ch.B.
Medical Registrar, Victoria Hospital, Blackpool

Hypothermic myxoedema coma is an uncommon condition in which interest has grown recently (Lancet, 1956). Only 15 cases have been reported, and those since 1953. Three further cases are reported, each of interest in itself. Case 1 is the first reported case of hypothermic coma in juvenile myxoedema. Case 2 is the oldest reported case. Case 3 is the second reported case to have survived over three months.

Case 1

A youth aged 19 was admitted to hospital in coma on November 21, 1956. At the age of 12 he developed weakness of his legs, and from that time his walking deteriorated, although he remained mentally alert. During the 12 months before admission he became increasingly lethargic, spending most of his time asleep before the fire. On the day of admission he could not be roused.

On examination he was deeply unconscious. Physically he had the appearance of a boy of 12. His skin was soft, dry, and cold; his lips were thick and a large tongue protruded from his mouth. Axillary and pubic hair were present. His genitalia showed normal development. The rectal temperature was 82° F. (27.8° C.); the apex rate 50 a minute; respiratory rate 2 a minute; B.P. 80/60 mm. Hg.

Investigations.—Hb, 98%; W.B.C., 19,000/c.mm., mainly polymorphs; blood cholesterol, 200 mg./100 ml.; serum sodium, 144 mEq/l.; serum potassium, 6.7 mEq/l.; plasma chlorides, 63 mEq/l.; CO₂ combining power, 41 mm./l.; blood sugar, 100 mg./100 ml. E.C.G. twelve hours after admission showed low-voltage complexes in all leads in sinus rhythm at 100/minute. X-ray examination of the chest was negative.

Treatment was begun immediately: (1) Warmth:—He was immersed in a lukewarm bath until the rectal temperature rose to 89° F. (31.7° C.), and then nursed between electric blankets until his temperature reached 95° F. (35° C.), eight hours after admission. He was then maintained at this level by intermittent heating from the electric blankets. (2) L-thyroxine sodium, 0.02 mg. four-hourly, was given sublingually. (3) Cortisone:—100 mg. of hydrocortisone hemisuccinate was given intravenously over the first 12 hours, then 50 mg. of cortisone acetate intramuscularly six-hourly. (4) Penicillin, 500,000 units, was given twice daily.

Twelve hours after admission the pulse rate rose to 100, respirations to 10, and the B.P. to 110/70. Three hours later he regained consciousness and asked for a cup of tea. His voice was deep and his speech slow. He knew who he was and took an interest in his surroundings. Twenty-eight hours after admission he had an epileptiform fit and became comatose. Respiration ceased, and was maintained by intermittent positive-pressure inflation through a cuffed endotracheal tube via a tracheotomy. He died 78 hours after admission.

Post-mortem Findings

External appearances:—The body was that of an adolescent male with thick lips, low receding forehead, and slanting eyes; there was also a recent tracheotomy wound. In some places the tissues were gelatinous. **Central nervous system:**—The brain weighed 1,280 g.; no significant abnormality was seen. **Trachea and lungs:**—The right lung weighed 280 g. and the left 270 g.; both pleural spaces contained large quantities of straw-coloured fluid; both lungs were congested. **Cardiovascular system:**—The heart weighed 240 g.; the pericardium contained straw-coloured fluid; no significant abnormality was found. **Alimentary**

tract:—The liver weighed 880 g.; no significant abnormality was found in the tract. **Urogenitals:**—The kidneys together weighed 250 g. **Reticulo-endothelial system:**—The spleen weighed 100 g. and showed no significant abnormality. **Endocrine system:**—The adrenals were normal in size and appearance; the testes were in the scrotum and showed no significant abnormality; the thyroid was small and rather firm, probably fibrous; the pituitary was not examined as the sella turcica was removed intact.

Histology.—The thyroid gland was dissected off the trachea and found to weigh 27 g. Histological examination revealed that its weight was in fact considerably less, as much of the tissue weighed was voluntary muscle. This muscle contained localized areas of pale homogenous fibres whose appearance suggested focal degeneration or necrosis. Such thyroid tissue as there was looked fairly normal, although there was definitely some increase in the inter-acinar fibrous tissue. There was a fibrin thrombus in one thyroid artery. In the testis there was no active spermatogenesis. The Leydig cells were very scanty indeed and did not stain characteristically. The pituitary was normal in size and histological appearance.

Case 2

A widow aged 80 was admitted to hospital on November 26, 1957, with a fractured neck of femur. Before operation her condition was good; pulse 60, B.P. 130/70, temperature 97° F. (36.1° C.). Smith-Petersen nailing was carried out under general anaesthesia. Post-operatively she became cold and cyanosed, with a systolic B.P. of 95 mm. Hg. Plasma was given intravenously. Later she lapsed into coma with a pulse rate of 50, respirations 4, and a temperature reported as subnormal.

In retrospect it was realized that this was a case of myxoedema. Further information obtained from her brother showed that for three years she had become increasingly tired, sleeping most of the day and night. Her voice was gruff.

Examination now showed her to be deeply unconscious, with a rectal temperature of 91° F. (32.8° C.). Her skin was dry and coarse, her hair and eyebrows were scanty. No other abnormality was detected. Treatment was commenced: (1) warmth by a bed cradle, the patient protected by a blanket; (2) L-thyroxine sodium, 0.05 mg. sublingually four-hourly; (3) cortisone acetate, 50 mg. intramuscularly four-hourly; (4) penicillin, 500,000 units twice daily.

The patient died within 12 hours without regaining consciousness.

Investigations.—Hb, 60%; W.B.C. 2,600/c.mm., 65% neutrophils; serum cholesterol, 280 mg./100 ml. E.C.G. low-voltage complexes in sinus rhythm at 45/minute.

Post-mortem Findings

The body was that of an obese woman aged about 80 and 5 ft. 3 in. (160 cm.) in height. Rigor mortis was present. An old, sound surgical scar was present in the right inguinal region and a fresh surgical incision over the left hip. There was bruising of the right shoulder, right cheek, and right forehead. The skull was not injured. The brain showed no significant abnormality apart from one or two minor localized subarachnoid haemorrhages. The pituitary was small but of normal appearance. The mouth, tongue, larynx, oesophagus, and trachea were healthy. The thyroid gland was small, pale, firm, and fibrous. The lungs were oedematous and there was bilateral basal bronchopneumonia. The heart was dilated. The myocardium was flabby. There was some coronary atherosclerosis but little in the aorta.

The stomach was empty. The bowel was healthy, although the proximal part of the colon was dilated. The liver showed a minor degree of passive venous congestion. The spleen was of normal size but soft. The kidneys were healthy, as was the bladder. The uterus had a fundal fibroid. The pancreas and adrenals appeared normal. The adrenal glands together weighed 13 g. Histological examination showed no significant abnormality in the adrenal glands or in the ovary, breast, and pituitary. The thyroid

gland, which weighed 17 g., was pale, firm, and fibrous. Histological examination showed it to consist almost entirely of fibrous tissue in which there were a few groups of atrophic thyroid acini, each group being infiltrated by lymphocytes. There were a number of large blood vessels in the fibrous tissue, some of which were calcified.

The appearances were those of a primary failure of the thyroid gland and suggestive of a long-standing case of Hashimoto's disease.

Case 3

A spinster aged 79 was admitted to hospital in coma on December 17, 1957. She had remained well until five months before admission, when she became slowly lethargic and intolerant of cold. On the evening of admission she was found comatose in a chair before a warm fire in a well-ventilated room.

On admission she was unconscious, with no response to noxious stimuli. Her skin was smooth and dry, and had a corpse-like coldness. Her body hair was completely absent, and had been from the age of 18. The rectal temperature was 91° F. (32.8° C.), pulse palpable, apex rate 60, systolic B.P. 100 mm. Hg.

Investigations.—Hb, 84%; W.B.C., 10,200, normal differential count; blood cholesterol, 200 mg./100 ml.; serum sodium, 152 mEq/l.; serum potassium, 5.1 mEq/l.; plasma chlorides, 69 mEq/l.; C.S.U., a trace of protein only; liver-function tests, within normal limits; Kahn negative; blood urea, 44 mg./100 ml.; urea clearance, 60% of average normal function. E.C.G. showed low-voltage complexes in all leads.

Treatment was begun immediately: (1) Nursed between blankets, no external heat; (2) L-triiodothyronine, 0.08 mg. intravenously on admission, and 0.02 mg. sublingually four-hourly; (3) cortisone acetate, 50 mg. four-hourly intramuscularly; (4) crystalline penicillin, 500,000 units intramuscularly twice daily.

Twelve hours after admission her temperature had risen to 97° F. (36.1° C.). She spoke occasionally in a slow deep voice. A further 0.08 mg. of triiodothyronine was given intravenously. Thirty-six hours after admission her temperature was 100° F. (37.8° C.) and a few crepitations could be heard at the left base. She was then given cortisone, 50 mg. six-hourly orally. Forty-eight hours after admission she relapsed into coma once more, but recovered 12 hours after receiving a further dose of 0.08 mg. of triiodothyronine intravenously. From that time she made an uneventful recovery, at first on oral L-thyroxine sodium and later thyroid B.P.

Although tests on pituitary function could not be carried out owing to lack of co-operation, the fact that the patient gave a further response to intravenous triiodothyronine after lapsing into coma a second time and that she has remained greatly improved on thyroid alone for three months shows this to be a case of true myxoedema and not hypopituitarism.

Sheehan (1956) states that thyroid given alone has no beneficial effect on the symptoms of hypopituitarism.

Discussion

Hypothermic coma is the natural termination of untreated, uncomplicated myxoedema. Its occurrence has been recognized only within the last five years, although a similar picture presenting in hypopituitarism has been known for longer (Sheehan and Summers, 1952).

In addition to these three cases, 15 cases have been reported to date (Le Marquand, Hausmann, and Hemsted, 1953, 1955; Summers, 1953; Malden, 1955; Reid, 1955; Marshall and McCaughey, 1956; Dyson and Wood, 1956; Anderson and Hausmann, 1956). Of these, only one reported in the series of Malden survived. Karhausen and Zylberszac (1955) described a case without hypothermia.

The rarity of this condition is more apparent than real. Including this series, five series account for 16 patients. Once seen and recognized, the clinical picture is never forgotten. The patient is corpse-like in appearance. Occasional respirations indicate that life is still present. The usual features of myxoedema are present.

Sheehan and Summers (1952), in discussing hypopituitary hypothermic coma, state that a major factor causing the failure to recognize a hypothermic state is that the clinical thermometer records only to 95° F. (35° C.), anything lower being recorded only as subnormal. They emphasize that all patients with subnormal temperatures must have their temperatures measured by a low-reading thermometer. Hypothermic coma has not been reported previously in juvenile myxoedema.

Precipitating Factors.—**Cold:**—The reported cases show a marked seasonal incidence occurring between October and April. **Trauma:**—Case 2 went into coma following the fracture of her femur and the subsequent operative procedures. It is likely that during periods of stress the requirement of thyroid hormone increases like that of the adrenal corticosteroids.

Treatment

The condition is due directly to lack of thyroid hormone. Treatment is to give this. Although this appears simple, 15 of the 17 patients have died.

1. **Thyroid Hormone.**—3:5:3-L-triiodothyronine is the most active thyroid hormone readily available. Dyson and Wood (1956) gave a dose of 1,200 mg. followed by 1,000 mg. 36 hours later. Anderson and Hausmann (1956) described a case given 50 mg. in which anginal pain and cardiac failure developed. Both patients died. Goolden and Burrell (1957) suggest that 10 mg. 12-hourly be used initially. The third patient in this series received approximately 80 mg. of L-triiodothyronine intravenously per 24 hours. This produced a clinical response without untoward effects in a patient aged 79. It is suggested that thyroid hormone acts as a metabolic catalyst at cellular level. As such it would be less effective at low temperature. Hypothyroid patients with low temperatures probably tolerate thyroid hormone better than those at normal body temperature, the tolerance increasing with the degree of body hypothermia. If this is true, as I believe it is, then one should give an amount of triiodothyronine proportionate to the degree of hypothermia, reducing the amount as the body temperature rises to normal, then slowly increasing to the optimum dosage. A suggested scheme would be to give 100 mg. 12-hourly until the body temperature begins to rise, then reduce to 50 mg. 12-hourly or lower, depending on response of temperature and pulse rate. Maintenance dosage could then be worked up gradually when the patient is able to take the triiodothyronine orally.

2. **Rewarming.**—This can be done by immersion in warm water, by nursing between blankets, or by heat cradle. Care must be taken to avoid cutaneous vasodilatation. Rewarming is illogical and probably dangerous. Hypothermia is only a symptom of the disease state and will improve as the latter responds to treatment. Administered thyroid hormone will produce warmth that is diffuse, gradual, and physiological. No external heat was applied to the third patient in this series, who survived.

3. Intravenous fluids should be restricted on three accounts: (1) the danger of myxoedema heart failure; (2) the occurrence of acute tubular necrosis has been demonstrated secondary to hypothermic muscle damage (Marshall and McCaughey, 1956); and (3) the physiological requirement of fluid is small, as fluid loss is reduced and metabolic need low. Our successful case was given no intravenous fluid.

4. Antibiotic cover must be given.

Two further cases of severe myxoedema with marked hypothermia have come under our care. They have not been included in this series, as coma and death occurred rapidly before treatment could be initiated. In the case which came to necropsy no cause of death other than myxoedema was found. This suggests that hypothermia is an indication to start treatment immediately even when coma does not appear imminent.

Summary

Hypothermic myxoedema is an uncommon condition with a high mortality rate, recognized only in the last

five years. Three further cases are presented; one is the first reported case of coma in juvenile myxoedema, another the second case reported to have survived. This patient is still alive nine months after starting treatment.

The treatment is reviewed and discussed. It is suggested that hypothermia in itself is an indication for immediate treatment, that the application of external warmth is unwarranted, and that thyroid hormone be given in a dosage related to the degree of hypothermia.

I wish to express my appreciation of the valuable assistance given by Dr. Peter Harvey, consultant pathologist, who carried out the post-mortem examinations and microhistology. I am indebted to Dr. P. R. Duncan and Dr. I. McD. G. Stewart, consultant physicians, and to Mr. J. K. Wright, consultant orthopaedic surgeon, for permission to report the cases under their care.

Note.—Since this paper was accepted for publication a further case of myxoedema coma has been reported by S. J. Surtees and S. Ginsberg, *Postgrad. med. J.*, 1958, **36**, 443. Their patient was resuscitated but died of cardiac failure a month later.

Medical Memorandum

Bilateral Polycystic Disease of Kidney Complicated by Intestinal Obstruction

The following case of bilateral polycystic disease of the kidney developed acute large-gut obstruction two days after admission to hospital. The case is reported because of the development of this unusual complication.

CASE REPORT

A Sea Dyak woman aged 38 was admitted to a small out-station hospital in Sarawak, British Borneo, on July 1, 1957, 17 days after delivery of a stillborn child. She complained of cough with white sputum since delivery and frequency of micturition for two days, urine being voided a countless number of times day and night. For the 24 hours prior to admission she complained of a dull aching pain in the left lower chest, left hypochondrium, and left loin, worse on coughing, and a colicky pain in the left loin. She had haematuria for 24 hours, blood occurring throughout the stream.

On admission she was very ill and toxic, with a temperature of 103° F. (39.4° C.), and pulse 112. There was a hard fixed tender mass with an irregular surface in the left loin extending downwards below the level of the umbilicus. The right kidney was palpable, with a soft smooth mass about the size of an orange comprising the lower pole. Air entry was reduced at the left lung base, and there were fine inspiratory and expiratory rales. Blood: Hb, 45% (Sahli); red cells, 2,600,000; white cells, 8,800 (polymorphs 70%, lymphocytes 28%, eosinophils 1%, large monocytes 1%); E.S.R., 137, Westergren. Urine: acid, albumin ++, over 100 red cells per high-power field. Blood urea was 70 mg. per 100 ml.

A clinical diagnosis of bilateral polycystic kidneys with infection of the left kidney was made. Unfortunately further investigation could not be carried out in a small out-station hospital with limited laboratory and no x-ray facilities.

Procaine penicillin, 500,000 units twice daily, and streptomycin, 0.5 g. twice daily, brought little change in her general condition. Two days after admission she complained of generalized colicky abdominal pain. She had passed a very small stool that morning and no flatus all day.

There was moderate distension of the lower abdomen, most pronounced in the right iliac fossa, with marked visible peristalsis. An enema gave a very poor result.

Operation.—The abdomen was explored through a McBurney incision. The lower ileum, caecum, and ascending and transverse colon were greatly distended. The descending and pelvic colon were collapsed. Through the upper part of the wound the lower pole of the right kidney was seen to be covered with cysts up to 1 in. (2.5 cm.) in diameter, varying from blue to brown in colour. The whole right kidney was felt to be involved. The left kidney was greatly enlarged. Details were obliterated by pericapsular oedema. A caecostomy was performed and a Paul tube inserted.

Post-operatively the patient was put on daily washouts through the caecostomy and was given sulphaguanidine to prepare her for any further operative intervention required.

After operation the pains in her left lower chest, left hypochondrium, and left loin started to subside, and had disappeared by July 6, the third post-operative day. The left kidney was correspondingly smaller, softer, and no longer tender. From admission to operation her temperature had shown daily variations between 103 and 99° F. (39.4 and 37.2° C.). It fell rapidly after operation, and she was apyrexial on July 7. On July 8 the Paul tube fell out and she opened her bowels. She continued to have a normal daily motion until discharge from hospital.

On July 12 the caecostomy was separated from the abdominal parietes and closed. Appendicectomy was carried out to avoid future confusion. The abdomen was closed in layers.

She was discharged from hospital on August 2 feeling very well, having refused further investigation and treatment at a larger hospital. Four months after operation she remained well and symptom-free.

COMMENT

Cleland (1951) reported that Dr. W. A. Giles removed a polycystic kidney (side not stated) causing intestinal obstruction in 1905. No other reference to this complication was found in the literature.

The development of acute intestinal obstruction in this patient gave rise to some diagnostic confusion, occurring as it did in a small out-station hospital where diagnosis mainly rests on history and physical examination. It caused a primary inflammatory lesion of the large bowel to be considered as an alternative diagnosis. In view of the limited surgical facilities available, the formation of a caecostomy was decided upon as the simplest way of relieving the obstruction. The decision was not regretted in view of the beneficial effect it had on the course of the illness.

A possible explanation of the clinical picture described is that ulceration of the splenic flexure occurred secondary to infection of the adjacent polycystic kidney. The passage of faeces over the ulcer perpetuated the renal infection and the colon became obstructed by inflammatory oedema. The renal infection and ulceration of the colon resolved rapidly when the colon was defunctioned by caecostomy.

The case reported does not bear out the statement of Duff (1948) that infection of a polycystic kidney affects the prognosis adversely, at any rate so far as the immediate prognosis is concerned. It is possible that the prognosis in this case may be favourably affected by a diet mainly consisting of rice with little added protein.

I wish to thank the Director of Medical Services, Sarawak, for permission to publish.

P. W. BEDFORD, M.B., Ch.B., B.Sc.,
Medical Officer, Simanggang Government Hospital, Sarawak.

Reviews

CANCER

Cancer. Edited by Ronald W. Raven, O.B.E. (Mil.), T.D., F.R.C.S. (Vol. 1—pp. 539+19+x; Vol. 2—pp. 641+24+ix; Vol. 3—pp. 483+18+viii; illustrated. 85s. each volume.) London: Butterworth and Co. (Publishers), Ltd. 1957-8.

The publication of this systematic work on cancer was expected with interest, and the first three volumes which have now appeared are certainly satisfying. The production is all that one could wish; the volumes are of a handy size, the illustrations numerous and apposite, the contributors acknowledged experts, the articles well documented, and the editing careful and efficient. Though all three volumes are of general interest, they will each have their special appeal to different sections of the profession. The first volume will be of great interest to the research worker and biochemist. After a brief chapter on the historical aspects of cancer (by Dr. Bett) there come two articles by the late Sir Ernest Kennaway dealing with the carcinogenic properties of cholesterol and the incubation period of cancer; the latter is a hitherto rather neglected subject. Then follows a chapter on the general question of carcinogenesis and two informative articles on the biochemistry of cell division and its relation to cancer; this section will be invaluable to the research worker, but the uninitiated (such as the reviewer) will have to make their own glossary of initials—for example, D.A.B., A.A.F., D.N.A., 5H.T., and the like. The volume ends with excellent accounts of the relation of viruses, hormones, radiation, and environmental factors to the causation of cancer. A chapter on the genetic control of cancer is also included. The second volume will greatly please the clinician and the morbid anatomist, for it describes with a wealth of illustration the local features of cancer in the different parts of the body. It is a volume to be viewed rather than reviewed.

Volume 3 opens with a thought-stimulating chapter on the immunological aspects of cancer by Professor H. N. Green, who brings evidence to show that "antigenic loss is the *raison d'être* of the cancer cell." The value of comparative pathology is then stressed in a chapter by J. R. M. Innes, who writes on the malignant diseases of domestic animals. The interesting statistical survey by Percy Stocks affords little comfort to those who are fond of cigarette-smoking. There is a section of more than 100 pages on the geography of cancer; both the epidemiologist and the general reader will want to study this. Occupational cancer is nowadays attracting increasing attention, and the hundred pages devoted to this subject are noteworthy; the possible relationship between occupational exposure and leukaemia is well discussed by Ethel Browning. There is a short section on that debatable subject—cancer education. One notes that in the U.S.A. special instruction is given to nurses on the subject of cancer and that a "Cancer Source Book for Nurses" has been distributed gratis to 131,000 nurses and nursing instructors. Volume 3 ends with a short section on some simple methods of value in the diagnosis of cancer; the useful caution is given that when "cytology is used as the only diagnostic aid, false negative reports are very much more serious."

These three excellent volumes whet our appetite for those still to come.

ZACHARY COPE.

LAURENCE-MOON SYNDROME

On Hereditary Digital Anomalies. Part III: *The Laurence-Moon Syndrome*. By Julia Bell, M.A., F.R.C.P. (The Treasury of Human Inheritance, vol. 5.) (Pp. 51-96; illustrated. 20s.) London: Cambridge University Press. 1958.

This full analysis of the literature on the Laurence-Moon syndrome follows the arrangements in the other volumes in the series. The relatively short text of 14 pages is based on 189 papers; the seven plates contain 181 pedigrees, all but

a few being pedigrees of families showing the syndrome. The hard core of the monograph consists of the 26 pages of summaries of the individual papers.

In presenting a critical analysis of the literature, Dr. Julia Bell stresses that adiposity and the ocular defect are the two most constant features, being present in over 90% of cases; mental defect is almost as frequent; the digital anomaly is noted in some 70% of cases, and genital hypoplasia in just over 50%. This latter she regards as an understatement—a view supported by the fact that the incidence recorded for females is considerably lower than that recorded for males. The expectation of life for patients with this syndrome appears to be rather low, whilst the incidence of stillbirths and deaths early in life is probably high. Dr. Bell holds that the syndrome may be even more extensive than is suggested by its bizarre component—malformations of the urogenital tract in particular may be common—and stresses the need for examination of stillborn sibs of affected individuals, especially as post-mortem examinations of patients with the syndrome have so far given only sparse results.

A clarification of the pathology of the syndrome would help in two other directions. On the one hand it has been questioned whether the syndrome is not itself a mixture of two distinct affections—one being the syndrome as usually understood and the other an allied condition with neurological components—the findings apparently present in the original cases recorded by Laurence and Moon and subsequently by Jonathan Hutchinson. On the other hand the status of allied syndromes, such as the cases recorded by Biemond, by Kapuscinski, by Refsum, and by others, also requires definition. It is clear that this recessive affection with its exceptionally high rate of consanguinity—somewhere between 25 and 40%—is not polygenic but pleiotropic in type, but the limits of this pleiotropism are by no means clear. Dr. Bell's review should help matters forward, but it is rather puzzling why this study should appear as part of the volume on hereditary digital anomalies.

ARNOLD SORSBY.

HYPNOTIC PAINTING IN TREATMENT

Hypnography: A Study in the Therapeutic Use of Hypnotic Painting. By Ainslie Meares, M.B., B.S., B.Agr.Sc., D.P.M. (Pp. 271+viii; illustrated. 58s. 6d.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1957.

In the 4,000 years over which the vast literature on hypnosis extends it has included contributions which have in their time materially changed the trend of psychopathological thinking. But this precious metal lies hid beneath a deep layer of dross—mystical, bombastic, repetitive, and burdened with the alchemistic speculations inevitably stimulated by an unsolved phenomenon of nature, as hypnosis still is. Any part of the annual spate of first and last editions on this subject has, therefore, to be scanned with the question well in mind, "Does it add anything to the sum?" A case can be made out for saying that Dr. Meares has made a modest addition to the technique of using hypnosis as a means of exploring the mental mechanisms which underly psychoneurotic breakdown. The author is a practising psychotherapist bent on finding shorter and more economic ways to therapeutic insight than can be attained by orthodox psycho-analysis. From his previous writings it is evident that he combines great technical experience of hypnosis with an interest in the psychodynamic and symbolic meaning of artistic expression. He claims no more than that the uninhibited symbolism of the drawings made in the hypnotic state is as much of a *via regia* to unconscious motive as is the interpretation of dreams, and that in this condition the patient's distortions and defences are less in evidence. His material, consisting of five chronic psychoneurotic patients with evident constitutional loading, is small, and the subsequent fate of these is not discussed in detail. The technique, however, including the author's methods of passive and non-authoritarian induction

of hypnosis, is most convincingly described, and the results are reproduced in terms of black-and-white paintings. Description and theory are kept apart, so that the reader need not be biased by the author's interpretations. No excessive claim is made for the method, which is presented simply as a projective medium likely to produce material which might not otherwise come to light for a long time and which serves to signpost the progress of insight therapy. The pictures are less decorative than the symbolic paintings in the author's *The Door to Serenity*, and many of them are uninhibited *graphiti* which would arrest the eye of any zealous customs official—were this not Psychiatry. The emphasis is on the revelation of traumatic experiences in the early manner of Breuer and Freud, and one is tempted to think that Melbourne is not far behind old Vienna in producing exotic material.

The book is as well produced as it should be for the price. The pictures and therapeutic dialogue make easy reading marred only, perhaps, by the quotations of set-book banality which precede each chapter.

ALEXANDER KENNEDY.

POPULAR INTERPRETATION OF MEDICINE

Medicine and Man. The Story of the Art and Science of Healing. By Ritchie Calder, C.B.E. (Pp. 256. 16s.) London: George Allen and Unwin, Ltd. 1958.

Science, growing ever more complex and more highly specialized, has become steadily less intelligible to the average man. Accordingly it is desirable, and even essential, that the message of science should be interpreted and rewritten in popular language. The interpretation of science is not an easy branch of literature, as it demands a combination of qualities possessed by only a few authors. Among them Mr. Ritchie Calder takes a high place. He has already delighted many readers with his *Profile of Science*, his *Science Makes Sense*, and other works, and now he has turned his attention to medicine, the science of humanity.

Medicine no less than science demands interpretation, and it is of great importance that the story should be presented in language as accurate as it is attractive. The present author fulfils all our needs for correct statement. In the compass of 250 pages he has packed an amazing mass of detail regarding the art and science of healing. His book contains 12 chapters, and within them no fewer than 139 smaller sections, each of which might be read in isolation, although it forms part of a coherent and fascinating narrative. Taking a wide survey of time and space, the writer scans the pages of history from the days of demons and demi-gods to those of the World Health Organization, and discusses treatment from "eye of newt and toe of frog" to folic acid and penicillin. Naturally, he employs the historical approach, the most logical basis of modern medicine, but his book does not pretend to be either a history of medicine or a work of reference. It is rather a popular account of medical science and practice as it stands to-day and of the varied sources from which modern medical knowledge has been drawn. As is shown in the early chapters, some of these sources were in unexpected quarters. The witch, the monk, the soldier, the dairymaid, and many other folk remote from medicine as we know it, each contributed a share, albeit unwittingly. The early magico-religious attitude towards sickness and disease, however irrational it may appear to us to-day, at least laid stress upon the importance of the whole man and of the interrelationship of mind and body.

The five central chapters of the book deal with "The Great Advances," and include a wealth of information, classified under interesting subheadings, such as "Brain Waves," "Alice-in-Wonderland Drugs," "Rasputin Stomach," "Emotion Buffer," and "Radio-active Mosquitoes." Medical readers will find here not only much food for thought but also assistance in the solution of that daily problem of what to tell the patient. "Victory over Pain" and "Victory over Germs" are the next subjects of

discussion, the former giving a brief but informative history of anaesthesia, the latter a picture of the antibiotic weapons which have been so effective in the microscopic war of recent years. Unsolved mysteries are mentioned, as are "Jungle Moulds" (chloromycetin), "Butterfly Wings," "Smoking and Cancer," "Stroke," and "Allergies," to quote only a few more titles. The treatise ends with the definition of health as "complete physical, mental and social well-being, and not merely the absence of disease or infirmities," and with a quotation from Descartes: "If there is any possible means of increasing the common wisdom and ability of mankind, it must be sought in medicine."

This new interpretation of medicine and of its spectacular achievement deserves to be read thoughtfully by doctor and patient alike.

DOUGLAS GUTHRIE.

PUERTO RICANS IN NEW YORK

80 Puerto Rican Families in New York City. Health and Disease Studied in Context. By Beatrice Bishop Berle, M.D. (Pp. 331+xii. 38s.) New York: Columbia University Press. London: Oxford University Press. 1958.

As American citizens Puerto Ricans can move freely within the United States, and many of them go to New York for the same reasons as Jamaicans go to Birmingham—in the hope of improving their circumstances. Because in addition to their poverty they face language and other difficulties, their arrival in increasing numbers has created serious problems for the city authorities. Dr. Berle's book reports the results of a study of 80 families for whom she provided medical services. These families were living in slum property, and the greater part of the book is concerned with their social circumstances—education, religion, reasons for immigration, family organization, housing, difficulties of language and communication, and welfare. There is also a brief account of medical conditions encountered in the Puerto Ricans, with proposals for their medical care.

T. McKEOWN.

The principal change in the twelfth edition of *Cunningham's Manual of Practical Anatomy* (London, Oxford University Press. Vol. I: Upper and Lower Limbs, pp. 394, 25s.; Vol. II: Thorax and Abdomen, pp. 492, 28s.; Vol. III: Head and Neck, Brain, pp. 520, 28s.) is the use of English equivalents of the Paris Nomenclature approved in 1955. Some of the more familiar terms of the older Birmingham Revision have, however, been retained pending adoption of the new nomenclature in its entirety. Another change, which will appeal to the student, is the use of a new waterproof binding material which will permit cleaning with soap and water after use in the dissecting-room. In this edition, which has been revised by the late Professor J. C. Brash, a number of the illustrations in use since the first edition have been replaced.

Recent Outbreaks of Infectious Diseases (408 pp.; H. K. Lewis and Co. Ltd., 1957, 35s.) is a well-documented account of epidemics of viral, rickettsial, and bacterial infections which have occurred in Britain in recent years, by S. Left, Medical Officer of Health for Willesden. A general description of each disease, with historical background and clinical features, is included, and space is also given to an outbreak of lead poisoning in Rotherham and the "smog" incident in London in December, 1952.

Absorption Spectrophotometry, by G. F. Lothian (2nd ed., pp. 246; Hilger and Watts Ltd., 52s.), is a concise account of the principles, practical applications, and techniques of absorption spectrophotometry. In this edition more detailed attention is devoted to photoelectric instruments, which have largely displaced photographic and visual methods. An extensive bibliography is included.

The second edition of *Systemic Ophthalmology*, edited by Professor Arnold Sorsby (pp. 701+xiv; Butterworth and Co., Ltd., £5 5s.), has been revised throughout; some new chapters have been added dealing with subjects in which particularly rapid advances have been made. The book, which is of composite authorship, deals with the many conditions in which ocular disease is related to systemic disorders. It is fully illustrated, the coloured plates being especially well reproduced.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY NOVEMBER 8 1958

DRUGS AND LIVER DISEASE

Drugs may adversely affect the liver in several ways—for instance, by causing hepatic necrosis, intrahepatic biliary obstruction, or fatty change in the hepatic cells. In addition the syndrome of hepatic precoma and coma may be caused or aggravated by drugs given to a patient with pre-existing liver disease.

Acute hepatic necrosis, characterized clinically by jaundice, hepatomegaly, and in severe cases hepatic coma, haemorrhagic manifestations, and rapidly deepening jaundice, may be caused by a variety of toxic agents. The chlorinated hydrocarbons such as carbon tetrachloride, benzene, and quinoline derivatives, muscarine, and various metallic compounds are examples of such agents. Drugs used in the treatment of epilepsy—namely, phenytoin sodium¹ and phenacemide ("phenurone")²—have been similarly implicated, and recent reports^{3,4} show that the use of a derivative of isoniazid, iproniazid ("marsilid"), will cause both abnormal liver function tests and jaundice associated with hepatic necrosis in some patients treated with it.⁵ Originally introduced as an anti-tuberculous agent it has more recently been claimed to be of use in the treatment of myocardial ischaemia and as a "psychic energizer." Fatalities from hepatic necrosis have followed its use and that of another nicotinic acid derivative pyrazinamide,⁶ which also limits this drug's value as an antituberculous agent.

The list of drugs causing jaundice by another mechanism—namely, intrahepatic biliary obstruction—is an ever-lengthening one. At present owing to its common usage chlorpromazine ("largactil") is the most important, for jaundice occurs in 1–2% of cases

treated, but other drugs, including arsphenamine, dinitrophenol, methyltestosterone, norethandrolone ("nilevar"), thiouracil, *p*-aminosalicylic acid (P.A.S.), sulphadiazine, and methimazole, may also produce this syndrome. Clinically, after a latent period of up to three weeks, an obstructive type of jaundice with pruritus, pale stools, and dark urine begins. Usually this condition is clinically mild, but severe cases have been reported following arsphenamine and chlorpromazine. Jaundice of seventeen months' duration with skin xanthomata and gross increase of the serum cholesterol has followed arsphenamine. A similar case of 13 months' duration has followed chlorpromazine.⁷ In a recent communication to the Section of Gastroenterology at the British Medical Association's Annual Meeting, Drs. A. E. Read and Sheila Sherlock reported one case where the jaundice following chlorpromazine had lasted over two years. Cases of jaundice and hepatic dysfunction due to promazine have been described indicating that this drug is not without some risk in this respect.^{8,9} Allied to this problem is that of the treatment of the pruritus associated with jaundice caused by drugs. At least two preparations—namely, norethandrolone and methyltestosterone, which are effective in the treatment of pruritus—also can produce intrahepatic obstructive jaundice.

Fatty change in the liver has recently been produced experimentally in baboons by J. Gillman and C. Gilbert by altering the hormonal balance between insulin, thyroxine, and adrenal corticosteroids.¹⁰ It is possible that to the list of toxic properties of steroid drugs must be added that of fatty change in the liver, a point of clinical importance in view of their widespread use.

The syndrome of hepatic precoma and coma is thought to be due to the entry of nitrogenous products absorbed from the bowel into the systemic circulation via abnormal collateral channels bypassing a damaged liver.¹¹ The level of ammonia in the systemic circulation has been widely used as a measure of these toxic products.^{12,13} Certain diuretic drugs have been shown to bring about clinical and neuropsychiatric deterioration when given to patients with chronic liver damage and fluid retention. Ammonium chloride administered to potentiate the action of mercurial diuretics is toxic, presumably owing directly to its content of ammonia. Acetazolamide ("diamox") can also cause neuropsychiatric deterioration,¹⁴ and this has been correlated with failure of peripheral tissues to remove ammonia adequately from the systemic circulation.¹⁵ Chlorothiazide is similarly toxic to patients with chronic disease of the liver, particularly if a good diuretic

response is obtained by its use.¹⁶ As the action of chlorothiazide is in part similar to that of acetazolamide, it would seem reasonable to assume that toxic manifestations appear because of interference at a peripheral site with metabolism of the ammonium ion. Other factors, however, including loss of potassium, may be of importance. It is worth keeping a watch for signs of liver damage when patients receive drugs that have been recently introduced.

OPEN DOORS

There has been a great liberalizing move in British mental hospitals in the past ten years. Many ward doors have been permanently unlocked, leave privileges increased, easier discharges allowed, and great efforts made to provide occupational therapy and work for all. The strait-jacket and the padded room have fallen into disfavour. As each old hospital is converted to the new methods, the same improvements are noted: less restraint, with more consideration of patients as individuals, is followed by fewer escapes, fewer fights, less incontinence, and a smaller bill for barbiturates and other sedatives.¹ Now these methods are beginning to spread on the other side of the Atlantic. The Milbank Memorial Fund of New York last year organized a conference² at which D. Macmillan described the work of Mapperley Hospital, Nottingham, and emphasized how it is possible to run a mental hospital without a single locked door, and virtually without the use of certification. This year the president's address³ at the meeting of the American Psychiatric Association at San Francisco called for the abolition of the enormous old-fashioned state mental hospitals—some have 10,000 beds—and a fresh start along the lines already becoming familiar in Britain.

This is not the first decade in which the gospel of "no restraint" and of "occupation" has been preached⁴; indeed, the story of the mental hospital seems to show a perpetual swing back and forth between periods of harsh restriction and therapeutic freedom.⁵ If the present open-door policy is to be a permanent step forward and not just another pause of the pendulum it will have to be proved to do therapeutic good, so that faith may come to be supported

by works, and it will have to overcome a difficulty of communication. At present it is not always appreciated that "the unlocked door is just a symbol and should not be made a fetish."⁶ Some hospitals are not applying the full prescription: either they do not know it, or they have not full confidence in it. It is not sufficient to unlock the majority of doors and provide more occupational therapy. The essential is a change of outlook in the staff, particularly the nurses, who are sometimes inclined to view the patients simply as naughty children. The open-door programme is a way of inducing them to try understanding instead of punishing, because it makes their work easier, more interesting, and possibly more fruitful. Macmillan himself believes that so long as there remains one locked ward in a hospital the nurse can still threaten the patient with imprisonment, the easy but incomplete solution,⁷ and that it is only when all doors are open that the new relationship between staff and patients can begin.

Another important part of the policy is the emphasis on individuality. Every patient must have clothes which are his own, a bed, a locker, a chair, which are recognizably his and respected as such by the staff, and a social role, such as a particular ward duty, which is recognized as his too.⁸ The job of all the staff, ward orderlies, porters, gardeners, as well as nurses and occupational therapists, is to make friends with individual patients, and so influence them and help to understand them. This is the way that a mental hospital changes from an institution into a therapeutic community. But this is still only half the prescription. The other half is in the hospital's external relations. By domiciliary visits, out-patient clinics, and close contact with general practitioners and with the local health authority, the physicians and social workers of the hospital will often be working with the patient and his relatives even before he first comes into hospital, and should continue an affectionate concern for both patient and family after discharge. Long and careful follow-up care is the corollary of early discharge. This may help the patient to avoid further serious breakdown, but it also serves to educate and reassure the public—and this is the crux of the matter. People are sent into a mental hospital only when they can no longer be tolerated by people outside, and they can be discharged again as soon as their behaviour returns within the tolerable limits. Different societies have different tolerances, and what they will stand can be altered by education, and by new modes of treatment or care which serve as guarantees of their security. The patient for early discharge need not be free of psychotic symptoms and

signs: it is sufficient that his behaviour conform to society's minimum demand. It is not whether he hears voices which is the test, but what he does about them. The success of the open-door policy, therefore, in the long run depends on public tolerance.

TRANSFUSION TREATMENT OF RADIATION DISEASE

During the last decade much experimental work has been done on the treatment and prevention of radiation disease. Protection by chemical means^{1,2} has to be given before exposure in order to be effective, and consequently is of no help in treating either radiation casualties or radiotherapy patients who show an unwanted reaction. The most promising experimental treatment in animals is the injection after exposure of spleen homogenates or bone marrow. The injected cells colonize the irradiated animal and supply it with blood for at least some weeks after exposure. Owing to the temporary destruction of the immune response by irradiation of the whole body, the animals accept grafts from genetically different strains and even from other species. Possible human applications of this treatment have awakened interest, particularly in relation to the treatment of leukaemia, aplastic anaemia, and the possible grafting of a kidney in some forms of uraemia.³

Haemorrhage, thrombocytopenia, anaemia, and agranulocytosis are prominent among the killing effects of acute radiation, and naturally various forms of blood transfusions have been used experimentally in animals to combat their effects. American work has shown that in dogs normal whole blood was of little value^{4,5} unless a massive cross-transfusion was undertaken.⁶ Transfusions of leucocyte concentrates in dogs were considered promising, as the transfused leucocytes were found to migrate to sites of infection.^{7,8} Concentrates of platelets when transfused into irradiated dogs and rats were found to correct defects in haemostasis.^{11,12} This response is of interest because dogs resemble man in being very prone to post-irradiation haemorrhage. A rather different

type of transfusion treatment was found to be successful in mice.^{11,12} A particular type of transplantable carcinoma induces a leukaemoid reaction, and blood taken from mice bearing this tumour was given to irradiated (non-tumour-bearing) mice of the same strain: a single injection was found to give protection. The leukaemoid blood contained very large numbers of mature and much smaller numbers of immature granulocytes, but the single injection contained too few granulocytes to combat infection. The most likely explanation of the beneficial effect was that the leukaemoid blood acted in a similar way to marrow injections and repopulated the damaged haemopoietic tissue by means of the immature cells it contained.¹²

Professor Bagdasarov has recently described Russian experience with transfusion therapy in radiation disease.¹³ Platelet concentrates and leucocyte concentrates with some platelet contamination reduced the death rate in dogs subjected to high doses of x rays and also greatly improved their haematological response. Leucocyte concentrates, again with platelet contamination, were also given to patients with low white-cell counts after radiotherapy. Good results were claimed in 80% of 250 cases, but only 3 were described. In the most striking, a post-irradiation white count was raised from 2,600 per c.mm. to 4,900 per c.mm. by means of five transfusions, even though a second course of radiotherapy was given at the same time.

Transfusion treatment probably acts merely as replacement therapy, but, given the correct conditions, the leucocyte concentrates may possibly act in a similar way to bone-marrow grafts and leukaemoid blood transfusions. Recently experiments have been reported¹⁴ in which normal human blood was incubated *in vitro* with tritium-labelled thymidine, a radioactive precursor of D.N.A. Labelling was seen in a small percentage of large mononuclear cells, which were identified as monocytes or large- and medium-sized lymphocytes. This strongly suggests that in normal blood a few leucocytes are actively synthesizing D.N.A. preparatory to mitosis, and the authors were inclined to regard them as totipotential haemopoietic cells in transit. If this conclusion is correct, leucocyte concentrates could colonize damaged haemopoietic tissue if a large enough dose of whole-body irradiation was given to overcome the immune response. This may have occurred in the case of the heavily irradiated dogs,^{7,8,15} but is most unlikely to have taken place in the patients given radiotherapy,¹³ who, having received irradiation to only part of the body, would retain an intact immune reaction.

SERUM TRANSAMINASE IN MYOCARDIAL
INFARCTION

The important features of serum glutamic oxaloacetic transaminase (S.G.O.T.) in clinical medicine have already been noted in these columns.^{1 2} It is an enzyme which is concerned in the reversible transfer of amino groups, and is therefore present in many tissues, particularly the heart, liver, brain, and kidneys. Damage to these and other tissues results in the liberation of the enzyme into the serum, where it can be estimated by relatively simple biochemical techniques.^{3 4} Care should be taken to avoid haemolysis when obtaining a sample of blood. Interest has centred round the value of S.G.O.T. as a test for myocardial infarction, and there is now enough evidence on which to base an estimate of its place in diagnosis. When an infarct has occurred the level of S.G.O.T. rises quickly during the first day or two and then quickly falls to normal again by about the fifth day. The peak concentration, which may be ten or twenty times the normal level (5-40 units per ml.), is usually reached between 36 and 72 hours after the onset. False negatives—that is, no rise in the presence of a confirmed infarct—are said to occur in 5-10% of cases, but some of these may be due to failure to detect a very transient increase in S.G.O.T. High values, on the other hand, are found in association with liver disease, acute pancreatitis, cerebrovascular accidents, and myocarditis, and after operations, severe trauma, or haemolysis. Neither pericarditis nor pulmonary infarction causes any alteration in S.G.O.T.

The authors of the two papers we publish this week have attempted not only to assess the usefulness of the test but also to define its relation to some of the finer points of diagnosis and prognosis in myocardial infarction. Dr. H. A. Dewar and his colleagues, for example, have found that the rise in S.G.O.T. appears twenty-four hours earlier than fever or a rise in the sedimentation rate. It is a "more prompt, more striking, more brief, more sensitive, and more specific" indication of infarction than either of these signs. Perhaps its greatest value is in patients in whom the electrocardiographic evidence is equivocal because of previous ischaemic episodes or the presence of arrhythmias, bundle-branch block, or the effects of digitalis. Another use is in distinguishing infarction from so-called "acute coronary insufficiency," especially in those already under treatment or with minimal electrocardiographic changes. It may, however, be difficult to decide what to regard as an abnormal level of S.G.O.T. in these patients if single estimations only are done, since it is clear that values within the normal range may not be normal for a particular individual.⁵ For this and other reasons Dr. R. Bruce and his colleagues recommend daily estimations during the first week, not only to follow the course of the acute episode but also to establish a baseline for the individual. They have also tried to base a prognosis on

the peak concentration of S.G.O.T. found in their patients. Thus the average figure in 16 patients who recovered was 111 units, contrasting with a figure of 576 units in the seven who died. Once again such figures may be misleading when applied to the individual patient, for while experimental and clinical data suggest that there is a good correlation between the extent of the infarct and the height of S.G.O.T., many other factors are concerned in the outcome of the illness. Moreover, as Dewar and his colleagues point out, some of the highest titres are found in patients who develop acute heart failure associated with pulmonary oedema or hepatic centrilobular necrosis. Further work on the relation of S.G.O.T. to other factors which affect prognosis may prove rewarding, since the value of the test in the diagnosis of myocardial infarction appears to be firmly established.

HEALTH IN INDUSTRY

The publication of the first separate annual report¹ on industrial health by the Chief Inspector of Factories marks a departure from the long-established practice of presenting all aspects of the work of the factory inspectorate in a single volume. From now onwards these separate annual reports will be the chief source of information in the field of industrial health. While to a great extent this field is within the special sphere of the medical branch of the factory inspectorate, it is also the concern of the general inspectorate and of the other specialist branches, engineering and chemicals. The present report reviews the year's activities, including new legislation, industrial health surveys, advisory panels and committees of inquiry into various subjects, and accounts of certain industrial diseases and accidents. The subject of industrial dermatitis has been selected for a special chapter on its own. The report mentions that the Factories (Ionizing Radiations) Special Regulations, dealing with the use of "sealed sources," are still in draft, having been submitted for comment to representatives of the organizations mainly concerned and to other interested persons. Consideration is now being given to the preparation of regulations for the use of unsealed sources generally. Industrial health surveys were carried out in Halifax² and in the Potteries with a view to obtaining information about environmental conditions, existing medical and nursing services, and the adequacy or otherwise of precautions against general and specific hazards to health. An inquiry into the provisions made for giving first aid revealed some inadequacies, and discussions followed between representatives of various governmental departments and the societies responsible for the recruitment and training of first-aid workers.

Among the industrial diseases on which the report comments, lead poisoning showed a slightly increased incidence, but there were no fatal cases. A relatively new working process, entailing the use of isocyanates, caused an outbreak of acute illness, with asthma as its

outstanding symptom. Industrial dermatitis is still considered one of the principal causes of disability and lost time in industry. Figures recorded by the Ministry of Pensions and National Insurance for 1955-6 showed that the average duration of incapacity was 38 days for males and 51 days for females: the total time lost amounted to 0.86m. days, compared with 0.93m. days for 1954-5. Voluntary notifications to the factory department of the Ministry of Labour and National Service also suggested that the steady decline which has taken place during recent years was continuing. Among the many causes of industrial dermatitis mineral oil holds a prominent place; though this form of dermatitis is not often responsible for absence from work, it carries the risk of epitheliomatous ulceration. The problem presented by skin sensitization is a particularly difficult one, since repeated exposure to skin irritants may result in severe and lasting dermatitis. Once again the importance of thorough cleansing as a preventive measure is emphasized; it is even more important than the use of barrier creams. Separate reviews on selected subjects are to appear in future annual reports, and if they maintain the same high standard as the review on industrial dermatitis in this year's report they should make a valuable contribution to the study of industrial health.

LIVE INFLUENZA VACCINES

In an emergency due to the appearance of a novel and dangerous strain of influenza it would be impossible to manufacture enough conventional vaccine for millions of people in a short time.¹ There simply could not be provided, quickly, enough fertile eggs or egg incubators. In theory an attenuated living virus might be given intranasally in a dilute form and prove far more practicable in that a small number of eggs might provide enormous numbers of vaccine doses. Early attempts to achieve this end were not very promising. Viruses tested either were not sufficiently attenuated or did not produce satisfactory rises in antibody. Workers in the U.S.S.R. have for several years been testing live influenza vaccines, and promising experiments on these lines with the Asian virus grown in tissue culture were lately reported by V. M. Zhdanov² and his colleagues. Small-scale trials in Great Britain have been reported by A. Isaacs and his colleagues,^{3 4} but the results were not very encouraging. However, the matter is being further pursued in this country and there is good contact with Russian workers. Several important questions have to be answered: Will a live vaccine give substantial immunity with a negligible number of untoward reactions? Is there danger of reversion of the attenuated virus to virulence? Can the vaccine be made on a large scale cheaply and rapidly, without the need for a fantastic number of eggs? It can readily be seen that these important questions are not likely to receive quick answers.

COST OF HOSPITAL DEPARTMENTS

Formidable as they are, the hospital costing returns¹ published last week deserve some study, for they claim to be the answer to the criticisms of the old costing returns, which they replaced for some hospitals on April 1, 1957. The old returns raised all sorts of pertinent questions about the comparative costs of apparently comparable hospitals without, however, providing the answers. It was therefore hoped that by means of the new returns, under which the costs would be analysed by departments—wards, works and maintenance, medical service departments, administration, laundry, and so on, each with its own share of a hospital's staff bill—an explanation would be forthcoming of why the cost of maintaining a patient in, say, the London Hospital was nearly £6 a week less than in St. Thomas's (according to the costing returns for 1956-7). In particular, since out-patient expenditure was henceforward to be separately costed, it was hoped that a truer picture of in-patient costs would be obtained than by the old returns, under which out-patient costs were eliminated by assuming that five out-patient attendances represented one in-patient day. In the event, the new returns, which cover some 200 hospitals spending more than £150,000 a year each, show that for the teaching hospitals, both in London and in the provinces, the formula was not far out, although it rather underestimated out-patient costs. In the acute non-teaching hospitals the formula underestimated them even more and should have been more like four to one. But the most interesting point that emerges from the analysis of out-patient costs is the big difference between the cost of a new out-patient in the London teaching hospitals and in other hospitals. The average cost in acute non-teaching hospitals in England and Wales for each out-patient attendance is 17s. 2d.; in provincial teaching hospitals it is 18s. 4d.; and in London teaching hospitals, £1 1s. 9d. The average cost of a new out-patient, on the other hand, in the three groups respectively is £2 12s. 10d., £2 16s. 6d., and £4 5s. 9d. The explanation is not apparently that more elaborate diagnostic techniques are used in the London teaching hospitals than elsewhere, because the analysis of out-patient costs does not include their share of the cost of the x-ray department or pathological laboratory, or indeed any of the medical-service departments—which must surely detract from its usefulness. In fact, the only explanation that can be gathered from these returns is that the proportion of new out-patients to total out-patient attendances is lower in the London teaching hospitals.

Thus tantalizing queries are provoked by the new returns as much as by the old. What the new returns do is to throw the questions a stage farther back. That is, if one hospital's in-patient costs are shown to be noticeably higher than in another similar hospital, one can see from these returns whether it spends more than the average in the wards, or on administration, or on works and maintenance, and so on. St. George's Hospital, for instance, which has the highest in-patient cost

¹ *Brit. med. J.*, 1957, 1, 573.² *Ibid.*, 1958, 1, 568.³ Reitman, S., and Frankel, S., *Amer. J. clin. Path.*, 1957, 28, 56.⁴ King, J., *J. med. Lab. Technol.*, 1958, 15, 17.⁵ Goble, A. of the undergraduate teaching hospitals (£39 2s. 9d. a week, compared with the London's £28 18s. 8d. and an average for the acute London teaching hospitals of £33 11s. 3d.), has a direct expenditure in the wards of about £1 2s. a week more than the average; it also has a heavy bill for works and maintenance and an occupancy rate for its staffed beds that is lower than the average. But the returns do not, of course, give the reasons for these differences. The unit costs of one hospital's diagnostic x-ray department may be twice as high as another's, so may be those of its boiler-house. But is this the result of inefficient equipment or inefficient management? Does a higher cost for the physiotherapy department represent better service, a swifter rehabilitation of patients, or sheer extravagance? It is to be hoped that the returns will provoke this sort of question among hospital authorities, and that they will insist on getting the answers; otherwise the cost of costing will merely be one more item in the heavy bill that the nation has to pay for maintaining its hospitals.

DISORDERED SOCIETY

The Home Secretary told the House of Commons last week that Britain had half as much crime again as before the war. The increase in indictable offences which began in 1955 was still rising steeply during the early part of 1958. A disturbingly high number of crimes were committed by youths between 16 and 21 years of age, and there had been a recent increase of offences committed by children under 17. Mentioning the grave lack of knowledge which hampered the work of the police and the courts, Mr. Butler said that the new research unit in the Home Office was now well established, and in due course the Institute of Criminology at Cambridge would be getting under way. In the light of Mr. Butler's remarks about lack of knowledge the recently issued annual report of the Institute for the Scientific Treatment of Delinquency is of particular interest, for the first of the objects of the Institute is "to initiate and promote scientific research into the causes and prevention of crime." If, as may be assumed from Mr. Butler's speech, other methods are failing to stop the rise in the number of young criminals, then the scientific study of the causes of crime and of the treatment of offenders should be much more actively encouraged. As the report of the Institute for the Scientific Treatment of Delinquency states: "There is more need now for the I.S.T.D. than at any other time in its existence."

The clinical work of the I.S.T.D. was taken over by the National Health Service in 1948, and its main activities are now research, education, and the publication of the *British Journal of Delinquency*. Research, which is under the directorship of Dr. H. Mannheim, is hampered by lack of funds, and education is "the one direction in which it is possible to make headway without risk of financial loss." The educational activities of the I.S.T.D. have two clear aims: "First, to support the authority of social and psychological science to establish as it were an enclave within the field of penal

method. The second is to show that this can be done only by close study of the actual case-material, by proving in fact that crime is a form of behaviour disorder to be correlated with other social and psychological disorders and treated along similar lines." It is logical therefore for the Institute to press for the establishment of "observation centres" where selected offenders could be diagnosed and treated. By encouraging research on these and other lines the Home Secretary might not in the future have to give such a depressing account of what he called "a deep disorder in society."

NOBEL PRIZE IN MEDICINE

The three American geneticists who share the Nobel Prize in Medicine and Physiology have done their experimental work with organisms which are almost as different from man as living organisms could be. Yet so similar is all life at the cellular level, whether plant or animal, that these workers' researches with fungi and bacteria have contributed greatly to the development of theoretical genetics, and from them a fuller understanding of human genetics may be expected to spring. Professor G. W. Beadle, of the California Institute of Technology, and Dr. E. Tatum, of the Rockefeller Institute in New York, have shown that in the common fungal mould of bread and other substances, *Neurospora crassa*, distinct genetic changes are constantly associated with specific biochemical changes. They are thus getting at the precise mechanism by which the chromosomes in each cell nucleus transmit inherited characters. The advantage of using the somewhat recondite organism *Neurospora* is that the segregation of its genes in sexual reproduction is matched by a spatial separation of the resulting spores. By micromanipulation the spores bearing assorted genes can be plated out separately for growth on the same or different media. Thus the effect of chemical variations in the media can be studied against genetic variations in the spores, and it was found that a single genetic change resulted in a single change in dietary requirements. Professor Beadle, who is at present Eastman Visiting Professor at Oxford, is aged 55, and Dr. Tatum is 48. They share half the Nobel prize.

The other half of the prize goes to Professor J. Lederburg, aged 33, of the University of Wisconsin. With Tatum, Lederburg studied bacteria (chiefly *Escherichia coli*) with genetically altered dietary requirements, and was able to show that at least some of them undergo sexual reproduction. Later he showed, in collaboration with his wife, that bacteria could incorporate in themselves genetic material obtained from bacteriophage, and transmit it to other strains. Instead of more or less homogeneous vegetative cells dividing by simple fission, bacteria are found to be complex organisms showing segregation and recombination of genetic material in reproduction. Lederburg's work is a major contribution to the foundation of bacterial genetics, now a rapidly growing and elaborate branch of science.

Drug Treatment of Disease

DRUGS IN TREATMENT OF EPILEPSY

BY

DENIS WILLIAMS, C.B.E., M.D., D.Sc., F.R.C.P.

Physician, National Hospital, Queen Square; Neurologist, St. George's Hospital

This paper is concerned solely with the medical treatment of epilepsy. To conform with the intention of this series of articles the word "medical" is used in its narrowest sense—pharmacological—and "epilepsy" in its widest—to include recurring discrete disorder of sensation, behaviour, or consciousness of any sort due to cerebral disturbances, whatever the prime cause. The treatment is of fits of all kinds, whether symptomatic of brain disease (for example, trauma), of disease elsewhere (for example, vascular disease), or of unknown origin (idiopathic). It would be wise to consider this against the wider, and perhaps more important, aspects of epilepsy which were presented as a symposium in this *Journal* on March 22, 1958.

Kinds of Epilepsy

For pharmacological as well as other reasons the precise form of epilepsy must be recognized on clinical grounds and, if in doubt, with the help of the electroencephalogram, because, for instance, drugs which may benefit one form of petit mal due to local brain damage may aggravate the other form with the characteristic spike-and-wave discharge in the electroencephalogram. For our present purpose epilepsy is divided into:

- The general epilepsies:
 - Grand mal.
 - Petit mal.
- Focal epilepsies.

Grand mal is a pure tonic-clonic fit, which is the same whatever the cause. Petit mal includes the brief, frequent, stereotyped "absences" of childhood and myoclonic jerking. And the focal epilepsies include all other attacks however diverse or elaborate. Treatment of grand mal and focal attacks is so similar that they will be considered together, and the word anticonvulsant will be used generically whether or not an actual convulsion occurs in the attack.

Even after full investigation and medical or surgical treatment of the cause of the fits, medical treatment of the fits themselves is subservient to management of the patient's attitude, his life, and its background. Indeed, continuation of medical treatment may become inevitable because continuing stress in the life perpetuates epilepsy in a predisposed person.

Types of Drug

The most successful anticonvulsants for practical use in the ambulant patient can be listed thus:

- (a) Barbiturates, especially phenobarbitone and methylphenobarbitone.
- (b) Hydantoins—phenytoin ("epanutin") and methoin ("mesontoin").
- (c) Primidone ("mysoline").
- (d) Diones—troxidone ("tridione") and paramethadione ("paradione").
- (e) Others, especially acetazolamide ("diamox"), phenoximide ("milontin"), and phenacemide ("phenurone").

Though they derive from different chemical sources it is remarkable how closely similar the basic molecular formula of each group of the better anticonvulsants is.

Time of Administration

The average time of effective concentration after ingestion of an anticonvulsant is from six to eight hours, but the time of administration must be judged by the time of occurrence of fits. Some people always have them by day, some always by night, and the peak period is within an hour or so of rising. Therefore, the day's dose may be given on retiring, on rising, or spaced through the day. When fits are more frequent at the menstrual period a much larger dose may be given in that week.

Barbiturates

Occasionally, bromides have been given as a last desperate attempt to stop fits when all else had failed. But they are mentioned first to dismiss them with the comment that, though they stopped many fits, they did the epileptic person much harm in turning him into a handicapped, retarded dullard with bromism.

The first drug of choice remains phenobarbitone. This shares with aspirin and alcohol the stigma of abuse, but it remains an excellent anticonvulsant. It is safe, of very low toxicity, with little tendency to sensitivity. Do not, however, discount as neurotic the occasional patient who complains bitterly of sleepiness on a tiny dose, for some cannot tolerate it and many become depressed with it, though most become used to it after a few weeks.

It is always wise to begin treatment with phenobarbitone, $\frac{1}{2}$ gr. (32 mg.) once or twice in the day, but not to use much more than this in the first instance. Children, who will require a smaller dose according to their size, may be very tolerant of it, but sometimes become irritable and difficult while taking it. If so, stop it, for they will not mend. If fits continue in spite of a reasonably small dose of phenobarbitone, do not push it, for the patient will probably become retarded or depressed, and his distress and difficulty in continuing his pattern of life will bring more fits. Instead, go on to the hydantoins.

Phemitone ("prominal"), which is methylphenobarbitone, is converted to phenobarbitone in the stomach. Its anticonvulsant dose is double that of phenobarbitone, and though its pharmacological effect should be the same, patients who are sleepy with phenobarbitone may be content with phemitone (1–3 gr. (65–200 mg.) in a dose). It is worth trying. Long-acting phenobarbitone in an "enseal" is also advised for the same purpose.

Initial sensitivity to phenobarbitone or phemitone is unusual, but the physician is occasionally surprised to see a rash which, developing years after beginning treatment, disappears on withdrawing the barbiturate.

The effects of overdosage are subtle and serious, for the sensitive patient becomes intellectually retarded, slothful, sleepy, and sometimes very depressed. These symptoms are serious because they are insidious, not recognized for what they are, and greatly handicap the epileptic in pursuing his way in life. They should be avoided, even at the cost of an occasional fit; their continuation may lead to a vicious spiral downward, with a return of fits. Never, therefore, push barbiturates or have recourse to the amphetamines to try to offset these effects. Instead, limit the dose of phenobarbitone to the patient's toleration, and add another non-sedative anticonvulsant, of which the hydantoins are the best.

Hydantoins

When phenobarbitone has been given to an adult up to a total of three $\frac{1}{2}$ -gr. (32-mg.) doses in the day and further treatment is needed, add phenytoin sodium (diphenyl hydantoin sodium, epanutin) 0.1 g. twice or three times a day. It may be given in a larger dose at morning or evening if fits are diurnal or nocturnal only. It is a wise generalization that the margin between the effective anti-convulsant and toxic amount is small, so that the hydantoins must be given in fairly large doses, 0.3 g. daily being usual. Most adults will develop toxic effects if they take 0.4 g. daily for a few weeks, for the substance slowly accumulates, and it may be necessary to give 0.3 g. and 0.4 g. on alternate days to control fits without toxicity.

Sensitivity results in a rash with pyrexia and transient adenitis just like German measles or measles, but can be controlled by an antihistaminic such as promethazine hydrochloride, given for 10 days. The drug may also cause the unique hyperplasia of the gums, especially in children, macrocytosis, or rarely macrocytic anaemia, gastric disturbances, and most commonly ataxia, incoordination, and diplopia. It is wise to give patients having phenytoin crude vitamin B as "bemax" or "marmite"; to encourage dental hygiene; and to reduce treatment for two days from time to time if the patient becomes unsteady. Indigestion is relieved by giving the drug with meals, or with sodium bicarbonate. More serious, though rare, complications such as exfoliative dermatitis call for its immediate withdrawal, but there is no need to carry out repeated blood counts.

Methoin (mesontoin, or methyl-phenyl-ethyl-hydantoinate) has the same dose and similar therapeutic effect. It does not cause gum hypertrophy, but may make the patient drowsy, and is more likely to cause blood changes than is phenytoin sodium. It can be given as an alternative when gingivitis is troublesome.

It is so useful to give the hydantoins and phenobarbitone together that they can be obtained in the same capsule—phenobarbitone 0.05 g. and phenytoin sodium 0.1 g., to be given two or three times a day.

Primidone

Primidone (mysoline) has been successful in major epilepsy where other anticonvulsants have failed. It is not often toxic, but it has a sedative action, particularly when given with phenobarbitone, so that I never use these two substances together. Primidone is still much more expensive than the anticonvulsants already mentioned, so it is sensible to use phenobarbitone and phenytoin before trying it. Begin with very small doses indeed, gradually increasing from half a 0.25-g. tablet to three or more a day, because some people tolerate it very badly, are drowsy, ataxic, and may have vertigo and vomiting.

Once established, treatment with primidone seems uneventful. It can, with benefit, be combined with phenytoin, particularly in major epilepsy, but it is unlikely to be so successful with focal attacks, or minor attacks of any kind.

Treatment of Petit Mal

True petit mal is much more difficult to treat successfully than are other forms of epilepsy. Fortunately, however, unless the short attacks are very frequent, they may be no more than a nuisance, and a child may live in reasonable adjustment to them. In consequence, if attacks are resistant to treatment or the patient intolerant of it, it may be expedient to cease, letting the child continue otherwise normally, as an alternative to a drugged life.

The substances so far mentioned are usually of little value in treating true petit mal, though some brief "absences" may really be unrecognized focal attacks, and so respond to phenobarbitone or phenytoin. In general,

sedatives make true petit mal worse, and stimulants improve it. In addition, children with petit mal are apt to become aggressive, surly, and unsocial with phenobarbitone, and so have more attacks. Conversely, amphetamine, dextro-amphetamine, and caffeine may greatly benefit patients with petit mal and improve their behaviour. It is important in view of the specificity of treatment to be guided by the electroencephalogram as well as by the characteristics of the attacks.

Diones

Troxidone (tridione) is sometimes drastically successful in controlling petit mal. When it is successful it seems to work in quite a small dose, and increasing the dose does not improve the therapeutic response. Adults or large children can take three or four 0.3-g. tablets a day, smaller children three or more 0.15-g. tablets according to size.

Many patients have toxic responses, but fortunately these are usually not serious. Most commonly there is glaring vision, when objects glow and sparkle in bright light, while hiccups or nausea also occur; but these symptoms do not often call for withdrawal of the drug. Rashes may be seen initially but often subside; occasionally blood dyscrasias occur—aplastic anaemia and granulopenia. It is much more important to watch the child's health than to do frequent blood counts, because harmless fluctuations in the count may be encountered and a sudden aplasia missed. I give special attention to details of health and do not do serial blood counts, and so far have been able to regulate treatment without harm to the child. If troxidone is moderately successful, see if paramethadione (paradione) in the same dose is better, otherwise stop treatment.

Other Drugs

Amphetamine.—Amphetamine sulphate, methylamphetamine, or dextroamphetamine, 5 mg., may be effective in true petit mal. They may reduce attacks and improve the child's behaviour. They should be tried if petit mal is frequent, and children tolerate them well. Methylamphetamine has the fewest side-effects. Caffeine citrate 5 gr. (0.32 g.) may help children benefited by amphetamine.

Acetazolamide (diamox) has recently been given with other anticonvulsants because, as well as being a diuretic, it is a carbonic anhydrase inhibitor and lowers blood pH. Reports have varied, and results are often disappointing, but occasionally the addition of acetazolamide (0.25 g. once or twice a day) to existing anticonvulsants, has been followed by striking improvement. There are minor toxic effects, and rare serious ones. Acetazolamide is expensive, but a short trial of its effects will quickly establish its value in any one case.

Phenacemide (phenurone) 0.5 g. one to three times a day has serious toxic effects. This is a great pity, because it is a most effective agent in all forms of epilepsy. Frequently, there is improvement in the refractory case, to be followed by anorexia, nausea, liver damage, or blood disorder. It also causes psychosis. It should, I think, be used only as a last resort when attacks are out of control and the patient is under close observation.

Among other substances, **phensuximide** (milontin) 0.5 g. three to four times a day is the most well tried. It is effective in petit mal epilepsy, and can be tried after the substances already mentioned.

A final note of warning. If several drugs have been tried, and more than two are being used, the patient is probably suffering more than he is gaining by them.

Status epilepticus remains a very dangerous complication which must be brought under control as soon as possible. Paraldehyde (5 ml. intramuscularly) repeated every two or three hours until attacks have stopped is probably still the safest drug. Intravenous anaesthesia can also be used, but an anaesthetist with positive-pressure apparatus should be available.

INSTITUTE OF ORTHOPAEDICS**OPENING OF NEW RESEARCH LABORATORIES**

On October 31 Sir HENRY DALE, O.M., F.R.S., on behalf of the Wellcome Trustees, opened a new research block for the Institute of Orthopaedics (London University). The block is at Stanmore, where the country section of the Royal National Orthopaedic Hospital is located. The Wellcome Trustees had given £43,000 towards the building and London University about £20,000. Sir HENRY FLOYD, chairman of the Hospital, presided over a distinguished company which included Lord COTTESLOE, chairman of the North-west Metropolitan Board, Sir FRANCIS FRASER, director of the British Postgraduate Medical Federation, and Mr. H. J. SEDDON and Mr. H. JACKSON BURROWS, director and dean, respectively, of the Institute.

Development of the Institute

The Institute of Orthopaedics was established in 1946, under the aegis of the British Postgraduate Medical Federation. At first, the only accommodation available was that provided by the Royal National Orthopaedic Hospital: one floor of the town section at Great Portland Street was converted into laboratories, a lecture-room, and a library; and laboratories for clinical pathology and bacteriology were provided at the country section at Stanmore, where an animal house was erected. In 1951 a metabolic unit was opened, and London University approved a scheme for the erection of an H-shaped laboratory building at Stanmore. Money was provided for the first wing and a department of biochemistry was opened in 1952. During the next two years the laboratories for morbid anatomy and for clinical research at the town section were extended, and the Wellcome Trustees provided £2,000 for the equipment of an orthopaedic museum.

The opening of the research block at Stanmore represents the completion of the research block at Stanmore represents the completion of the Institute's plan. The new building has four sections. Biochemistry is already well established under the direction of Dr. P. G. WALKER, who is engaged in the investigation of enzymes concerned in the breakdown of hyaluronic acid and chondroitin sulphate. Of the new sections one is for the housing of experimental animals. Another wing is devoted entirely to clinical pathology and bacteriology, where Dr. CHARLES LACK is engaged in a number of investigations which include the preparation of plasminogen, the preparation and characteristics of staphylokinase, serological tests for staphylococcal infection, the action of plasmin on cartilage, and the mechanism of the destruction of cartilage in suppurative arthritis. The fourth wing, for clinical research, contains a combined common-room, lecture-room, and library, a viewing-room for studying series of radiographs, and three laboratories, one of which is already occupied by Dr. ANGUS MCPHERSON, who is working on visceral-somatic spinal reflexes. The old bacteriological laboratory has been converted into a small department of experimental surgery and has been named after Sir Henry Dale. There will now be ample opportunity for registrars and clinical research assistants to carry out modest investigations under the guidance of senior workers.

The department of morbid anatomy at Great Portland Street, under Dr. HUBERT SISSONS, who has made a particular study of bone disorders and of muscle atrophy, will be able to spread a little into the department of experimental surgery at the country hospital. Also at Stanmore, Dr. JOHN SCALES has built up a department of biomechanics and surgical materials. He is concerned with the fate of metallic implants in the body, the design of prostheses, and the applications of plastics in orthopaedics. Finally Dr. REGINALD NASSIM is directing a study of bone disorders, jointly with the hospital, in a metabolic ward.

London as a Postgraduate Centre

Speaking at the opening ceremony, Sir HENRY DALE said it was indeed a pleasure for him and his fellow trustees to see for themselves how much had been achieved with the

grant they had been able to make from the Wellcome Trust. He had no doubt that the decision of the University of London to develop and organize the facilities offered by the great metropolis and its hospitals for medical education at an advanced postgraduate stage was a step of the greatest importance for the progressive use of medical knowledge, now advancing with such impressive rapidity. Orthopaedics had enjoyed during the past half-century, and especially during its more recent decades, at least as great and even dramatic a development in the range of its possibilities, and in the effectiveness of its methods, as had any of the other major departments of medicine and surgery. It had given them, accordingly, a special pleasure to be able to do something to assist the further and even more rapid advance of the subject.

Mr. SEDDON then thanked Sir Henry Dale for opening the building, and proceeded to describe the various departments.

BRITISH ORTHOPAEDIC ASSOCIATION**AUTUMN MEETING AT OXFORD**

The fortieth annual meeting of the British Orthopaedic Association was held from October 2 to 4 at the Nuffield Orthopaedic Centre, Oxford, under the presidency of Mr. NORMAN CAPENER. After the usual instructional course on the first day, a number of papers were read, some of which are summarized here. Sir HARRY PLATT made the meeting memorable by delivering the first Founders' Lecture. Taking the title "Quick, Thy Tablets, Memory!" he described the association's origins and the great figures connected with its foundation forty years ago.

Bone Growth

Professor J. TRUETA (Oxford) said that he and his colleagues had collected data suggesting the main function of the blood vessels reaching the growth-plate from its epiphyseal side was to nourish the repeatedly dividing cartilage cells, whereas the peculiarly arranged vessels underlying the metaphyseal side of the plate were mainly, and perhaps only, concerned with the calcification of the giant cartilage cells. Interruption of these metaphyseal vessels, or their occlusion by pressure, caused a total failure not only of calcification but also of the degeneration of the giant cells. The picture was radiographically and histologically similar to rickets.

Mr. J. D. MORGAN (Oxford) said the epiphyseal plate matured only when ossification of the shaft had extended sufficiently to form the metaphyseal end-plate, subsequent growth being in the direction of the cartilage-cell columns which formed at right angles to the base of the plate. At the upper end of the femur the metaphyseal end-plate was wedge-shaped, growth in length being proportional to the angle formed and probably at first equal to that at the lower end. The two sides of the wedge eventually separated as the epiphyses for the head and greater trochanter developed, but at first most of the growth in length came from the capital side, resulting in the coxa valga normal in infancy which persisted if the trochanteric epiphysis for any reason closed prematurely. If the capital epiphysis closed early from congenital deformity, injury, infection, or paralysis, the trochanteric epiphysis took over control of longitudinal growth, and any operative procedures in such circumstances must therefore avoid damaging the latter. It was only if both parts were closed that gross shortening occurred. At the lower end interruption of growth commonly affected only part of the epiphyseal plate, resulting in both shortening and distortion of the bone. Ischaemia, as in Perthes's disease, promoted growth in circumference of the epiphysis and hence widening of the bone. Disuse of the lesser trochanter, as in iliopsoas paralysis, resulted in failure of this area of the shaft to thicken normally.

Intrauterine Fracture and Congenital Coxa Vara

Mr. E. W. SOMERVILLE (Oxford) discussed congenital coxa vara, basing his argument on an example in which the mother had injured her abdomen six weeks before term. At

eight months of age the capital epiphysal centre had first become visible radiographically, in its normal position, together with a "ghost" of the missing neck, the upper femoral shaft lying at an angle to the bony lower part of the shaft. Arthrogram and exploration confirmed these findings, which he considered to be due to an intrauterine fracture of the cartilaginous femur. As a result primary ossification of the shaft, depending on its nutrient artery and the capillary loops formed from it, had been brought to a halt at the site of the fracture, and the metaphysal region had failed to ossify. In such circumstances an epiphysal plate did not develop, but ossification proceeded normally in the ossific centres of the head and great trochanter where the blood supply was intact, and spread unhindered into the metaphysal region. Here, later, irregular ossification occurred, and growth in length at the upper end of the femur was no longer possible.

Sir REGINALD WATSON-JONES (London) supported Mr. Somerville, and thought that this and similar conditions in this region were all due to birth fractures through cartilage. Mr. DAVID TREVOR (London) asked why, if that were so, the condition was so commonly bilateral, and Mr. J. C. SCOTT (Oxford) asked for an explanation of the frequent association of other congenital defects and of a familial incidence. Mr. SOMERVILLE agreed that many instances were not explicable as fractures, but thought that basically the underlying abnormality was one affecting the local blood supply rather than the cartilage itself.

Tendon Grafts and Tenolysis

Professor PAUL BRAND (Vellore) illustrated his contribution on the principles of free tendon-grafting with a film of outstanding quality showing the removal of a plantaris graft and its use in his operation for intrinsic paralysis of the hand. The principles he so convincingly propounded he summarized as follows: Tendon transfers are more regularly successful than free tendon-grafts because they have no suture line in the length of the tendon to cause adhesions, and because they carry their own blood supply and therefore do not need to grow new blood vessels which attach them to surrounding structures along their length. Frequently, however, it is difficult to spare a muscle with a long enough tendon without causing a secondary disability. In such cases a free tendon-graft from a more proximal muscle may be necessary. Secondary deformities following the Bunnell sublimis operation had led him to use a new operation, taking free grafts from a wrist-moving muscle. During the carrying out of 200 free tendon-graft operations for intrinsic paralysis of the hand they had worked out new methods which had improved the effectiveness of the grafts by minimizing the formation of adhesions. The ideal material for free grafts was the plantaris tendon. After giving the details of his method, Professor Brand then described a new operation for intrinsic paralysis of the hand. This involved the use of the extensor carpi radialis longus or brevis muscle, extended by four tendon-grafts through the interosseous spaces of the hand, anterior to the transverse metacarpal ligaments, which were inserted at the edge of the dorsal expansion of each finger.

Professor J. I. P. JAMES (Edinburgh) described his use of cortisone in tenolysis. Assuming that Carstam's work on the effectiveness of cortisone in preventing tendon adhesions in rabbits might be applicable to man, and after disappointing results with a small series of tenolyses without cortisone, Professor James had used corticotrophin or cortisone, starting treatment two days before operation and continuing it for 14 days post-operatively. The dosage he now used was 150 mg. of cortisone daily, with weaning afterwards and the usual precautions for steroid therapy. Dressings were changed after two days and active exercises then started: sepsis had not been a problem. Although there had been some failures, in a series of 22 patients the results were on the whole strikingly better than in cases done without cortisone. He had not been impressed that cortisone had helped in the few cases of tendon-grafting he had done under its cover.

Bone Grafts for Malposition and Non-union

Mr. R. G. TAYLOR (Oxford) reviewed 72 bone grafts performed between 1950 and 1955 for fractures of the shaft of long bones. Two-thirds were done because of fibrous union, and the remainder early for malunion, at an average period of three weeks after the fracture. If closed reduction failed or needed repeating more than 10 days after the fracture, Mr. Taylor considered open reduction and fixation by grafting to be usually the method of choice. In analysing the causes of fibrous union he noted that no case had occurred in 200 consecutive tibial shaft fractures, both simple and compound, in patients under 17; over this age the age of the patient was not a factor, nor was the site of fracture. Two-thirds of the failures to unite by bone had occurred in compound fractures, although these made up less than one-third of the total fractures seen. The severity of the injury, the amount of bone and skin lost, and infection were all factors making fibrous union more likely. Repeated manipulations after the tenth day were particularly harmful in this connexion, as was also distraction from any cause. He recommended the use of a combined onlay and inlay graft, the latter being firmly fixed with four screws. The fibrous zone was resected only if the bone ends needed realignment. In the 72 grafts there had been eight infections, of which seven occurred in previously compound fractures, and among these were the only two failures to produce bony union. The average period of total immobilization for tibial grafts was 104 days, with a further 40 days in a gaiter for two-thirds of them.

Vascular Occlusion Causing Backache

Dr. DAVID L. FILTZER (Baltimore) discussed vascular insufficiency as a cause of low back pain. He reviewed 50 cases that had been under the care of Dr. Bahnsen at the Johns Hopkins Hospital, of which 43 were in males. All had suffered occlusion of the lower aorta or the common iliac arteries, and 22% had had back pain of major or minor degree. In many a multiplicity of other diagnoses had been made before the correct diagnosis. All 50 had been proved by aortography and/or operation for endarterectomy or replacement by a homograft, procedures which had relieved back pain if it was present. Dr. Filtzer stressed that a tentative diagnosis of vascular insufficiency should be considered in every patient with backache, and emphasized particularly the importance of the history.

Other Contributions

Other papers were read by Mr. D. M. BROOKS (London) and Dr. A. ZAOUSSIS (Athens) on arthrodesis of the shoulder for paralysis of the upper limb, Mr. W. DE WYTT (Dublin) on a review of 45 cases of anterior vertebral fusion, Dr. J. CHALMERS (Chicago) and Dr. H. A. SISSONS (London) on an experimental comparison of bone-grafting materials in the dog, Mr. MICHAEL SQUIRE (Reading) on carpal mechanics and trauma, Mr. G. K. ROSE (Shrewsbury) on correction of the pronated foot, Mr. J. PIGGOT (Exeter) on dislocation of the hip in children, and Mr. J. W. DICKSON (Sheffield) on ectopic ossification in paraplegia. In addition there were clinical and scientific demonstrations at the Nuffield Orthopaedic Centre.

Motoring News

EARL'S COURT MOTOR SHOW

This year's Motor Show at Earl's Court was one of the most disappointing in recent years for the popular-car motorist. Several new models were available for buyers in the luxury class, but for under £1,000 the average family motorist would have found little to excite him, with the possible exception of the Austin A40. It is likely, however, that further popular models will appear within the next three or four months.

One group which showed promise this year was the ultra-lightweight range of two-cylinder models of up to 5 h.p.

The diminutive DAF from Holland, using a two-cylinder two-stroke power unit of 600 c.c., was worth admiring. Its interior was particularly well appointed and gave an atmosphere of comfort which befitted a larger car. Of similar dimensions was the new Goggomobil Royal. A native of Bavaria, the Goggomobil is a popular German economy car produced in large quantities, and this latest model, the Royal, now gives adequate comfort for four passengers for short journeys, and costs £710. It cannot, however, be called good value when compared with other British cars, but this is the price the buyer has to pay for individuality and, of course, economy. Likewise the British Berkeley, now with an alternative saloon model at £725, caters for the family motorist—albeit one with a very tiny family. Some more small newcomers were the N.S.U. Prinz and the Sport Prinz, the latter being a smart 85 m.p.h., 50 m.p.g. close-coupled saloon; the streamlined Frisksprint with 492 c.c. two-stroke engine by Excelsior, giving it a top speed of 90 m.p.h.; and the Stirling Opperman, made by the Unicar concern at Stirling Corner, near Elstree. This last is a new venture by this firm, and at £541 it may well capture one of the few small spaces left in the low-price group for an effective family runabout. With a 424 c.c. power unit it can offer 50 m.p.g. petrol consumption and accommodation for two adults and two children.

Larger models recently introduced and costing over £1,000 were the Aston Martin DB4, Humber Super Snipe, Rover 3-litre, Armstrong Siddeley Star, Bristol 426, Daimler Majestic, Mark IV Jaguar, twin-cam M.G.A., and the Peerless. Of these the Rover retains its characteristics as a "quality" car, although one which has lost some of the dignity of its smaller brothers, especially with regard to interior appointments, the instrument panel in particular. The Humber Super Snipe offers supreme luxury at a moderate price, but it still inherits the traditional Rootes Group body shape. Models with disk brakes are the latest Jaguar, the Mark IX, the twin-cam M.G.A., the Aston Martin DB4, the Bristol 406, the Daimler Majestic, and the Armstrong Siddeley Star, which has them on the front wheels only. All these models were new to Earl's Court on this occasion, having been introduced in the course of the past year.

The Jaguar Mark IX is a more powerful version of the current model, as is the 1½-litre M.G.A. The Aston Martin, the Bristol, and the Daimler are recent introductions. The Armstrong Siddeley Star is similar in appearance to the popular Sapphire but is fitted with a larger engine, now of 4 litres capacity, and incorporates many other detailed improvements.

The Austin A40 was one of the very few really new cars at the Show, being a further addition to the already extensive B.M.C. range. Unique in design, having done away with the external luggage boot, it is a good buy at £676 for the small-car motorist. But it is a small car. Rear seat accommodation is limited, and the headroom barely adequate for a tall passenger. The whole seat folds to allow adequate quantities of luggage to be carried, but the considerable quantities of luggage to be carried, but the opening flap is small by reason of the large fixed window above it, thus preventing bulky objects from being carried.

In the caravan section there were few revolutionary developments with the exception of motor caravans, which are rapidly coming into fashion. Such vehicles obviate the need for towing the conventional caravan at 30 m.p.h., in Britain anyway, and they are no more expensive to transport on boats or trains than conventional cars. They are also easy to manipulate in confined spaces. Martin Walter Ltd., of Folkestone, one of the largest firms in this field, convert Bedford and Ford vans, in particular, into comfortable two- and four-berth sleeping wagons with built-in cooking and washing facilities. Similar conversions are available on Volkswagen, Morris, and Austin chassis. No purchase tax is payable on vehicles of this sort, with the result that they represent excellent value for money.

New in the accessory line were Ward's pistol-grip spotlight for fixing to the windscreen pillar, the Continental-shaped wing mirror, and the folding camp chair by Desmo. the new Lucas S7 battery with one-piece venting system

instead of the customary removable plugs, coloured Dunlopillo cushions which fold, and a range of new small lamps by Marchal which can be used either as flashing indicators, side lamps, or fog lamps. A gayer touch has been given to many of the cars now on the market by the use of new pastel colours and two-tone schemes. Further varieties of leathercloth add more charm to interiors, while ribbed rubber and rubber-backed materials are appearing more and more on the floors of current popular models.

Technically this was not a very interesting exhibition, with most makers sticking to their well-tried power units and chassis layouts. Britain, however, leads the world with the disk brake, and it is likely that within a very few years these will be available on mass-produced models. Improved performance has been achieved by simply enlarging the capacities of present engines instead of redesigning the units to give additional B.H.P. on the same number of c.c.s. This policy of consolidation in the motor industry has certain advantages. The longer a model is in production and the more improvements which are incorporated into it the better it becomes, and the longer it stays on the production line the more money it earns for its company. This in turn allows the designers more time to develop their new models, and we shall look forward to these appearing soon in the low-price markets in time for buyers to take advantage of the recent hire-purchase rearrangements.

IAIN GELLATLY.

Nova et Vetera

"AH, MY OLD FRIEND DR. HARVEY"

The life of William Harvey has been studied for three centuries, and it might be imagined that little new could be said. It is interesting, therefore, to note that within the last few years fresh information has been published on the subject in this country and abroad, stimulated in part by the preparations for the celebration in 1957 of the tercentenary of Harvey's death. Among these contributions the following may be mentioned.

The discovery of the Harveian Oration for 1662, in all probability by Sir Charles Scarborough, records a tribute from a pupil to Harvey's ideals, knowledge, and zeal for investigation.¹ The account of Harvey's knowledge of neurology and psychiatry, gathered by Drs. Richard Hunter and Ida Macalpine,² reveals another side of Harvey's inquiring mind. The recent find among the muniments at Hatfield of the letter, dated 1605, from Dr. Lancelot Browne recommending his son-in-law, Dr. William Harvey, for the post of physician at the Tower of London indicates how early his professional talents were appreciated.³ The letter of Bishop Brian Duppa to Sir Justinian Isham of 1657 relates that Harvey paid attention to dietetics and nutrition and "would sometimes fast two days together"; that the bishop was with him the day before he died; and that Harvey's life "went out like a spark, without any violence or noise at all."⁴ In 1956 Dr. F. N. L. Poynter discovered in the poems of Dr. John Collop, published in 1656, a contemporary poem on Harvey of some merit.⁵ We have had new and better English translations of *De motu cordis* and of *De circulatione sanguinis*—the two anatomical essays addressed by Harvey in 1649 to Jean Riolan, jun.⁶—from the pen of Dr. K. J. Franklin, which only one who is at the same time physiologist, classical scholar, and medical historian could have achieved; and Dr. Louis Chauvois has published simultaneously in French and English a new life of Harvey.⁷ It is an impressive catalogue of biographical information, but the harvest is not yet exhausted.

Sir Geoffrey Keynes, who can equally delight and instruct us in new paths in surgery and in medical history, iconography, and English literature and poetry, is a leading authority on William Harvey. He is also a Fellow of the Royal College of Physicians, and his Harveian Oration⁸

for 1958 to the College is entitled: "Harvey through John Aubrey's Eyes." Sir Geoffrey, in studying Harvey's life, takes up the torch handed from Sir D'Arcy Power, who like him was a surgeon at St. Bartholomew's Hospital, Harvey's hospital. Sir Geoffrey reminds us that Harvey, like many of his contemporaries, practised surgery as well as medicine—he bequeathed to Sir Charles Scarborough all his little silver instruments of surgery. As Sir Thomas Barlow said in his Harveian Oration¹¹:

"I think we may rest content that our Harvey, who was universally admitted to be a great anatomist and naturalist, was also an experienced pathologist, a learned physician, and that he had the qualifications of a good all-round medical practitioner."

Aubrey's Picture

It is John Aubrey (1626-97), that prince of gossiping biographers, "with an unerring instinct for the telling detail," who in the *Brief Lives*¹² gives a vivid picture of Harvey's later years and of his personality. He had seen Harvey at Oxford in 1642, but it was not until 1651 that he became his friend. He is the only recorder of what Harvey looked like, of what he said, of his personal habits and foibles, and of the manner of his death. "Ah, my old friend, Dr. Harvey, I knew him right well!" he wrote. Aubrey was odd, irrelevant, and unsystematic, but he had a talent for description, an excellent memory, and desired to tell the unvarnished truth. Sir Geoffrey emphasizes these qualities of Aubrey as he proceeds to examine his word-portrait of William Harvey. Many writers on Harvey have used Aubrey's account, but in their "pilfering" have thrown doubt on his veracity. "A gossip, inaccurate and irrelevant," are some of the epithets applied to him. Can we trust his account of Harvey?

William Harvey's treatment was considerably in advance of his time. He prescribed the accustomed Galenic remedies, but was often sceptical as to their efficacy. In the case of Prince Maurice, who was suffering from a slow fever, Harvey stated that he and his colleagues resolved to give "very little physic, only a regular diet and cordial antidotes." The Prince made a good recovery. It was this scepticism, suggests Sir Geoffrey, that made Aubrey, while praising Harvey as an anatomist, consider him a bad physician, although he treasured his prescriptions, which are with his other papers in the British Museum. Aubrey certainly erred, after conceding that Harvey understood Latin and Greek pretty well, when he said that "he was no Critique, and he wrote very bad Latin. The *Circuitis Sanguinis* was, I take it, done into Latin by Sir George Ent." Of the truth of this statement there is no evidence, and, as regards Harvey's classical knowledge, Dr. Franklin has conclusively shown that he wrote scholarly Latin and that in translating his Latin into English passages can be discovered which are beautiful in either language. Harvey could write good English too, for in addition to his many great talents he was a man of letters. Sir Geoffrey suggests that it may have been a sight of the manuscript of Harvey's *De Motu Locali Animalium*, rough notes, which in spite of bad handwriting, abbreviations, and additions Dr. Gweneth Whitteridge, at the instance of the College of Physicians, has at length triumphantly translated and interpreted, which led Aubrey to decry Harvey's Latinity.

With the exceptions just mentioned, Sir Geoffrey Keynes finds that most of Aubrey's statements concerning Harvey are supported by additional evidence, such as that of Mrs. Harvey, his great-niece, who told Dr. Heberden of his oddities and foibles. Aubrey observed also Harvey's modesty about himself and his discoveries, his accessibility to younger men and his encouragement of them, which the Harveian Oration of Sir Charles Scarborough corroborates. Doubt has been thrown upon Aubrey's anecdote of Harvey being entrusted with the care of the young princes, Charles and James, at the battle of Edgehill in 1642.¹³ Sir Geoffrey, examining the evidence, shows that the account of the battle by an anonymous writer agrees with Aubrey's

(Continued at foot of next column)

To-day's Drugs

With the help of expert contributors we publish below notes on a selection of drugs in current use.

Aralen (Bayer Products Ltd.).

Avloclor (Imperial Chemical Pharmaceuticals).

Bemaphate (B.M. Laboratories Ltd.).

Resochin (Farbenfabriken Bayer A.G.: distributors, Levmedic Ltd.).

These are preparations of chloroquine phosphate in 250-mg. tablets. Chloroquine is the most rapidly acting schizonticide available for the treatment of acute malarial attacks. For this purpose it is administered in initial doses of 600 mg. (base) followed in 6 hours by a further 300 mg. (base) and by 300 mg. (base) on each of two successive days. (150 mg. base is equivalent to 250 mg. phosphate.) It is also a valuable malarial suppressive, when it may be given in doses of 300 mg. (base) weekly, or 150 mg. (base) twice weekly.

Encouraging results have recently been reported of its value in lupus erythematosus, for which it is given in the relatively large doses of 150 mg. (base) twice daily until nodules disappear, when the dose is reduced to 150 mg. daily. In rheumatism also the high dosage regime of 150-300 mg. (base) daily has been reported to be of some value. When using these large doses, deposits of the drug may occur in the cornea. Unless gross, however, these deposits may be visible only with the aid of a corneal microscope; the co-operation of an ophthalmologist is therefore worth seeking in controlling the treatment of lupus erythematosus and of rheumatism with chloroquine.

N.H.S. basic price: aralen, 100 tabs., 17s. 10d.; avloclor, 100 tabs., 12s. 11d.; bemaphate, 100 tabs., 14s. 3d.; resochin, 100 tabs., 14s. 8d.

(Continued from preceding column)

account; and it is strengthened by the portrait of the two princes at the battle which King Charles I presented to Harvey, no doubt to commemorate the occasion. The picture, for many years in the possession of the Harvey family, is now in the Scottish National Portrait Gallery in Edinburgh. Finally, "Aubrey's description of Harvey's last hours bears the stamp of truth."

After a searching examination, Sir Geoffrey Keynes considers that Aubrey's picture of William Harvey is in the main an accurate one, though his natural inclinations sometimes led him to misinterpret certain of Harvey's qualities. He concludes that Aubrey has bequeathed to us the most lifelike portrait of Harvey that we possess.

In this memorable Harveian Oration, with much learning and investigation, Sir Geoffrey Keynes has brought out for the first time the highlights of Aubrey's portrait of Harvey. In doing this he has not only justified Aubrey's veracity, but has made us see the great and good Harvey through John Aubrey's eyes.

Addiction to Unrestricted Drugs

SIR,—The communication from Drs. C. P. Seager and A. R. Foster (*Journal*, October 18, p. 950) describes seven addicts to chlorodyne, methylpentynol, preludin, or carbromal, all being psychopaths. They state that in three patients taking carbromal there was evidence of physical dependence, but do not describe the symptoms and signs to support this. If carbromal really does cause physical dependence it is of the greatest importance that this should be clearly established, and I hope that the writers will provide the evidence.

Their conclusion that all drugs which have a euphoriant or sedative action should be included in Schedule 4 of the Poisons Rules is alarming. If their view were adopted, to be consistent, we should also include the far more noxious and enjoyable drugs—alcohol and tobacco. We should, I suggest, think very carefully before recommending restrictions to legislators which would inevitably involve the practitioner in yet more work and which would do but little to protect a relatively small number of psychopaths.—I am, etc.,

London, W.1.

A. H. DOUTHWAITE.

SIR,—I read with much interest the timely article by Drs. C. P. Seager and A. R. Foster (*Journal*, October 18, p. 950). The dangers attendant upon the unrestricted sale of "persomnia" are well illustrated by the following case, recently under my care.

An intelligent male, aged 39, suffering from recurrent bouts of depression, had been addicted to persomnia for several years, consuming on an average about half a tin—16-20 tablets daily. Following a suicidal attempt in which he took 56 tablets over two days, he was admitted to an observation ward in a stuporous condition, showing a blood bromide level of 120 mg./100 ml. On becoming rational he expressed the desire to be cured of addiction, and was admitted to this hospital as a voluntary patient. After some two months, during which time he received electroplexy for his depression, followed by intensive supportive psychotherapy, he announced that he felt much improved and no longer had any craving for persomnia. However, while on a pass to seek employment, he procured a further supply of persomnia tablets, taking 14, and just managed to stagger to the hospital gates in a drowsy condition which necessitated a stomach wash-out. He again improved, and expressed appreciation for the opportunity to remain in hospital for a while, without passes and the temptation to obtain more persomnia.

The difficulties in treating this type of case seem to be immeasurably increased when the patient has unlimited access to the drug of his addiction, and it is possible that such people may never obtain relief until this and similar habit-forming dangerous drugs are placed on Schedule 4. Also advertisements in the national press and on independent television appear to have resulted in the widespread use of persomnia, as judged by the numbers of patients encountered in one's psychiatric practice who regularly take this preparation. Under such circumstances their treatment with orthodox medicines is rendered a complex and even dangerous undertaking. I therefore propose a speedy revision of the Poisons Rules whereby persomnia, and indeed some of the other drugs referred to by Drs. Seager and Foster, would not be obtainable without a doctor's prescription.—I am, etc.,

J. C. BARKER.

Banstead Hospital,
Sutton.

SIR,—The suggestion in the paper by Drs. C. P. Seager and A. R. Foster on "Addiction to Unrestricted Drugs" (*Journal*, October 18, p. 950) that "drugs which have euphoriant or sedative action should be placed on the list of Schedule 4 Poisons," and hence be obtainable only on prescription, is wise and timely.

For some time I have noted with concern evidence that a group of hypnotics, the open-chain ureides—carbromal and bromvaletone, and particularly the former—were being increasingly used for self-medication, and that they could produce addiction. Carbromal has long been considered by the medical profession and by pharmacologists to be a safe hypnotic, which indeed it is when administered under medical supervision. A new situation arose when proprietary preparations containing carbromal were widely advertised to the public through the national press as a "safe sedative." These preparations can be bought freely by the public in pharmacies and in some drug stores. It becomes increasingly obvious that the terms "safe" and "hypnotic" are contradictory where self-medication is concerned, for if one tablet is good then half a dozen are so often considered to be six times as good.

Instances of addiction or habituation to drugs such as carbromal are not easy to obtain; and are probably more readily available to the psychiatrist and general practitioner than the general physician. Three instances of carbromal addiction are reported in the paper by Drs. Seager and Foster. In personal communications Professor Aubrey Lewis was able to quote six instances of carbromal addiction under treatment at the Maudsley Hospital, and Dr. L. C. Cook four patients treated for this condition at Bexley Hospital.

A typical instance came under my care recently. Mrs. E. H., aged 51, was admitted deeply unconscious, having taken about 20 "persomnia" tablets (a preparation containing carbromal and bromvaletone). With energetic treatment she regained consciousness in two hours. She subsequently stated that, owing to insomnia and domestic worries, she had been taking the tablets regularly over the past three years. As indicated in advertisements in the national press, she thought they were safe. She admitted purchasing three 2s. 9d. tins of 40 tablets a week from chemists, some of whom had warned her to be cautious in taking them. She had a strong feeling of guilt and hid the tins from her husband, who was concerned about her addiction. A psychiatrist who saw her did not consider her condition psychotic. She also showed a carbromal rash on her legs.

Personal communications from four dermatologists, three on the staff of London teaching hospitals and one in a large London general hospital group, all indicated the increasing frequency of carbromal rashes. One estimated that carbromal eruptions occur three times as frequently as any other type of drug rash, two that it was the commonest drug rash seen, and the fourth that, "with the exception of penicillin, eruptions due to carbromal drug rashes were the most frequently seen in dermatological out-patient departments." E. W. Prosser Thomas¹ has recently drawn attention to the increasing incidence of carbromal rashes and lists fourteen proprietary preparations containing the drug. I had discovered fifteen. P. Borrie² drew attention to the condition in 1955. The rash is very distressing but not dangerous. Its high incidence indicates the extent of carbromal self-medication.

The Pharmaceutical Society of Great Britain have observed the situation with concern and in May last made the following recommendation,³ "That the Poisons Board be informed that in the Council's view there is a prima facie case for open-chain ureides to be included in the First and Fourth Schedules to the Poisons Rules, and suggesting that an inquiry be conducted by the Ministry of Health as to the extent of the abuse of such drugs and preparations containing them." The Home Secretary subsequently announced that the Poisons Board had decided that the matter be referred to the Committee on Drug Addiction for their consideration. Pending this deliberation the Pharmaceutical Society advised pharmacists to exercise the greatest care in the supply of preparations containing these drugs.⁴

Responsible public opinion appears to be aware of the danger of indiscriminate use of sedatives. *The Times*⁵ reports the National Council of Women of Great Britain as having passed a resolution at their annual conference urging the Minister of Health to prohibit the sale of "tranquilizers" to the public without a medical prescription. Tran-

Until recently it was generally supposed that, if a nerve is interrupted by injury or disease, no restitution of function can occur until new fibres grow out from the divided central stump to reach denervated structures. However, the nervous system possesses power additional to that normally understood by regeneration. In this phenomenon known as collateral sprouting, remaining intact nerve fibres, in response to a stimulus from adjacent degenerating fibres, give off side-branches or sprouts. These grow into near-by tracks left by the degenerating axons and are thereby guided to denervated endings.

This phenomenon of collateral sprouting is extraordinarily efficient in the autonomic nervous system. For example, in the cat, preganglionic denervation of the superior cervical ganglion was performed by resection of 3 cm. of the cervical sympathetic trunk. Several months later, histological examination and electrical stimulation of the cervical trunk showed that, whilst classical regeneration across the gap had not taken place, sprouting had occurred from efferent vagal fibres in the region of the nodose ganglion. As a result, the superior cervical ganglion had become partly re-innervated by efferent vagal fibres, thus producing a bizarre situation in which the pupil and micturating membrane became functionally linked with gastric and vascular reflexes.¹

In the case of gustatory sweating following injury or disease of the parotid gland, parasympathetic secretomotor fibres in the peripheral distribution of the auriculotemporal nerve will sprout and may acquire additional functional connexions with sweat glands, as we previously suggested.² Conversely, a cholinergic sympathetic fibre may come to innervate both sweat glands and parotid tissue. In comparable circumstances to these, we have shown that exaggerated responses occur, and are due to the summation of the effects of partial re-innervation and persisting hypersensitivity. It was therefore with particular interest that we noted that Glaister *et al.* had found that, in 8 out of 10 patients with gustatory sweating, the sweat glands showed an increased sensitivity to acetylcholine on the affected side.

The practical importance of considering collateral sprouting as a mechanism becomes evident in the recurrence of gustatory sweating after avulsion of the auriculotemporal nerve. Whether or not re-innervation is due to classical regeneration across the gap can be tested directly. If, however, it is due to collateral sprouting, then the essential therapeutic attack would be not to resect a greater length of nerve but to find the central level at which division of the nervous pathway eliminates from the affected area the supply of parent fibres from which appropriate sprouting can arise.—We are, etc.,

Sex Education for Students

SIR,—In the *Journal* of October 25 (p. 1029) you published an annotation on sex education for students. Some of the remarks in this are open to severe criticism and show little appreciation of the problems involved in the maturation of the individual or of the place of these problems in clinical medicine. The annotation states that "some students are scarcely sufficiently mature and stable to accept the emotional effort entailed in studying a subject of this kind." If this is true, how can such a person be fit to practise as a doctor? Surely the time to find out if this is the case is before qualification and not when it may well be too late for the doctor to make an adequate adjustment. The statement implies that maturity and understanding of marital problems is something picked up as the years roll by. This Victorian attitude would hardly be acceptable to modern psychiatry, and to ignore the problem amongst undergraduates is evading the responsibility which all teachers concerned should feel.

The second statement—"Not only is the student unaware of the emotional problems involved in marriage but often ignorant of his own ideas, fantasies, and prejudices about the sexual and marital relationship"—shows a considerable ignorance of medical students. One cannot lump medical students together as "the student," nor can one generalize in this way. Surely an average, intelligent medical student of 23 or 24 cannot spend three years among the patients of a teaching hospital and remain unaware of emotional problems of marriage. So much of clinical medicine is, in some way or another, bound up with family life and marital relations. So many illnesses are functional in nature, and so often an organic disease has a profound psychological overlay. How can one justifi-

ably divorce one of the major aetiological factors of modern medicine from clinical teaching?

Your annotation goes on to speak of a voluntary method of teaching, and says that "the drawback to this is the danger that those struggling with their own emotional problems are particularly attracted to the subject, and the resulting strain may precipitate a breakdown." That this is theoretically possible is no doubt true, but if we are to have remarks of this kind in the leading British medical journal then let them be backed up with facts and figures.

It is to be regretted that your annotation obscures the basic issues. Medical students need to have their own problems solved and to receive a good grounding in normal family life and the place of the family in society. If the student is helped with these, the psychiatric and gynaecological problems which occur can easily be dealt with in the proper place.—I am, etc.,

London, W.C.1.

Foetal Phonocardiography

SIR,—I note that Dr. C. N. Smyth and Miss Jennifer L. Farrow state in their paper in the *Journal* of October 25 (p. 1005) that they have paid little attention to the acoustic quality of the foetal heart sounds, and have limited their studies principally to time relationships. This is understandable in their case, as they used a moving-iron microphone. Sensitivity and robustness are not of themselves sufficient, especially now that first-class high-sensitivity pickups have been introduced.

I note with surprise that they found it necessary to use a loudspeaker which had to be situated in a different room to the microphone to prevent "howling round" or acoustic instability. Still, they found it fairly essential to have some form of acoustic heart signal in the same room as the patient, but they did this by the inelegant method of converting the foetal heart sounds into—quoting their own words—"plops," which would be heard by the pregnant woman. The foetal heart sounds can be demonstrated in the same room as the patient by the use of a proper pickup and close-fitting, suitable headphones, skilfully used. Acoustic feed-back is prevented as there is no direct acoustic path between the headphones and the proper pickup. This method permits the auscultator or auscultators to hear the foetal heart sounds at the same time as they are being recorded, without the patient hearing them.—I am, etc.,

Ergometrine with Hyaluronidase

SIR,—I was interested to see Dr. A. H. Labrum's letter (*Journal*, October 4, p. 857) regarding the intramuscular injection of ergometrine with hyaluronidase. He suggests that the addition of hyaluronidase both enhances and speeds the action of ergometrine but that the effect diminishes as the dose of ergometrine increases. The proof may not be adequate, but if his contentions are correct then any advantage of the hyaluronidase method could be achieved by merely increasing the dose of ergometrine alone; though I hardly think Dr. Labrum is suggesting this.

The widely varying figures quoted by Dr. Labrum well illustrate the difficulty of interpreting and comparing the results of different clinical trials; clearly, the incidence of post-partum haemorrhage in a particular series is influenced by other factors besides the type of ergometrine technique employed. Kimbell's results¹ were certainly excellent; but I am not surprised that good results have been reported giving ergometrine and hyaluronidase at the end of the second stage of labour. On the other hand I feel that the plain ergometrine injection is capable of good results too. Comparatively few figures are available, but they are not unimpressive. Thus, I might point out that Daley's² post-partum haemorrhage rate of 9.2% with the plain ergometrine technique (quoted by Dr. Labrum) represented a great improvement on an incidence of 15.7% in the control group, while in primigravidae only the

incidence of haemorrhage dropped from 13.2% to 5.2%. Such results scarcely justify the implication that to omit hyaluronidase from the intramuscular injection of ergometrine is to court disaster.

As I have already pointed out (*Journal*, September 13, p. 692), Mr. W. J. Garrett and I based our opinion of the intramuscular injection of ergometrine with hyaluronidase (*Journal*, July 19, p. 138) on objective measurements of its speed of action compared with ergometrine alone. Our observation showed that while hyaluronidase unquestionably accelerated the action of intramuscular ergometrine the latent period was reduced only by one-third. We readily acknowledged the value of the method as a "stop-gap" procedure; but, having regard to the greater difficulty in making the injection (Dutton³ reports a 19.5% failure rate) and the cost, it seemed to us that there was some doubt as to its superiority over the plain ergometrine technique as a routine method.—I am, etc.,

MOSTYN P. EMBREY.

SIR,—When Dr. J. N. Gale (*Journal*, October 25, p. 1044) advocates giving ergometrine after delivery of the placenta to avoid its retention he is bowing to tradition, not to the needs of present-day practice. The object of giving ergometrine with the anterior shoulder is to prevent post-partum haemorrhage, a condition which causes morbidity and mortality. In the recent Ministry of Health Report Number 97 on Confidential Enquiries into Maternal Deaths in England and Wales 1952-1954 (obtainable from Her Majesty's Stationery Office, price 3s. 6d. net) there were 113 deaths from post-partum haemorrhage, and "almost all the deaths in this group were entirely due to haemorrhage or a combination of shock and haemorrhage." Manual removal of the placenta in a fit patient is without risk; it is the results of manual removal in the exsanguinated patient which formerly brought the procedure into disrepute. It is a proved fact that the longer the third stage of labour the greater is the danger of post-partum haemorrhage. A contracted uterus does not bleed even with the placenta *in situ* and a contracted uterus cannot be inverted by cord traction. For dissertations on the modern management of the third stage of labour, I would refer Dr. Gale to the papers of Norman Kimbell¹ and F. C. R. Picton.²—I am, etc.,

Premonition of Death

SIR,—I hope we shall not be losing our sense of perspective on premonition of death. This symptom is more apt to occur when there is some genuine cause for it, whether it be known or unknown to the doctor, and hence is not lightly disregarded. Furthermore it is readily remembered when it proves an accurate forecast. Before we attach any greater importance to it than we do already we should remember that, unless a valid comparison is made with cases in which this premonition has proved false (by no means an easy thing to do), we should do well not to allow ourselves to wander on to the borders of spiritualism.

I have under my care an old lady of 86 who for the past eight years has at intervals of three to four months decided that her end was nigh and asked that her offspring be brought to her that she might bid them farewell. Since they visit her daily I have always felt constrained to treat her seriously every time it happens. One of these days she may be right—but so far she has merely been a cause of alarm to her relatives and anxiety to me.—I am, etc.,

A. LEWIS.

London, W.9.

Buzzers for Bed-wetters

SIR,—A clinic for the treatment of enuresis was started four years ago by the public health department of Croydon. During the past two years electrical anuretic machines have been loaned to those cases that have resisted simpler forms of treatment.¹ Up to date 45 children have used these machines and there have been no failures. (There have been two relapses following domestic upheaval after several months' complete dryness.) The average duration of treatment is two months.

The initial cost of the machines is five guineas, and, allowing for minor repairs and replacement of batteries, one machine will last for years of continuous use. The first machine bought for the clinic is two years old and still in service. The cost of one brand of pituitary snuff is 22s. 6d. for 25 capsules and insufflator. I believe that its use is quite well known, as several children attending the clinic have previously been treated with it unsuccessfully. In my experience the electric "buzzer" is a cheaper form of treatment than the use of pituitary snuff for several months as recommended by Dr. Clifford Allen (*Journal*, September 27, p. 799).—I am, etc.,

MARGARET WHITE.

Public Health Department
Croydon.

Infectious Mononucleosis

SIR,—In your leading article (*Journal*, October 11, p. 899) reference is made to the possible role of *Listeria monocytogenes* and of a virus in the causation of infectious mononucleosis. I would like to add that an organism intermediate between the Rickettsiae and the larger viruses was isolated in three cases of infectious mononucleosis in Japan in the years 1953, 1954, and 1955 (*Rickettsia sennetsu Misao-Kobayashi*). The experimental disease produced in human volunteers by the hypodermic injection of emulsions prepared from lymph nodes and spleens of mice experimentally infected with *R. sennetsu* was in every respect a typical glandular fever.¹

Much remains to be learned about the aetiology of infectious mononucleosis. It must, however, be emphasized that at our present state of knowledge—or lack of knowledge—of the causative agent(s) patients exhibiting the typical haematological picture should be considered as cases of infectious mononucleosis in spite of a negative Paul-Bunnell reaction. Tests for toxoplasma antibodies might, in a very small proportion of such cases, reveal the presence of toxoplasmosis, but the number of toxoplasma-positive cases will be infinitesimal.—I am, etc.,

S. VARADI.

City General Hospital,
Sheffield.

- 1 Misao, T., Kobayashi, Y., and Shirakawa, M., *Sang.*, 1957, 28, 785.

Prevention of Lung Cancer

SIR,—Mr. Leslie J. Temple has a peculiar way of bringing home to the public the hazards of excessive cigarette smoking (*Journal*, October 4, p. 858). He believes that holding inquests in cases of death from carcinoma of the bronchus would lead to moderation in cigarette smoking.

I saw this week a young girl in my surgery who is expecting her baby next month. She told me she is smoking 30-40 cigarettes a day and makes them herself, using strong tobacco. I told her that she was smoking too many cigarettes and asked her why. She replied, "I have not seen my husband for four days and I don't know where he is. I am worried and that is why I am smoking heavily." I believe this is the answer why some people smoke excessively—worries, tension, and the tempo of modern life and civilization.

Inquests are held every day in cases of road fatalities, but has that led to reduction in road accidents? What we need is not more inquests but a more and more psychiatric approach as to why people smoke excessively.—I am, etc.,

H. J. PRATAP.

Liverpool, 18.

Obituary

Sir JOHN MEGAW, K.C.I.E., D.Sc., M.B., B.Ch.

Sir John Megaw, a former Director-General of the Indian Medical Service, died at his home at Hawkhurst, Kent, on October 24 in his 85th year. He was known throughout the world as an authority on the rickettsioses, as a zealous advocate of population control by family planning, as a pioneer of air-conditioning in the tropics, and as the *fidus Achates* of Sir Leonard Rogers, who, now in his nineties, survives him.

Born on February 8, 1874, in Ballyboyland, not far from Ballymoney in Co. Antrim, John Wallace Dick Megaw was educated at the Belfast Royal Academical Institution and at Queen's College, Belfast, and graduated M.B., B.Ch., B.A.O., with first-class honours, at the Royal University of Ireland in 1899.

He had a brilliant student career, being Dunville student at Queen's and winning several scholarships and exhibitions, but after graduation he never took any other degree, being doubtful of the usefulness of time spent in acquiring "higher qualifications." His own university honoured him by conferring on him the D.Sc. (*hon. causa*) in 1934. He entered the Indian Medical

Service in 1900, and after a brief spell of military duty, during which he saw active service in China, he was transferred to civil employment in Bengal in 1903. During the ensuing ten years he spent much of his time in the varied employment undertaken by district medical officers in India. When resident medical officer in the Medical College Hospital, Calcutta, he helped Leonard Rogers with the clinical side of his cholera researches—the commencement of a life-long bond. Developing a special interest in pathology and bacteriology, Megaw underwent training in pathology and bacteriology when on furlough and study leave. In 1914 he was appointed professor of pathology at Lucknow University—a post which he later combined with that of principal. While in Lucknow he undertook and directed research on beriberi and dengue and sandfly fevers, and, as a result of a personal illness, on non-epidemic typhus fevers, a subject in which he took the liveliest interest throughout the rest of his life.

Founded by the drive and energy of Sir Leonard Rogers, through whose persuasive powers the necessary money was raised, the new Calcutta School of Tropical Medicine and Hygiene was fortunate in its first director, John Megaw, who took it over in 1931. He surrounded himself with an outstanding group of research workers and teachers: driving his colleagues hard, he encouraged them by his own example. During his term of office the output of research work of real worth was very striking. He commenced then his studies on the effects of heat and humidity on efficiency and did pioneer work on air-conditioning in the tropics. From 1921 to 1928, in his spare time, he edited the *Indian Medical Gazette*, and from 1928 to 1930 he was president of the South Indian and Madras Branch of the B.M.A.

Appointed C.I.E. in 1926, he became Inspector-General of Civil Hospitals in the Punjab in 1928, but a few months later he was promoted Surgeon-General with the Government of Madras. While in Madras he made his famous observation: "There is no quinine-resistant malaria—there

is much dispenser-resistant malaria." With Hawley he devised improved simple methods for estimating quinine in liquids, and many petty pilferers were dismayed.

In 1930 Megaw became Director-General of the I.M.S., and on his retirement in 1933 he was promoted K.C.I.E. During his tenure of that high office his statesmanlike qualities became apparent to all who met him or read his writings. The question of over-population of India was constantly in his thoughts; he strove unceasingly for the improvement of medical education—especially in the field of hygiene—and the need for training Indians to "take over" was keenly appreciated by him. On leaving India he succeeded his old friend Sir Leonard Rogers—with whom he had written a successful book entitled *Tropical Medicine*—as medical adviser to the Secretary of State for India and president of the India Office Medical Board. While in London he became a part-time lecturer at the School of Tropical Medicine and Hygiene. He gave up office in 1939 on reaching the age limit. He was Honorary Physician to the King from 1930 to 1934.

After retirement Megaw devoted his days to practical scientific farming in Kent, working with both hand and brain to make a success of his estate. His evenings and nights were devoted to his literary labours for the *Tropical Diseases Bulletin* and to the development of a new international language which, he hoped, might make the task of future abstracters of foreign literature less bothersome. He remained to the end modest and simple, but critical of loose arguments and mental woolliness. He was intensely interested in every branch of medical science, and on his death-bed suggested better ways of inserting the muscles of the lower limb so that a fallen invalid could get into bed more quickly before his nurse could discover that he had crept out.

In 1912 he married Helen Esmée Ward, who survives him. There were no children.

Dr. CHARLES WILCOCKS writes: Sir John Megaw did not end his association with research in tropical medicine when he retired from the Indian Medical Service, but his later interest was literary, and it was in this field that he made a very notable reputation after retirement. For several years he served on the honorary managing committee of the Bureau of Hygiene and Tropical Diseases, and from 1941 onwards he undertook to review papers on the rickettsial diseases and other fevers for the *Tropical Diseases Bulletin* and the *Bulletin of War Medicine*. His interest in these diseases had been stimulated in India by an attack of what he recognized as tick typhus, and he had built up a system of classification by vector—louse, flea, tick, mite—which certainly simplified and clarified our conception of these diseases, and which, he maintained, fitted in remarkably well with the results of the specific rickettsia-agglutination test and the complement-fixation test. He preferred this though that test is, because with the Weil-Felix test, useful for louse-borne and the flea-borne diseases cannot be distinguished, and in the tick-borne group the reactions are highly irregular.

The rickettsial diseases became very important during the second world war, when epidemics of louse typhus swept North Africa and Italy, scrub typhus was a major complication of the Far Eastern campaigns, and Q fever was for a time something of an enigma round the Mediterranean. Megaw took very seriously the work of reviewing papers on these subjects, written in many languages (none of which seemed to give him any trouble), and his cool and critical scrutiny of these papers, and his faculty of giving in few words the essence of their information, was widely appreciated throughout the world. His comments were quoted and discussed by the most eminent of research workers, and his opinions were constantly sought. It was always a pleasure to receive his manuscript. His facts were correct and there were no wasted words, and his language was clear and definite and characteristic. His writing was always

interesting, and it had a certain graceful quality which came, I think, as an unconscious by-product of the clarity of his thought. *Nullum quod tetigit non ornavit*.

Megaw kept up to date with medicine, and was as familiar with the work on dengue and the related fevers, and on plague, as he was with typhus. When we asked him to do something outside his usual line the reply would always be, "Send it along and I'll see what I can do," and the result would be superb. He was a statesman, as could be seen from his published appreciation of the Bore Report on medical services for India, published in 1946, and he was generous. We have lost a great man.

IVOR J. DAVIES, C.B.E., M.D., F.R.C.P.

Dr. Ivor Davies, consulting physician to the Cardiff Royal Infirmary and the Ministry of Pensions hospital at Rookwood, Cardiff, died at his home at Aberystwyth a few days after his 78th birthday.

Ivor Jones Davies was born on October 22, 1880. Beginning his medical studies at University College, Cardiff, where he won several scholarships, he went on to St. Bartholomew's Hospital, graduating M.B., B.S. of London University in 1906. After holding a number of resident appointments at the Royal Free Hospital, including that of house-surgeon to Sir James Berry, he took the M.R.C.P. and proceeded to the M.D. in 1911. Returning to practice in Cardiff, he soon became established as a consulting physician, though his work was interrupted by service in the first world war. He was a pioneer in pulmonary diseases caused by dust, though essentially a general physician, and his contribution to the literature included a paper on goitre in South Wales, a subject which had particularly interested him since his association with Sir James Berry. One of his earliest papers, published in this *Journal*, was on the subject of carbon monoxide poisoning after an explosion in a coal mine. Dr. Davies was appointed first assistant to the first professor of medicine (Dr. A. M. Kennedy) in the newly established medical unit at the Cardiff Royal Infirmary. In 1922 he became a full physician there, and three years later he was elected F.R.C.P. When the B.M.A. held its Annual Meeting in Cardiff in 1928 he served as a vice-president of the Section of Medicine. For his work at the Ministry of Pensions hospital at Rookwood he was appointed C.B.E. in 1953.

L. R. writes: Dr. Ivor Davies had recently attended the meeting in Cardiff of the Fellows and Members of the Royal College of Surgeons, where he had met many old friends and had been in good spirits. He was always a vivid, cheerful, kindly character with a keen sense of humour which made him one of the best of raconteurs. A lifelong supporter of the best interests of the Cardiff Medical School and of his profession, he paid frequent visits to London to keep in touch with the Royal College of Physicians, to which he became an examiner, and with his former associates at St. Bartholomew's. His practice soon became one of the busiest in South Wales, for it was generally realized that he was not only an able physician but one who had a lovable character which inspired confidence in both patients and practitioners. Perhaps his outstanding contribution to medicine in Wales was his staunch loyalty to the young medical school during its formative years; he frequently had to play an unpopular part at a time when birth pangs were sometimes acute through the obstruction of established custom. He was a devout Churchman, a Rotarian, and a keen student of both Welsh and medical history. In 1943 he retired from the Cardiff Royal Infirmary and six years later went to live in Aberystwyth, his wife's home town, but from time to time he visited Cardiff to see his old friends and his patients at the Ministry of Pensions hospital. He leaves a widow and two daughters, to whom we extend our sympathy.

J. V. LANDOR, M.D., M.R.C.P., D.P.H.
D.T.M.&H.

Dr. J. V. Landor, who spent the greater part of his professional life in the Colonial Medical Service, died at the Royal North Shore Hospital, Sydney, New South Wales, on September 12.

Joseph Victor Landor (formerly Landau) was born in 1897. He received his medical training at St. Bartholomew's Hospital and graduated M.B., B.S. from London University in 1920, taking the London Conjoint diploma in the same year. Proceeding to the M.D. in state medicine in 1925, he took the D.P.H. of the English Royal Colleges in the following year and the D.T.M.&H. in 1927. He was elected M.R.C.P. in 1932. After holding the appointment of house-surgeon at the Royal Northern Hospital, Holloway Road, London, he entered the Colonial Medical Service in 1927 and served until 1946. He was chairman of the Southern Division of the Malaya Branch of the British Medical Association in 1935-6. In 1947 he went to Australia and became assistant chief medical referee to the Government Insurance Office in Sydney, New South Wales. He leaves a widow.

A former colleague writes: In the Colonial Medical Service Dr. J. V. Landor worked as a medical officer in Singapore, Lahore, and Penang before being promoted to the post of physician to the General Hospital, Singapore, where he remained until his retirement. While in Lahore his duties included the medical care of prisoners in the gaol, among whom he observed symptoms of an ill-defined nutritional disorder. Working in collaboration with the medical officer of the Singapore gaol, where a similar condition occurred, the symptoms were described and the aetiology of them was studied. At the time of this work vitamin B was known to consist of the anti-beriberi factor B₁ and a heat-stable factor B₂. The "prison disease" was considered to be due to a deficiency in this latter part, and later, when riboflavin was discovered, it became evident that part of the syndrome that had been described resulted from lack of this vitamin. When the Japanese invaded Malaya Dr. Landor was interned in Singapore for three and a half years and was himself exposed to the dangers of the deficiency conditions he had helped to describe. During those years of internment he worked in the camp as dermatologist, and his special experience in dietetic disorders was put to good use in the service of his companions. Ariboflavinosis, pellagra, and other obscure skin conditions, probably nutritional in origin, became increasingly common as the years of confinement passed. The quiet skill and care with which he diagnosed and attempted with inadequate means to treat his patients was appreciated by all who were interned with him, and his work was a valuable contribution to the maintenance of the morale of the camp. He kept careful records of the dermatological lesions that he had seen, and as soon as he was released he published an account of his observations in the *British Journal of Dermatology* in 1948. After the war had ended he returned to his post of physician in Singapore, but, owing to ill-health, was soon forced to retire. He then settled in Australia, where he lived until his death.

C. M. OCKWELL, M.D., F.R.C.S., D.P.H.

Dr. C. M. Ockwell, who formerly practised in Dartford and was medical officer of health for Crayford, Kent, for over a quarter of a century, died at Guy's Hospital on October 17. He was 74 years of age.

Charles Melton Ockwell received his medical training at Guy's Hospital, qualifying M.R.C.S., L.R.C.P. in 1906. He was admitted to the F.R.C.S. in 1919, took the Cambridge D.P.H. in 1920, graduated M.B., B.S. of London in 1930, and proceeded to the M.D. in 1934. After qualification he was in general practice at Burgh, Lincolnshire, for a few

years before joining Dr. M. W. Renton in partnership at Dartford in 1914. During the first world war he was a surgeon at a base hospital at Fécamp for a year, and thenceforward until the end of the war ophthalmic specialist at the Royal Herbert Hospital, Woolwich, and at Paddington military hospital. After the war he became interested in preventive medicine. Appointed medical officer of health for Crayford in 1921, his duties were extended a few years later to include the Swanscombe urban and Dartford rural districts. Later he was appointed venereologist under the Kent County Council. Ultimately he became a full-time medical officer of health. In Crayford he developed the maternity and child welfare services, and was one of the first medical officers to offer diphtheria immunization to the children in his area. When the National Health Service came into being in 1948 he was graded consultant dermatologist and venereologist. A member of the British Medical Association for 40 years, he was chairman of the Dartford Division in 1924-5 and again in 1934-5, and president of the Kent Branch in 1937-8. He was also a member of the Library Subcommittee at Headquarters from 1933 to 1943. He resigned his appointment of medical officer of health for Crayford in 1947, and retired almost completely four years later. He kept up his interest in medicine to the end, however, and since his official retirement had acted as locum tenent on numerous occasions. In 1951 he married Miss Kathleen Keirle and moved to a new house on the Pilgrim's Way at Kemsing. His death has caused keen distress among his many friends and colleagues, for he was very popular and his reputation as a doctor was deservedly high.

RICHARD COLBY, M.R.C.S., L.R.C.P.

Dr. Richard Colby, who had been in general practice at West Wickham, Kent, for the last 14 years, died at Farnborough Hospital on October 2. He was 47 years of age.

Richard Colby (formerly Kobylinski) was born in Berlin on February 24, 1911, and studied medicine there and at Heidelberg. He was within three months of qualification in 1933 when he was forced to leave Germany on account of Nazi oppression. He came to England, where he had to begin his studies (including those for matriculation) all over again. After receiving his clinical training at St. Bartholomew's Hospital he qualified M.R.C.S., L.R.C.P. in 1940. He then held appointments at Warlingham Park Hospital, Poplar Hospital, and Mayday Hospital, Croydon, before entering general practice at West Wickham in 1944. He was chairman of the Bromley Division of the British Medical Association in 1955-6, and was a member of the Kent local medical committee and medical adviser to the Bromley branch of the Marriage Guidance Council.

K. B., a local colleague, writes: For the past ten years Dr. Richard Colby was associated with the work of the Bromley branch of the Marriage Guidance Council and was its special representative at the yearly and half-yearly conferences arranged by the London headquarters. It was because of his sympathy for all unhappy people that he tackled the work with tremendous enthusiasm and spent many hours both with the couples who came to him and in giving talks so that the work of the council became known. He will be greatly missed by his colleagues and patients.

M. S. writes: Twelve years ago I was invited by Richard Colby to join him in partnership in general practice in West Wickham and Hayes, Kent. During these years I grew to know his personality intimately and to admire his work. He was a man of great zest and enthusiasm for many extra-medical activities. Despite his knowledge that his vascular system was suspect, he spent many of his off-duty hours in working for such causes as refugee relief, the "Save the Children" Fund, the Marriage Guidance Council, and the personal problems of patients and friends. To him the protection and preservation of the welfare of children were of

paramount importance, and he was willing to give of himself for such causes. His own family life was undoubtedly the most happy and united that I have ever met. He leaves a courageous widow, two sons, and a daughter. They will miss him, as shall I and my family, my other partner and his family, and all our patients.

E. C. BEDDOWS, O.B.E., M.C., M.R.C.S., L.R.C.P.

Brigadier E. C. Beddows, who had had a distinguished career in the R.A.M.C., died at Gullane, East Lothian, on October 3. He was 72 years of age.

Edward Charles Beddows was born at Wolverhampton on April 27, 1886, and studied medicine at Birmingham, qualifying M.R.C.S., L.R.C.P. in 1911. After qualification he held house appointments at Birmingham General Hospital before entering the R.A.M.C. as a lieutenant in 1913. Serving in France throughout the first world war, he was awarded the Military Cross in 1915, and in the same year was mentioned in dispatches. Between the two world wars he served in India, Gibraltar, and Shanghai, as well as at home. By the time the second world war broke out in 1939 he had attained the rank of lieutenant-colonel, and was with the British Expeditionary Force in France soon after the war began. Later he took part in the landings in Italy and Sicily. Promoted colonel in 1940, he was assistant director of medical services at No. 6 Base Area in 1943-4; deputy director of medical services for the North Africa District in 1944-5; and assistant director of medical services for the Berlin District in 1945-6. He was wounded at Bari in 1943. He was appointed O.B.E. in 1944 for distinguished services in Italy, and an Officer of the Legion of Merit of the United States of America in 1947. When he retired in 1946 he was granted the honorary rank of brigadier. He leaves a widow.

Medical Notes in Parliament

NEW SESSION'S EMPHASIS ON SOCIAL REFORM

In the new session—possibly the last of the present Parliament—the legislative stage has been set to focus attention on social reform. The Queen's Speech, on October 28, set forth the objective—"It will be the special care of my Government to introduce measures to promote the social well-being of my people"—and some of the method. If the Bill to provide pensions related to earnings is likely to be the most controversial, that to give effect to many of the recommendations of the Royal Commission on Mental Health and to replace the existing law on mental health is likely to occupy the most time. The PRIME MINISTER has indicated that it will be a "large" Bill; and the leader of the Opposition has expressed the hope that there will not be any great controversy about it.

Financing Mental Care

That there will be controversy about the financing of the new arrangements, however, seems certain. In the opening debates of the session two Opposition speakers, Mr. JAMES GRIFFITHS, the deputy leader, and Mr. ARTHUR BLENKINSOP, a former Parliamentary Secretary at the Ministry of Health, have voiced their concern at the likely effect of the block grant system of Exchequer aid on local authorities' resources for this purpose. Mr. Griffiths, with this reservation, promised constructive help and co-operation with the Bill when it comes to the House early next year. But later on the same day (October 29) Mr. Blenkinsop adopted a much sharper approach. To him, the Government were making an "empty promise" unless they produced a better

statement of their intentions about finance than any so far given. The Royal Commission, he said, had made clear their own view that their recommendations could not be carried out effectively unless additional funds were available to enable local authorities to establish community care for the large numbers who ought not to be in mental hospitals and institutions. Some suspected, from what they knew of the discussions that had taken place, that the financial provision would not be present; and they believed that the introduction of the block grant system had destroyed the hope of effective progress in mental health and the care of the aged.

Factories Acts

The promise of legislation to amend and strengthen the Factories Acts, while welcomed, has also revived the Labour Party's grievance about the Government's failure to do anything about the the Gowers Report and so improve the conditions of shop and office workers.

Prison Reform

The increase in crime also received mention in the Speech. "My Government view [it] with gravity. In the light of the most up-to-date knowledge and research they will seek to improve the penal system and to make methods of dealing with offenders more effective." This is a subject on which the HOME SECRETARY has more than once indicated that he proposes to make haste slowly, in order to ensure that the changes shall be soundly based. The first lines of advance are to be drawn—probably in a White Paper, or some similar document—which Mr. Butler will present in a month or two, giving a full picture of what he has in mind. Thereafter there will be a process of testing public opinion, and obtaining the authority and guidance of those engaged in the administration of justice. Early legislation would not be advisable, but some would eventually be necessary.

This emerged from a debate on the subject to which the Commons devoted their time on October 31. The broad indications Mr. BUTLER gave point to an endeavour to secure more adequate treatment of the prisoner as an individual. For this, he said, there was needed a much more precise method of classification, and means to remove the jumbled grouping together of prisoners of all kinds, particularly the young with the old, so that they could be treated in suitable units. This entailed a considerable building programme. In dealing with young offenders the first rule was to preserve elasticity of judgment and diversity of treatment. He had put some ideas, which would in due course require legislation, to the Advisory Council on the Treatment of Offenders. The essential element was that, after sentence, more discretion should be left to the Prison Commissioners, Borstal governors, and others to handle young people as suited to their nature. This would mean for some a quicker period of training, education, redemption, and cure; and for the more obdurate the threat of longer detention. Figures Mr. Butler gave can be briefly summed up: Britain has half as much crime again as before the war. In spite of spectacular peaks and troughs in the statistics, the ground lost since 1939 had never been recovered. This was no sudden crisis, but a deep disorder in society. What was serious was the high rate of crime among young men between 16 and 21, for offences of all kinds. What was encouraging was that children under 14 had a better record than their predecessors, who as adults were now causing such anxiety. These severe problems of society could not be dealt with by the Government alone. They must enlist the co-operation of the whole country, the family, the churches, the schools. He refused to operate on insufficient information, but proposed to do a thorough and lasting job.

Prescription Charges

The speech in which Mr. HAROLD WILSON moved the Opposition amendment on November 3 criticizing the

Government's economic policy, including "taking the lid off" measures against inflation, was barbed with a direct challenge to the Prime Minister on prescription charges. Two years ago, he recalled, when Mr. Macmillan was playing his "Mac the Knife" role as Chancellor of the Exchequer, he introduced a series of mean and vicious cuts of which the worst was the individual prescription charge. They were told at the time that this was essential for fighting inflation. Now the fight was off. The real enemy was recognized as a lack of spending power, not a surplus. To test the sincerity of the Prime Minister—that was how Mr. Wilson introduced his question—would the Government now remove the restrictions?

Rebuilding of Teaching Hospitals

Mr. A. BLENKINSOP (Newcastle upon Tyne, East, Lab.) asked the Minister of Health on November 3 what consultations took place with regional hospital boards regarding plans for the rebuilding of teaching hospitals. Mr. D. WALKER-SMITH.—I rely on boards of governors to consult the appropriate regional hospital boards, who are moreover represented by their own nominees on the boards of governors. Mr. BLENKINSOP, emphasizing that there should be full consultation to avoid wasteful decisions, asked him if he would look into the particular case of the North-east Metropolitan Board, to see if they were consulted about the changed plans for the new Charing Cross Hospital. Mr. WALKER-SMITH accepted the desirability of full consultation in all cases. If Mr. Blenkinsop had any question relating to a specific project he should put a question about it.

Medico-Legal

"INCURABLY OF UNSOUND MIND"

[FROM OUR LEGAL CORRESPONDENT]

By section 1 (1) of the Divorce (Insanity and Desertion) Act, 1958, a person is deemed to be under "care and treatment" for the purposes of section 1 (2) of the Matrimonial Causes Act, 1950, when receiving treatment for mental illness as a resident in hospital without certification. What was said to be the first case under the new section was heard before Mr. Commissioner Latey, Q.C., in the High Court recently, and judgment was given on October 28 (*The Times*, October 29).

The facts were that the parties were married in 1926, and had three children. The wife became a chronic alcoholic, and her condition became so bad in the colonial territory where her husband worked that in March, 1951, after being sent home to England, she was admitted to a mental hospital where she became a voluntary patient. She was transferred to Tone Vale Hospital, and there her condition improved so that in 1952 it was suggested that she might return home under supervision, but her husband, who had the children to look after, did not agree. Accordingly she remained in Tone Vale Hospital as an in-patient. The medical superintendent's evidence was that she was suffering from dementia and that no further improvement was possible, though he did not think she ought to be certified. It was therefore apparent that she had the volition either to stay in the hospital or to leave it.

Meanwhile after some years the husband began to live with his housekeeper, and, wishing to marry her, he petitioned for a dissolution of his marriage on the ground that his wife was incurably of unsound mind and had been under care and treatment continuously for the last five years for her condition.

In his judgment the Commissioner said that with the consent of counsel he had seen the specialist's report on the

wife which, as in all such cases, had been obtained by the Official Solicitor in his capacity of the wife's guardian *ad litem*. This was to the effect that the wife had become feeble-minded and childish, needed much nursing attention, and was in the light of present medical knowledge incurably insane. The Commissioner held therefore that the wife was incurably of unsound mind within the meaning of the section. He added that, in view of the recent policy of extending the range of voluntary patients and de-certifying certified patients, it might be that a large proportion of mental patients whether certified or voluntary would not come under the category of persons incurably of unsound mind within the Act, but each case must be considered on its merits.

The husband in this case got his decree, the Court exercising its discretion in his favour notwithstanding his adultery.

Vital Statistics

Industrial Accidents and Diseases

The number of workpeople (other than seamen) in the United Kingdom whose deaths from accidents in the course of their employment were reported in September was 104, compared with 55 in the previous month and 96 in September, 1957.

The numbers of cases of industrial diseases in the United Kingdom reported during September, 1958, were as follows: lead poisoning 4, aniline poisoning 3, compressed air illness 1, epitheliomatous ulceration 14, chrome ulceration 16; total 38. There were 2 deaths from epitheliomatous ulceration, 1 due to pitch and tar, and 1 to mineral oil.—*Ministry of Labour Gazette*, October, 1958.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the years 1949-57 are shown thus - - - - -, the figures for 1958 thus ———. Except for the curves showing notifications in 1958, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Week Ending October 25

The largest fluctuations in the notifications of infectious diseases in England and Wales during the week ending October 25 were increases of 493 for measles, from 3,739 to 4,232, 118 for whooping-cough, from 476 to 594, and decreases of 133 for dysentery, from 658 to 525, and 31 for food-poisoning, from 259 to 228.

The largest rises in the incidence of measles were 88 in Lancashire, from 456 to 544 (Liverpool C.B. 108); 63 in Derbyshire, from 78 to 141 (Chesterfield R.D. 46); 63 in Lincolnshire, from 102 to 165 (Gainsborough U.D. 72); the largest exception to an increasing trend was a fall of 59 in Buckinghamshire, from 88 to 29. The notifications of scarlet fever, 803, were 8 more than in the preceding week, and no large fluctuations were reported in the local returns. A small rise in the incidence of whooping-cough was reported from many areas, but the largest variation in trend was a fall of 24 in Lancashire, from 71 to 47. 4 cases of diphtheria were notified, 6 fewer than in the preceding week, and 3 of these cases were from the outbreak in London.

The notifications of acute poliomyelitis numbered 75, and these cases were 15 more for paralytic and 10 fewer for non-paralytic cases than in the preceding week. The largest returns were in Lancashire 19 (Manchester C.B. 3, Blackpool C.B. 2, Padiham U.D. 2, Burnley R.D. 2); Yorkshire West Riding 11 (Leeds C.B. 4, Bradford C.B. 3, Ripon M.B. 2); London 6 (Fulham 2, Islington 2).

The largest returns for dysentery were Yorkshire West Riding 113 (Huddersfield C.B. 43, Dearne U.D. 28, Huddersfield C.B. 11, Mexborough U.D. 10), London 61 (Islington 17, Battersea 12), Glamorganshire 55 (Rhondda M.B. 23, Barry M.B. 19), Lancashire 47 (Liverpool C.B. 23), and Warwickshire 36 (Coventry C.B. 28).

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending October 18 (No. 42) and corresponding week 1957.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the whole of England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

‡ Includes puerperal pyrexia.

Medical News

P.R.F.P.S.—Mr. A. H. JACOBS, surgeon-in-charge of the urological department at Glasgow Royal Infirmary, was elected president of the Royal Faculty of Physicians and Surgeons of Glasgow at the annual meeting on November 3. He succeeds Professor STANLEY ALSTEAD.

Royal College of Physicians.—At the quarterly comitia held on October 30, with the president, Professor ROBERT PLATT, in the chair, it was announced that THE QUEEN had accepted the invitation to become Visitor to the College. The following were elected councillors of the College: Dr. W. D. W. BROOKS, Dr. M. I. A. HUNTER, Dr. G. E. GODBER, and Dr. W. H. McMENEMEY. Dr. C. E. NEWMAN was elected to the committee of management of the Conjoint Board. Professor R. PLATT, Sir HAROLD BOLDERO, Dr. R. R. BOMFORD, Dr. G. W. HAYWARD, and Dr. S. R. F. WHITTAKER were elected to the standing joint committee of the three Royal Colleges. The appointment of Dr. L. G. NORMAN as Milroy lecturer for 1960 was announced: his subject would be "The Medical Aspects of the Prevention of Road Accidents." The award of the Gilbert Blane medal to Surgeon Commander W. E. CROCKER, R.N., was announced.

M.R.C.P.—The following, having satisfied the censors' board, were elected Members of the Royal College of Physicians of London:

H. B. Anstall, N. A. Beardwell, D. R. Bell, P. Blackledge, J. H. Briggs, W. C. Cockburn, J. E. Cooper, M. A. Cowan, S. G. Elkington, M. G. Gelder, H. B. Griffith, J. H. Highman, J. R. Hobbs, A. D. Isaacs, Y. K. Lee, W. A. Lishman, M. S. Losowsky, P. E. S. Loubser, T. McKendrick, P. Markman, R. D. Montgomery, P. D. Mulcahy, S. Naimi, K. R. Norton, R. D. G. Peachey, S. Posen, D. D. Reid, P. A. Russell, E. A. Ryan, J. Schneider, D. G. Smith, J. R. Smythies, G. M. Stern, D. W. Sumner, J. R. Tighe, A. E. P. Twort, P. G. Wallis, M. F. R. Waters, D. J. Weatherall, D. N. Whitmore, and F. W. Wright.

Department of Virology, Glasgow.—We reproduce here the architect's drawing for the building of the new department of virology at Glasgow University, of which Professor M. G. P. STOKER was recently appointed as its first head (*Journal*, April 26, p. 1013). This is stated to be the first university department to be devoted solely to the study of

viruses. The institute, designed by Messrs. Basil Spence and Partners, will be at the intersection of Church Street and Moy Street, Glasgow, and is expected to be finished in 1960. The cost is being met from a £225,000 grant from the Scottish Hospital Endowments Research Trust. The institute, besides providing for the department's teaching and research on viruses and virus diseases, will also house a Medical Research Council unit and part of the university department of genetics. The building will be sealed and have a full plenum system of ventilation to facilitate sterility. The basement will be equipped with an electron microscope, dark-rooms, and instrument workshops. On the ground floor there will be an animal block, media and glass-washing rooms, etc. The first and second floors will

provide biochemical and other laboratories, including facilities for chromatography, cytology, and work with radioisotopes, and a classroom. On the top floor there will be a library, offices, and rooms for quiet study.

Gairdner Foundation Awards.—Among the seven recipients of the Gairdner Foundation's first international awards for work on arthritis and heart diseases are Professor W. D. M. PATON (Royal College of Surgeons) and Professor ELEANOR ZAIMIS (Royal Free Hospital). They receive an award of \$5,000 for their discovery of the methonium compounds, "the first drugs to be proven practical and effective in treatment of high blood pressure." The Foundation's award of merit (a prize of \$25,000) is shared between Dr. ALFRED BLALOCK and Dr. HELEN B. TAUSSIG (Johns Hopkins University) for their contributions to cardiac surgery. Other awards of \$5,000 go to Drs. H. M. ROSE and C. RAGAN (New York) for their laboratory test for rheumatoid arthritis, and to Dr. W. G. BIGELOW (Toronto) for his use of hypothermia in cardiac operations. The awards will be presented next May in Toronto, the home city of the Gairdner Foundation.

Human Relations in Industry.—The joint M.R.C.-D.S.I.R. committee on human relations in industry has issued its final report (H.M.S.O., London, price 3s. net). In it the committee reviews the research it has sponsored and indicates the lessons that may be drawn from its experience. Published under the same cover as the "final report" is the report of the joint committee on individual efficiency in industry. This committee, under the chairmanship of Sir FREDERIC BARTLETT, F.R.S., was appointed in 1953 to advise on research in this field.

Norman McAlister Gregg Prize.—The Ophthalmological Society of New South Wales announces that the Norman McAlister Gregg Prize will be awarded in 1959. The prize, which consists of 100 guineas and a bronze medallion, will be awarded to the British subject whose submitted original work, on any subject, is deemed to be the most valuable contribution to knowledge of ophthalmology. Intending candidates should notify Dr. JOHN HORNBROOK, 147, Macquarie Street, Sydney, at least two months before the closing date, which is October 31, 1959.

Christmas Seals.—N.A.P.T. and the National Spastics Society are selling Christmas seals this year. The National Association for the Prevention of Tuberculosis and Diseases of the Chest and Heart offers seals in sheets of 100 different designs illustrating familiar British flowers, price 4s. for 100. The seals are obtainable from Tavistock House North, Tavistock Square, London, W.C.1. The National Spastics Society offers sets of 120 seals in 12 designs, asking 1d. a seal. The seals are obtainable from 28, Fitzroy Square, London, W.1.

Sheffield University.—Dr. M. W. PARTINGTON has been appointed a temporary lecturer in child health. The University also announces a grant of \$8,000 from the Rockefeller Foundation to the department of biochemistry. This will enable the department to buy a refrigerated centrifuge.

London University.—The title of reader in biology in the University of London has been conferred on Dr. H. KALMUS in respect of his post at University College.

U.S. Air Force Surgeon General.—Major-General OLIVER K. NIESS will succeed Major-General DAN C. OGLE as surgeon general of the United States Air Force on December 1.

Sir Harry Platt left on October 30 for a lecture tour in India, Pakistan, and Ceylon arranged by the British Council. He expects to be back early in January.

"Family Doctor."—The November issue includes articles on sleep by Drs. F. R. C. Casson and W. H. S. Wallace, winter clothes by Dr. O. G. Edholm, and the common cold by Dr. K. C. Hutchin. There is also a description of the endocrine glands.

COMING EVENTS

London Medical Exhibition.—At the New Hall of the Royal Horticultural Society, Greycoat Street, Westminster, London, S.W.1, November 10-14 (11 a.m.-6.30 p.m.; on November 13 the time of closing is 7.30 p.m.).

Allergic Disorders.—The British Society for Immunology and the British Association of Allergists will hold a joint symposium on "Immunological Aspects of Allergic Disorders" at the Wellcome Building, Euston Road, on November 14 and 15. Further details from Dr. R. G. WHITE, London Hospital, London, E.1.

Fellowship for Freedom in Medicine.—Annual general and extraordinary general meetings will be held at Caxton Hall, Westminster, at 2 p.m. on November 15.

Charles West Lecture.—Dr. E. MILDRED CREAK will lecture on "Child Health and Child Psychiatry—Neighbour or Colleagues?" on November 18, at 5 p.m., at the Royal College of Physicians, Pall Mall East.

Faculty of Radiologists.—Fourth Crookshank Lecture on "The Contribution of X Rays to the Basic Medical Sciences" will be given by Lord COHEN of BIRKENHEAD on November 21, at 5 p.m., at the Royal College of Surgeons, Lincoln's Inn Fields.

College of General Practitioners.—Symposium on Dyspepsia, November 23, at 10 a.m.-4 p.m. at the Wellcome Building, Euston Road, London, N.W.1.

NEW ISSUES

SPECIALIST JOURNALS AND ABSTRACTS

The journals listed below are obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

Archives of Disease in Childhood.—Issued six times a year (£4 4s. annually). The new issue, Vol. 33, No. 171, includes:

SEVERE INFANTILE HYPERCALCAEMIA, WITH SPECIAL REFERENCE TO THE FACIES. M. C. Joseph and D. Paton.
CONGENITAL ABSENCE OF THE INTRAHEPATIC BILE DUCTS. Leonard Haas and Richard H. Dobbs.
REPLACEMENT TRANSFUSION AS A MEANS OF PREVENTING KERNICTERUS OF PREMATURITY. V. Mary Crosbie, Patricia G. Wallis, and Anna M. Walsh.
SERUM TRANSAMINASE VARIATIONS IN CHILDHOOD. Paolo Tolentino and Marcella Rossi.

A TEST FOR COELIAC DISEASE. W. W. Payne and V. Jenkinson.
A LONGITUDINAL STUDY OF THE GROWTH AND DEVELOPMENT OF PREMATURELY AND MATURELY BORN CHILDREN.
PART I. INTRODUCTION. Cecil Mary Drillean.
PART II. PHYSICAL DEVELOPMENT. Cecil Mary Drillean.

PANCREATITIS IN YOUNG CHILDREN. J. Collins.
HERPES ZOSTER OPHTHALMICUS IN CHILDREN. S. M. Tucker.
OBSERVATIONS ON THE BROMIDE PARTITION TEST IN THE DIAGNOSIS OF NON-PURULENT MENINGITIS. V. S. Nicol and H. T. Fawcett.
PNEUMATOSIS INTESTINALIS IN CHINESE CHILDREN. C. S. Muir.
PHYSICAL DEVELOPMENT OF SCHOOLGIRLS IN UPPER BURMA. C. V. Foll.
THE PREVALENCE OF DENTAL CARIES IN RELATION TO MATURITY. J. N. Mansbridge.

FAMILIAL DYSAUTONOMIA. T. McKendrick.
AUTOPSY FINDINGS IN A CASE OF PITUITARY DWARFISM. A. T. Sandison.
INSUFFICIENT GLUCURONIDE FORMATION IN THE NEWBORN AND ITS RELATIONSHIP TO THE PATHOGENESIS OF ICTERUS NEONATORUM. M. Vest.
THE FIRST ARCH SYNDROME. J. McKenzie.

British Journal of Industrial Medicine.—Issued four times a year (£3 annually). The new issue (Vol. 15, No. 4) includes:

CANCER OF THE LUNG AND NOSE IN NICKEL WORKERS. Richard Doll.
SOME OBSERVATIONS ON THE INCIDENCE OF RESPIRATORY CANCER IN NICKEL WORKERS. J. Gwynne Morran.
THE PATHOLOGY OF THE LUNGS IN FIVE NICKEL WORKERS. W. Jones Williams.
CHRONIC CHLOROFORM INTOXICATION. P. J. R. Challen, D. E. Hickish, and Joan Bedford.

COUNTING ERRORS DUE TO OVERLAPPING PARTICLES IN THERMAL PRECIPITATOR SAMPLES. S. A. Roach.
RESPIRATORY FUNCTION OF WITWATERSRAND GOLD-MINERS. Saul Zwi and Margaret R. Becklake.
A STATISTICAL STUDY OF COAL-MINING ACCIDENTS. F. D. K. Liddell and Joan May.

ASEPTIC NECROSIS OF BONE IN CAISSON DISEASE. John D. Thomson and Andrew B. Young.
SOME NOTES ON THE EFFECTS OF EXCESSIVE NOISE ON THE HEARING OF A GROUP OF WORKERS. G. F. Keatinge and S. Lancr.
AN INVESTIGATION OF SOME HEALTH HAZARDS IN AN INERT-GAS TUNGSTEN-ARC WELDING-SHOP. P. J. R. Challen, D. E. Hickish, and Joan Bedford.

THE ESTIMATION OF GASEOUS ACID IN DOMESTIC PREMISES. J. J. Phair.
R. J. Shephard, G. C. R. Carey, and M. L. Thomson.
QUARRY BANK MILL: I THE STORY OF THE MILL. Robert Murray.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, November 10

GUY'S HOSPITAL.—At Anatomy Lecture Theatre, 5.15 p.m., lecture-demonstration in endocrinology by Dr. P. M. F. Bishop: Hypothyroidism. Guest speaker, Professor D. Hubble.

● INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—At Chelsea Hospital for Women, 4.30 p.m., Guest lecture by Miss G. Hill: Menorrhagia.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Dr. B. Ackner: Psychiatric Aspects of Organic Cerebral Disease.

UNIVERSITY COLLEGE LONDON: DEPARTMENT OF BIOCHEMISTRY.—At Physiology Theatre, Gower Street, W.C.1, 5 p.m., Dr. J. R. Postgate: Sulphur Bacteria—Reductive Stages of the Bacterial Sulphur Cycle.

Tuesday, November 11

BIRMINGHAM MEDICAL INSTITUTE: SECTION OF PSYCHIATRY.—8 p.m., Dr. Edward Glover: Psycho-analysis and Modern Social Medicine.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. P. F. Borrie: Circulatory and Vascular Reactions.

MANCHESTER MEDICAL SOCIETY: SECTION OF SURGERY.—At Clinical Sciences Building, York Place, 7.30 for 8 p.m., Dr. J. K. Steward: Tumours in Childhood.

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—4 p.m., Blackham Lecture, 1958, by Brigadier Sir John Boyd, Kt., F.R.S.: Yellow Fever and its Prevention. (Illustrated.)

ST. ANDREWS UNIVERSITY.—At Physiology Department Lecture Theatre, 5 p.m., Dr. H. D. Allwood: Investigation of Pulmonary Embolism.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Institute Theatre, 5 p.m., Dr. George Crosby: Gynaecology in General Practice.

UNIVERSITY COLLEGE LONDON: DEPARTMENT OF PHARMACOLOGY.—At Physiology Theatre, Gower Street, W.C.1, 5.30 p.m., Professor J. F. Danielli, F.R.S.: Generalized Cell Theory and its Relevance to Certain Problems of Drug Action.

WEST END HOSPITAL FOR NEUROLOGY AND NEUROSURGERY.—5.30 p.m., Dr. G. A. D. Gordon: Neuro-radiological Investigations.

Wednesday, November 12

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. J. A. Dudgeon: Virus Diseases.

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. A. M. C. Macpherson: Some Chest Diseases in Childhood.

INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Mr. J. D. Fergusson: Prostatic Cancer.

MANCHESTER MEDICAL SOCIETY.—At Physiology Theatre, Manchester University, 4.30 for 5 p.m., Dr. A. F. Rogers: A Doctor in Antarctica.

● NATIONAL COLLEGE OF RUBBER TECHNOLOGY, Northern Polytechnic, Holloway Road, N.—6.30 p.m., Professor C. G. Rob: Synthetic Materials in Vascular Surgery.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Guest Lecture by Professor C. H. Gray: Role of the Endocrine Organs in Diabetes Mellitus.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—5 p.m., Weild Lecture by Professor D. W. Smithers: On the Pathogenesis of Cancer.

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—3.30 p.m., Mr. H. Beric Wright: Environmental Medicine in Industry.

Thursday, November 13

HONEYMAN GILLESPIE LECTURES.—At Anatomy Theatre, University New Buildings, Teviot Place, Edinburgh, 5 p.m., Professor G. I. Scott: Optic Nerves.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Robert Jones Lecture by Mr. Norman Capener: Spondylolisthesis: Spinal Strain.

ROYAL MEDICO-PSYCHOLOGICAL ASSOCIATION: PSYCHOTHERAPY AND SOCIAL PSYCHIATRY SECTION.—At 11, Chandos Street, Cavendish Square, W., 8 p.m., Dr. E. B. Strauss: Value of Narcoanalysis in Psychiatric Practice.

Dr. W. A. H. Stevenson and Dr. R. A. Sandison will take part in the discussion.

ROYAL MEDICO-PSYCHOLOGICAL ASSOCIATION.—At Royal Society of Medicine, 2.15 p.m., Maudsley Lecture by Dr. Leo Kanner (Baltimore): Trends in Child Psychiatry.

ST. ANDREWS UNIVERSITY.—At Physiology Department Lecture Theatre, 5 p.m., Professor H. Gruneberg, F.R.S.: Causes of Congenital Defects.

Friday, November 14

BIOCHEMICAL SOCIETY.—At National Institute of Medical Research, Ridge-way, Mill Hill, N.W.1, 2 p.m., 377th meeting.

HILL END HOSPITAL CLINICAL SOCIETY.—At Hill End Hospital, St. Albans, 8.30 p.m., talk by Dr. R. Robertson. Members of Mid-Herts Division, B.M.A., are invited.

● INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. S. C. Gold: clinical demonstration.

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. E. H. Hudson: clinical demonstration.

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—4.30 p.m., Annual Address by T. G. Wilson: Modern Treatment of Deafness in Historical Perspective.

PLYMOUTH MEDICAL SOCIETY.—At Freedom Fields, 8.30 p.m., joint meeting with Plymouth Division, B.M.A. Mr. T. Holmes Sellers: Thoracic Surgery.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—(1) 10 a.m., Guest lecture by Professor W. C. Wilson: Ins and Outs of Surgical Practice. (2) 4 p.m., Guest lecture by Professor W. M. Arnott: Regional Distribution of Blood Flow in Low Output Syndromes.

Saturday, November 15

KENT PAEDIATRIC AND CHILD HEALTH SOCIETY.—At Children's Department, Farnborough Hospital, Kent, 3 p.m., Dr. Peter Scott: Crime and Adolescence.

Sunday, November 16

MANCHESTER UNIVERSITY: FACULTY OF MEDICINE AND NORTH-WEST ENGLAND FACULTY, COLLEGE OF GENERAL PRACTITIONERS.—At Theatre 1, England Sciences Building, York Place, 11 a.m., Mr. Gordon Jack and Dr. F. W. A. Turnbull: Influence of Modern Advances on One's Approach to Chest Disease.

APPOINTMENTS

BIRMINGHAM REGIONAL HOSPITAL BOARD.—T. L. Pilkington, M.R.C.S., L.R.C.P., D.P.M., Whole-time Consultant Psychiatrist and Deputy Medical Superintendent to Lea Colony, Bromsgrove, and Lea Castle Colony, Kidderminster; N. K. Shinton, M.B., Ch.B., M.R.C.P., Whole-time Consultant Pathologist to the Coventry Group of Hospitals; W. N. Boyd, M.B., Ch.B., F.R.C.S.Ed., D.M.R.D., Part-time Consultant Radiologist to the Stoke-on-Trent Group of Hospitals; J. A. Litchfield, M.D., M.R.C.P., Part-time Consultant Physician (Geriatrics) to the Mid-Worcestershire Group of Hospitals; A. V. Jenkins, M.B., B.S., F.F.A.R.C.S., Whole-time Consultant Anaesthetist to Birmingham (Selly Oak) group of hospitals; W. Sewell, F.R.C.S., Part-time Consultant Surgeon (seven notional half-days weekly) to Stoke-on-Trent group of hospitals; H. S. Trafford, M.B., Ch.B., F.R.C.S.Ed., D.Obst.R.C.O.G., Whole-time Consultant Surgeon to Stoke-on-Trent group of hospitals.

FREED LOUIS F., M.A., M.D., D.Phil., D.P.M., F.R.S.S.Afr., of Johannesburg, South African Editor of *Vita Humana*, international journal of human development. Dr. Freed is lecturer in the Department of Psychiatry of the University of the Witwatersrand.

FRIZELLE, G. M., T.D., M.D., D.P.H., Medical Officer of Health, East Hertfordshire Combined Districts.

GATHERER, ALEXANDER, M.B., Ch.B., D.P.H., Deputy Medical Officer of Health and Deputy Principal School Medical Officer to the County Borough of Warrington.

HOARE, E. D., M.D., Director of Department of Clinical Pathology at the London Clinic.

HOSPITAL FOR SICK CHILDREN, Great Ormond Street, London, W.C.—Marion V. Miles, M.R.C.S., L.R.C.P., D.C.H., House-physician; E. J. Guthrie, M.B., B.Ch., House-surgeon to Orthopaedic and Plastic Departments; D. Y. Mackenzie, M.D., M.R.C.P., D.C.H., Registrar to Departments of Physical Medicine; A. Birch, M.B., Ch.B., F.R.C.S.Ed., Registrar Medical Registrar; Dorcen A. Birch, M.B., Ch.B., F.R.C.S.Ed., Registrar to Ear, Nose, and Throat Department; D. E. Sturdy, M.B., B.S., F.R.C.S., Surgical Registrar; Alice E. M. Van Waterschoot, M.B., B.S., D.Obst.R.C.O.G., D.A., Junior Anaesthetic Registrar.

LIVERPOOL REGIONAL HOSPITAL BOARD.—J. K. Wilson, M.D., M.R.C.O.G., D.Obst.R.C.O.G., Part-time Consultant Obstetrician and Gynaecologist for two sessions per week at Ormskirk County Hospital; A. S. Woodcock, M.D., Consultant Pathologist (whole-time or maximum part-time sessions) at M.D., Consultant Pathologist; H. E. Parry, M.B., B.S., M.R.C.P., Whiston and Ranshill Hospitals; P. B. O'Neill, M.B., B.S., F.R.C.S., D.C.H., Whole-time Consultant Physician and Deputy Medical Superintendent (Resident) at Fazakerley Hospital; P. B. O'Neill, M.B., B.S., F.R.C.S., D.L.O., Part-time Consultant Otorhinolaryngologist for seven sessions at D.L.O., Part-time Consultant Otorhinolaryngologist for five sessions at St. Helens, Warrington, Ormskirk, and Runcorn areas; W. M. Owen, M.B., B.S., F.R.C.S., D.L.O., Part-time Consultant Otorhinolaryngologist for two sessions at Clatterbridge and Wirral Hospitals; J. Siegler, M.B., B.S., F.R.C.S., D.L.O., Assistant Consultant Otorhinolaryngologist for two sessions at Bootle, Walton, and John Bagot Hospitals; C. M. Ogilvie, M.D., M.R.C.P., Part-time Consultant Physician for four sessions in the Regional Thoracic Surgery Unit at Broadgreen Hospital; E. Walker, M.D., D.P.H., D.M.R.D., Part-time Consultant Radiologist for four sessions at Sefton General Hospital; I. M. Cuthill, M.B., Ch.B., M.R.C.P.Ed., Whole-time Assistant Chest Physician in the Chester and District area.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Durber.—On September 16, 1958, at the City General Hospital, Stoke-upon-Trent, Staffs, to Phyllis (formerly Walton), wife of Dr. C. E. Durber, a sister for Peter and David—Penelope Joy.

Mitchell.—On October 26, 1958, at Scunthorpe Maternity Home, to Drs. W. P. and Jane (formerly Higson) Mitchell, of High Street, Belton, Doncaster, Yorks, a son.

O'Kelly.—On October 10, 1958, at Farnborough, Hants, to Dorothy Mary, S.R.N., S.C.M., wife of Captain Frank O'Kelly, R.A.M.C., a brother for Margaret and Julie.

DEATHS

Chapman.—On October 16, 1958, at Hastings, Sussex, Donald Poyntz Chapman, M.R.C.S., L.R.C.P., of Wingarth, Tydehams, Newbury, Berks, Surgeon Commander, R.N. (retired), aged 82.

Dobson.—On October 12, 1958, at The House, Warrington Hospital, Appley Bridge, near Wigan, Lancs, Jonathan Dobson, F.R.C.S., aged 51.

Druitt.—On October 12, 1958, Daniel Cuthbert Druitt, M.R.C.S., L.R.C.P., of Glencables, Petworth, Sussex, aged 74.

Fraser.—On October 14, 1958, in a nursing-home, Bournemouth, Hants, Sarah Louise Fraser, M.B.E., M.D., late of York, aged 84.

Fridjohn.—On October 14, 1958, at Ellaston, Ham Common, Richmond, Surrey, Maurice Henry Fridjohn, M.D., aged 54.

Hill.—On October 8, 1958, at Rosedene, 56, Buckingham Way, Wallington, Surrey, Robert McCowan Hill, D.S.O., M.B., Ch.B., aged 75.

Julian.—On August 19, 1958, Frederick Bennett Julian, M.C., M.B., B.Ch., M.Sc., of Hatton House, Mather Avenue, Liverpool, aged 65.

Lamont.—On September 3, 1958, at Seaton, Devon, Charles Antony Lamont (formerly Lavery), M.B., Ch.B., F.R.F.P.S., late Squadron Leader, R.C.A.F.

Lewin.—On October 16, 1958, at Mole Cottage, Great Molewood, Hertford, George Lewin, M.B., B.S., late of 1, Haling Park Road, South Croydon, aged 82.

Mackenna.—On October 16, 1958, at Mansion House Road, Paisley, John George Mackenna, M.B., Ch.B., D.P.H.

Miller.—On October 11, 1958, at 34, Clarendon Court, London, W., Arthur Alphonse Miller, F.R.C.S.Ed., D.L.O., of 20, Harley Street, London, W.

Ockwell.—On October 17, 1958, at Guy's Hospital, London, E.C., Charles Melton Ockwell, M.D., F.R.C.S., D.P.H., of The Coppice, Pilgrim's Way, Kensing, Kent, aged 74.

Paterson.—On October 2, 1958, at 140, Mugdock Road, Milngavie, Glasgow, Robert Lamb Paterson, M.B., Ch.B., D.P.H., late of Suienkama, South Africa.

Popham.—On October 9, 1958, Cyril Popham, O.B.E., L.R.C.P.&S.I., L.R.F.P.S., Colonel, late R.A.M.C., of Centre Oak, Blackwater, Camberley, Surrey.

Wakefield.—On October 4, 1958, at Birklands, Kendal, Westmorland, Roger William Wakefield, M.B., B.Ch., J.P., aged 92.

Widdup.—On October 6, 1958, in Australia, Alec Harley Widdup, M.B., B.Chir., formerly of Thornton-in-Craven, Skipton, Yorks.

Any Questions?

We publish below a selection of those questions and answers which seem of general interest. It is regretted that it is not possible to supply answers to all questions submitted.

P.A.S. and Pulmonary Tuberculosis

Q.—Is calcium B-P.A.S. as effective in the treatment of pulmonary tuberculosis as sodium P.A.S.?

A.—The most important effect of P.A.S. and its analogues in the treatment of pulmonary tuberculosis consists in its ability, when given in combination with streptomycin or isoniazid, to diminish the liability to the emergence of strains of tubercle bacilli resistant to the other drugs. The therapeutic effect of P.A.S. alone is considerably less than that of the other two commonly used drugs. There is good evidence that tolerable doses of sodium P.A.S. are effective in this respect.^{1,2} The best way of estimating the effectiveness of any alternative preparation to the sodium salt of P.A.S. is therefore to determine whether, when given in combination with streptomycin or isoniazid to patients whose organisms are known to be sensitive to the drugs used, it prevents the emergence of drug-resistant organisms. Evidence on this point is difficult to obtain, but Lewis³ has reported 39 patients who were admitted to hospital with pulmonary tuberculosis and were treated with calcium benzamidosalicylate (Ca B-P.A.S.) with streptomycin or isoniazid for a period of at least two months. Of these, at least 20 subsequently produced tubercle bacilli with impaired sensitivity to one or more of the standard drugs. Since some of these patients had been treated as out-patients, it was possible that not all of them had taken the prescribed drugs conscientiously, and drug sensitivity tests had not been done in most of them before treatment was begun. However, seven of them were known to have taken the drugs conscientiously and to have had sensitive organisms before Ca B-P.A.S. was given. In three of these bacilli resistant to isoniazid or streptomycin emerged, and in two more sputum remained positive after six or eight months of treatment, although sensitivity tests were not done. These results indicate that, in the commonly used dose of 14 g. a day, Ca B-P.A.S. is ineffective in preventing the emergence of organisms resistant to streptomycin or isoniazid. Undissociated B-P.A.S. is very much less active than P.A.S.⁴ and its therapeutic activity therefore depends upon its conversion to P.A.S. Lewis points out that, assuming complete hydrolysis of Ca B-P.A.S. and with the knowledge that only about 60% of an oral dose is absorbed from the gut, the dose of Ca B-P.A.S. which would correspond with the dose of sodium P.A.S. known to be effective in preventing emergence of resistance to streptomycin is no less than 48 g. daily. This is far above the customarily used dose, and it is doubtful if it would be tolerated any better than the normal dose of sodium P.A.S.

Oedema in Pre-eclampsia

Q.—Is it necessary to restrict the fluid intake in the control of oedema in pre-eclampsia?

A.—The best method of controlling the oedema of pre-eclampsia remains in doubt. Indeed, it is not established that the control of oedema *per se* by any method is of value. It is, nevertheless, usually attempted.

If the oedema is associated with sodium retention, as is generally believed to be the case in pre-eclampsia, the complete elimination of sodium from the diet is theoretically all that is necessary. In fact, however, a sodium-free diet is impracticable. It is therefore usual to compromise by

restricting both sodium and fluid. The avoidance of fluid to the extent of causing dehydration could be harmful and even result in uraemia. This is unlikely to happen in a waterlogged patient, in whom experience shows it to be safe to reduce the intake of fluid to 20 oz. (0.6 l.) in 24 hours. Moreover, no harm can result when the amount of fluid allowed is related to the output of urine, this being the usual clinical guide. The recently introduced orally administered saluretics (e.g., acetazolamide and chlorothiazide), unlike the older mercurial diuretics given by injection, do control the oedema of toxæmia. Chlorothiazide acts by increasing chloride excretion and this in turn raises the sodium output. It also has a less important action as a carbonic anhydrase inhibiting factor. This new drug is therefore being used without restricting the patient's intake of either fluid or sodium. However, in the presence of liver damage (and especially if the sodium intake is restricted) chlorothiazide can produce dangerous hypokalaemia.¹ There is, therefore, some reason to question the advisability of using this drug in the treatment of pregnancy toxæmia unless the patient is having potassium supplements and is in a hospital, where the electrolyte balance can be constantly controlled. Even then its value is doubtful. Although it may improve maternal oedema it does not—as judged by foetal survival rates—benefit significantly the underlying disease.²

There is at present probably no better method of controlling the oedema of pre-eclampsia than by physical rest (which is indicated on other grounds and which in itself promotes elimination of fluid), by reasonable restriction of the intake of fluid and sodium, and possibly by administering a simple sodium replacement diuretic such as ammonium chloride.

Treatment of Rabies

Q.—Where may supplies of rabies vaccine and serum be obtained in England and Wales?

A.—A Ministry of Health memorandum (H.M.(58)66), August, 1958, lists the following centres as holding supplies of rabies vaccine (for active immunization) and serum (for immediate passive protection) for the treatment of rabies.

London.—Central Public Health Laboratory, Colindale Avenue, N.W.9 (Colindale 7041).

Newcastle.—Public Health Laboratory, or Institute of Pathology, General Hospital, Westgate Road, Newcastle, 4 (Newcastle 38811).

Liverpool.—Public Health Laboratory, 126, Mount Pleasant, Liverpool (Royal 3636).

Wales.—Public Health Laboratory, Institute of Preventive Medicine, The Parade, Cardiff (Cardiff 29110 and 23967).

Collected Articles from the "British Medical Journal"

The following books are available through booksellers or from the Publishing Manager, B.M.A. House. Prices, which include postage, are now the same for both inland and overseas.

- Emergencies in General Practice* (26s. 9d.).
- Refresher Course for General Practitioners*, Volumes 2 and 3 (26s. 9d.).
- Clinical Pathology in General Practice* (22s. 3d.).
- Any Questions?*, Volumes 2 and 3 (8s. 3d. each).
